For the artificial production of quartz the author employed an aqueous solution of silicic acid (dialysed silica). Several quarter litre glass bulbs, 0·5 cm. thick, were half filled with a 10 per cent. aqueous solution of silica, and heated at 250° in an air-bath for several months. During the first day the silica separated out. In six months' time hard sandy grains were found in the white precipitate. These were collected and washed, and were found to consist of transparent, colourless, homogeneous, well-developed crystals of quartz, 0·5 mm. in size.

In preparing tridymite artificially, the natural process was imitated, that is, by means of molten magmas artificial frittings were effected. Two series of experiments were conducted:—1. Rocks rich in quartz were melted with basalts or melaphyres, and kept in the molten state for 1 to 8 hours. 2. Rocks rich in quartz were fritted or quite melted alone in a charcoal coke fire. Both series of experiments yielded excellent specimens of tridymite.

B. H. B.

**Artificial Production of Crystallised Silica and Orthoclase.** By K. DE CHROUSTCHOFF (*Compt. rend.*, 104, 602—603).—In part a description of the results given in the preceding Abstract. One of the quartz crystals showed several very small cavities with movable globules.

In other experiments the solution of dialysed silica was mixed with a small quantity of dialysed alumina and of potassium hydroxide, the mixture being heated in flasks at 300° for several months. Under these conditions crystals of quartz similar to those formed in the first experiments were obtained, mixed with a small quantity of thin

rhombic lamellæ, with the same properties as the adularian orthoclase obtained by Friedel and Sarasin. C. H. B.

**Composition of Felspars in the Island of Elba.** By A. FUNARO (*Gazzetta*, 16, 523—526).—It is generally held by geologists that the quartziferous porphyry of Elba is a structural variety of the granite in that island, the difference being dependent on variations in consolidations of the original magma. This view is supported by the following analyses, which indicate no marked difference in the chemical composition of these two species of rock. I. Granite. II. Gneissic schist. III. Quartziferous porphyry:—

|      | SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | CaO. | MgO. | K <sub>2</sub> O. | Na <sub>2</sub> O. |
|------|--------------------|----------------------------------|----------------------------------|------|------|-------------------|--------------------|
| I.   | 69·3               | 16·4                             | 4·5                              | 1·12 | 1·18 | 3·46              | 5·02               |
| II.  | 75·5               | 11·85                            | 4·55                             | 0·56 | 1·08 | 3·97              | 2·41               |
| III. | 70·1               | 16·25                            | 4·05                             | 1·32 | 0·54 | 4·2               | 4·27               |

With the analysis of the granite that of the gneissic schist is also compared, from which it appears that the composition of these rocks is very similar; the greatest difference is evident in the proportion of the silica. This result offers some confirmation of the view of geologists that granite is formed from gneiss and other more or less felspathic schists. Probably boron was present in minute quantities in the three species of rocks above described. V. H. V.

**The Scapolite Series.** By G. TSCHERMAK (*Jahrb. f. Min.*, 1887, 1, Ref., 232—234).—The author submits the arguments brought forward by Rammelsberg (*Abstr.*, 1886, 30 and 318) to severe criticism, and adheres to his theory that the members of the scapolite group are admixtures in different proportions of the two species meionite and marialite. The differences between the results of actual analyses of scapolite minerals and the theoretical results found by calculation, are quite insignificant. In conclusion, the author gives the following table, showing the calculated percentage compositions of the scapolite mixtures:—

| Meionite. | Marialite. | SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | CaO.  | Na <sub>2</sub> O. | Cl.  |
|-----------|------------|--------------------|----------------------------------|-------|--------------------|------|
| 100       | 0          | 40·45              | 34·38                            | 25·17 | —                  | —    |
| 90        | 10         | 42·80              | 32·75                            | 22·65 | 1·47               | 0·42 |
| 80        | 20         | 45·15              | 31·13                            | 20·13 | 2·94               | 0·84 |
| 70        | 30         | 47·50              | 29·50                            | 17·62 | 4·40               | 1·26 |
| 60        | 40         | 49·85              | 27·88                            | 15·10 | 5·87               | 1·68 |
| 50        | 50         | 52·20              | 26·25                            | 12·59 | 7·34               | 2·10 |
| 40        | 60         | 54·55              | 24·62                            | 10·07 | 8·81               | 2·52 |
| 30        | 70         | 56·90              | 23·00                            | 7·55  | 10·28              | 2·93 |
| 20        | 80         | 59·25              | 21·37                            | 5·03  | 11·75              | 3·35 |
| 10        | 90         | 61·60              | 19·74                            | 2·52  | 13·22              | 3·77 |
| 0         | 100        | 63·95              | 18·12                            | —     | 14·69              | 4·19 |

B. H. B.

**Artificial Production of Micas.** By P. HAUTEFEUILLE and L. P. DE SAINT-GILLES (*Compt. rend.*, 104, 508—510).—A mixture of

5 parts of the constituents of a highly ferruginous mica with 1 part of potassium silicofluoride melts between  $1000^{\circ}$  and a bright red heat, and loses fluorine somewhat rapidly in the form of silicon fluoride. If the mixture is allowed to crystallise whilst the proportion of fluorine remaining is still considerable, the solidified mass is more or less vesicular, but if the temperature is regulated so that crystallisation takes place when about 3 or 4 per cent. of fluorine is present, the product crystallises in the same form as mica, and has a similar composition. It forms thin pseudo-hexagonal plates, which are striated and macle, show polychroism, and melt before the blowpipe with intumescence. The crystals resemble the ferruginous mica of eruptive rocks, but have a slighter lower specific gravity, and are somewhat harder, but less elastic. These properties are well shown by magnetic crystals, which resemble the ferruginous micas of Vesuvius, and have the composition  $6\text{RO}, 2\text{R}_2\text{O}_3, 9\text{SiO}_2$ . By reducing the proportion of magnesia, crystals are obtained of the composition  $4\text{RO}, 2\text{R}_2\text{O}_3, 9\text{SiO}_2$ , which closely approaches that of chromium mica. These crystals are harder and less elastic than those of mica. In some cases the increased hardness and diminished elasticity are due to admixture with a hard vitreous substance.

The formation of crystallised minerals is facilitated by adding 10 per cent. of potassium arsenate to the fluorine-containing mixtures. If the silicate is allowed to solidify in an atmosphere of hydrogen, the product retains very little arsenic. The action of this gas produces intumescence, which facilitates the formation of geodes, and the latter contain crystals as much as 2 or 3 mm. in length.

**Talc, Pseudomorphite, and Muscovite from South Africa.** By E. COHEN (*Jahrb. f. Min.*, 1887, 1, Mem., 119—124).—The substances carved by the natives of South Africa are not only interesting ethnographically, but also mineralogically. They are found on investigation to be massive varieties of talc, chlorite, and muscovite.

The talc is of a light grey colour with yellowish-brown streaks. Its sp. gr. is 2.794. Analysis gave—

| $\text{SiO}_2$ . | $\text{Al}_2\text{O}_3$ . | $\text{Fe}_2\text{O}_3$ . | $\text{FeO}$ . | $\text{MgO}$ . | $\text{H}_2\text{O}$ . | Total. |
|------------------|---------------------------|---------------------------|----------------|----------------|------------------------|--------|
| 63.29            | 1.24                      | 0.16                      | 4.68           | 27.13          | 4.40                   | 100.90 |

The pseudophite was obtained from the Zoutpans Mountains in the Northern Transvaal. It closely resembles williamsite (serpentine). Its hardness, however, is less (2—3), and it fuses more easily. Analysis gave the following results :—

| $\text{SiO}_2$ . | $\text{Al}_2\text{O}_3$ . | $\text{Fe}_2\text{O}_3$ . | $\text{FeO}$ . | $\text{MgO}$ . | $\text{H}_2\text{O}$ . | Total. |
|------------------|---------------------------|---------------------------|----------------|----------------|------------------------|--------|
| 32.38            | 18.79                     | 0.80                      | 2.39           | 31.64          | 14.15                  | 100.15 |

Of the water, 0.06 per cent. was given off between  $100^{\circ}$  and  $300^{\circ}$ , the remainder on ignition. The sp. gr. is 2.647.

The hardness of all the varieties of massive muscovite examined is from  $2\frac{1}{2}$  to 3. Analyses are given of a green variety with green and brown streaks (I), a yellow variety with yellow-ochre streaks (II), and a red variety, with brown and violet streaks (III):—

|      | SiO <sub>2</sub> . | TiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | FeO.  | CaO.  | MgO.  |
|------|--------------------|--------------------|----------------------------------|----------------------------------|-------|-------|-------|
| I.   | 45·39              | 0·98               | 38·72                            | 0·61                             | —     | 0·45  | 0·17  |
| II.  | 43·61              | —                  | 35·61                            | trace                            | trace | trace | 0·79  |
| III. | 42·70              | —                  | 29·98                            | 7·62                             | 1·57  | 0·37  | trace |

|      | K <sub>2</sub> O. | Na <sub>2</sub> O. | H <sub>2</sub> O. | Total. | Sp. gr. |
|------|-------------------|--------------------|-------------------|--------|---------|
| I.   | 7·51              | 1·69               | 5·48              | 101·00 | 2·832   |
| II.  | —                 | —                  | 7·00              | —      | 2·847   |
| III. | 10·57             | 1·52               | 4·96              | 99·29  | 2·789   |

**Kersantite from Wüstewaltersdorf, in Silesia.** By E. DATHE (*Jahrb. f. Min.*, 1887, 1, Ref., 272—273).—The author has discovered a vein of kersantite in the culm beds at Wüstewaltersdorf, in Lower Silesia. The vein is 500 metres long and 80 to 100 metres broad. The principal constituents of the rock are plagioclase and magnesia-mica, with augite, hornblende, and quartz; whilst apatite, magnetite, and calcite occur as accessory or secondary minerals. An analysis of the rock gave the following results:—

| SiO <sub>2</sub> . | TiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | FeO. | MgO. | CaO. | K <sub>2</sub> O. | Na <sub>2</sub> O. |
|--------------------|--------------------|----------------------------------|----------------------------------|------|------|------|-------------------|--------------------|
| 56·18              | 0·45               | 15·51                            | 2·86                             | 3·94 | 5·46 | 3·69 | 3·21              | 4·07               |

| P <sub>2</sub> O <sub>5</sub> . | CO <sub>2</sub> . | H <sub>2</sub> O. | SO <sub>3</sub> . | Total. | Sp. gr. |
|---------------------------------|-------------------|-------------------|-------------------|--------|---------|
| 0·31                            | 0·95              | 3·19              | trace             | 99·82  | 2·7084  |

B. H. B.

**Andalusite from Marabastad, Transvaal.** By J. GÖTZ (*Jahrb. f. Min.*, 1887, 1, Mem., 211—212).—It has been stated that the andalusite in the ottrelite and andalusite schists of the Marabastad gold-fields in the Transvaal, might be disthene. The author has consequently made a fresh investigation of the mineral in question. The sp. gr. he finds to be 3·11; that of disthene is considerably greater. Analysis gave the following results:—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | TiO <sub>2</sub> . | Total. |
|--------------------|----------------------------------|--------------------|--------|
| 28·38              | 56·50                            | 15·14              | 100·02 |

The mineral cannot be disthene, on account of its specific gravity and the absence of perfect cleavage.

B. H. B.

**New Analyses of Norwegian Rocks.** By P. JANNASCH (*Ber.*, 20, 167—176).—In 1855, T. Kjerulf published a number of analyses of the interesting rocks occurring in the vicinity of Christiania. The gaps in his series are now filled by new analyses, by the author, of rocks from the same district. The rock of most frequent occurrence has received various names, such as Christiania syenite, Drammen granite, and syenite porphyry. In all its modifications the soda felspar is in excess of the potassium felspar. It thus differs from the granites and syenites of the same age, and belongs to the group of rocks termed *prædacite* by Lang. It differs from the diorites and diabases in the constant proportion of primary quartz. The mineral constitution of the rock is very variable, the prevailing constituents being felspars, of which the author distinguishes three series differing in age. The typical rock is that from the Tonsen Aas (analysis II),

whilst that from Drammen (I) and that from Vettakollen (III) must be regarded as products altered by the eruption. In the typical rock, albite-oligoclase-perthite predominates; in the Vettakollen rock the plagioclases of the first generation, which were absent in the typical rock, also occur; whilst in the Drammen rock the albite-microcline and orthoclase-albite-perthites prevail.

Seeing that the Christiania prædacite has hitherto been erroneously regarded as an orthoclase-quartz rock, the interesting question arises whether orthoclase-quartz rocks, in which potash feldspars are in excess of soda feldspars, are altogether absent from the eruptive rocks of the Silurian basin of Christiania. No analysis of the Drammen porphyry has hitherto been published. That given below (analysis IV), together with the results of the microscopical examination, prove the porphyry to be a true potash-feldspar rock. The percentage of the constituents of the rock calculated from analysis is as follows:—Orthoclase 42, albite 20, quartz 34, chlorite 2, iron pyrites 0·7, zircon 0·5, titaniferous iron ore 0·3.

**Eruptive Rocks from Krzeszowice, near Cracow.** By R. ZUBER (*Jahrb. f. Min.*, 1887, 1, Ref., 277—279).—The rocks are divided into two groups according to their petrographical character—syenite-porphyry, and melaphyre. The Zalas rock (analysis I) the author regards as syenite-porphyry. In this rock orthoclase occurs with plagioclase and biotite in a ground-mass of feldspar, biotite, and hornblende. Near the surface the rock assumes a reddish colour, secondary quartz, hæmatite, and limonite occurring (analysis II). The dark-red rock occurring at Mienkinia, hitherto regarded as felsite-porphyry, is found by the author to be syenite-porphyry (analysis III). All the remaining eruptive rocks of the district are stated to be melaphyres. The rocks are sometimes compact, sometimes amygdaloidal. They consist of plagioclase, orthoclase, augite, and magnetite. Analyses are given of the rocks from Tenezyn (IV) and from Poceba (V).

**Japanese Rocks.** By B. KOTÔ (*Jahrb. f. Min.*, 1887, **1**, Ref., 285—287).—The author gives the results of a microscopic examination of various rocks collected in the provinces of Izu, Kai, and Kozuke. Analyses are given of the labradorite and pyroxene from the pyroxene-andesite of Tokio, plagioclase-basalt from Funabara, diabase from Hinazura Pass, Kai, pyroxene-andesites from Izu-San, Amagin-San, and Miôgi-San (Kozuke) (compare *Jour. Geol. Soc.*, **40**, 431—457).

B. H. B.

**The Mazapil Meteoric Iron.** By W. E. HIDDEN (*Amer. J. Sci.*, **33**, 221—226).—Only eight meteoric irons are recorded as having been seen to fall. To this short list the author adds a ninth. This meteorite was seen to fall near Mazapil, in the State of Zacatecas, Mexico, at 9 P.M. on November 27, 1885, during the periodical star shower of the Bielids. When received by the author, the meteorite weighed 3950 grams. Its present weight is 3864 grams. It is a flat irregular mass, having a smooth surface covered with deep depressions. Its greatest length is 175 mm., and its greatest width is 60 mm. The lines of crystalline structure are somewhat similar to those of the Rowton iron, and very unlike the Mexican irons. In appearance, the mass bears a remarkable resemblance to the Hraschina, Agram iron. An analysis of a small fragment of the new meteorite gave the following results:—

| Fe.   | Ni.  | Co.  | P.   | Total. |
|-------|------|------|------|--------|
| 91·26 | 7·84 | 0·65 | 0·30 | 100·05 |

B. H. B.

**Meteorites from Kentucky and Mexico.** By G. F. KUNZ (*Amer. J. Sci.*, **33**, 228—235).—The author describes two new meteorites from Carroll Co., Kentucky, and Catorze, Mexico. The mass from Carroll Co. is especially interesting because it probably belongs to the same fall as the meteoric iron found on the altars of the Turner mounds, Little Miami Valley, Ohio. The Carroll Co. meteorite was found in 1880 at Eagle Station, about 60 miles from the mounds where Putnam found the meteoric iron and the ornaments made from it. The mass, which weighs 80 lbs., is almost square, measuring 19 cm. in thickness, 22 cm. in width, and 29 cm. in length. All the original crust has disappeared. The mass is largely made up

of fine yellow transparent olivine, resembling closely that of the Pallas iron. The meteorite belongs to the siderolites of Daubrée and to the pallasite-group. Its sp. gr. was found to be 4.41; the meteorite, like the Turner's mound and Atacama meteorites, consisting of three parts of olivine to one of iron. Analysis of the olivine gave the following results:—

| SiO <sub>2</sub> . | MgO.  | FeO.  | MnO + CoO. | Total. |
|--------------------|-------|-------|------------|--------|
| 37.90              | 41.65 | 19.66 | 0.42       | 99.63  |

The metallic portion gave on analysis the following results:—

| Fe.   | Ni.   | Co.  | P.   | Olivine. | Chromite. | Total. |
|-------|-------|------|------|----------|-----------|--------|
| 71.73 | 14.27 | 0.95 | 0.05 | 11.12    | 0.90      | 99.02  |

The balance is oxygen in the form of iron oxide, and undetermined constituents.

The Catorze mass, weighing 92 lbs., was found by a miner near Catorze, San Luis Potosi, Mexico, in 1885. It is 31.5 cm. long, 34.5 cm. wide, and 20 cm. thick. The iron belongs to Meunier's caillite-group, and shows the Widmanstätten lines very clearly. The sp. gr. was found to be 7.509. Analysis gave the following results:—

| Fe.      | Ni + Co. | P.   | Scale insoluble in HNO <sub>3</sub> . | Total. |
|----------|----------|------|---------------------------------------|--------|
| 90.09    | 9.07     | 0.24 | 0.60                                  | 100.00 |
| B. H. B. |          |      |                                       |        |

## Organic Chemistry.

**Action of Heat on Heptene.** By A. RENARD (*Compt. rend.*, 104. 574—576).—Heptene, C<sub>7</sub>H<sub>12</sub>, boiling at 103—105° was allowed to fall drop by drop into an iron tube which was heated to incipient redness, and was connected at the opposite end with a condensing arrangement. The products are a considerable volume of hydrogen mixed with a small quantity of gaseous hydrocarbons, a small quantity of carbon, and a large proportion of a brownish-yellow liquid which contains a small quantity of pentene, a large proportion of hexene, a small proportion of benzene, and a much larger proportion of toluene. This liquid also contains a considerable fraction boiling above 115°, about half of which boils between 115° and 180°, leaving a viscous residue which is solid at ordinary temperatures. This fraction has not been examined in detail, but it contains no hydrocarbons of the benzene series.

The pentene is either identical or isomeric with the pentene obtained by Greville Williams by the distillation of caoutchouc, or by Tilden in the pyrogenation of terebenthene.

Hexene, C<sub>6</sub>H<sub>10</sub>, the lower homologue of heptene, boils at 70—73°, and is soluble in alcohol, ether, and acetic acid; vapour-density, 2.97. It

rapidly absorbs oxygen, but exerts no action on ammoniacal cuprous chloride or ammonio-silver nitrate. It is violently attacked by bromine with evolution of hydrogen bromide, but if its ethereal solution is treated with bromine it yields the additive product  $C_6H_{10}Br_2$ , which after the evaporation of the ether forms a heavy oil, but soon decomposes with evolution of hydrogen bromide. Ordinary nitric acid attacks the hydrocarbon violently, but acid of sp. gr. 1.15 acts more gradually with evolution of carbonic oxide and carbonic anhydride, but no nitrogen oxides, and formation of a solution of formic, acetic, oxalic, and succinic acids. Gaseous hydrogen chloride produces a deep blue coloration. Hexine does not, like heptine, form a crystallisable hydrate with water. In contact with sulphuric acid, it polymerises with development of heat, and when the supernatant layer is distilled it yields dihexine,  $C_{12}H_{20}$ , a colourless liquid which boils at  $210-215^\circ$ , does not alter in contact with the air, and is not attacked by sulphuric acid.

The principal products of the action of heat on heptine are hydrogen and toluene, together with smaller proportions of the lower homologues of heptine, pentine, and hexine. The benzene is doubtless a product of the decomposition of some of the hexine. C. H. B.

**Bismuth Thiocyanate.** By G. BENDER (*Ber.*, **20**, 723—726).—Bismuth thiocyanate,  $Bi(CNS)_3$ , is prepared by treating bismuth hydroxide with very dilute hydrogen thiocyanate solution (sp. gr. = 1.006). The solution takes place very slowly, and a small quantity of a yellow substance separates, probably consisting of basic salts (Meitzendorf (*Ann. Phys. Chem.*, **56**, 63). The product is evaporated in a water-bath, when a red, amorphous substance separates; on cooling, pure bismuth thiocyanate separates in aggregates of rather large crystals mostly of a bright-orange colour, but also partly amber-coloured. The crystals are rhombic;  $a : b : c = 0.76134 : 1 : 0.28423$ . It is decomposed by cold water into a yellow, amorphous substance and a red solution; when heated at  $80^\circ$ , it also decomposes. Cold nitric acid dissolves it with a red colour; in a short time an evolution of gas takes place, and a clear solution is formed containing all the sulphur in the form of sulphuric acid. N. H. M.

**Action of Potassium Permanganate on Dextrose in Neutral Solution.** By A. SMOLKA (*Monatsh. Chem.*, **8**, 1—26).—When dextrose is boiled with excess of potassium permanganate, it is completely oxidised to water and carbonic anhydride with separation of a potassium hydromanganite,  $KH_3Mn_4O_{10}$ . With excess of permanganate in the cold the action is the same, a trace of oxalic acid, however, being also formed.

By successively decreasing the amount of potassium permanganate, and allowing the action to take place at the ordinary temperature, there are obtained, in addition to water and carbonic anhydride, oxalic acid and formic acid, or the two latter alone, and a quantity of dextrose remains unaltered, depending on the amount of oxidising agent employed. The permanganate is reduced, partly to manganic, and partly to manganous oxide. The relative amounts of the products

of oxidation are variable even with the same proportions of dextrose and permanganate, and appear to be dependent on the temperature and concentration of the solutions.

G. H. M.

**Compounds of Phenylhydrazine with the Sugars.** By E. FISCHER (*Ber.*, 20, 821—834).—Previous experiments by the author have shown that those sugars which reduce Fehling's solution combine with phenylhydrazine to form crystalline compounds sparingly soluble in water (*Abstr.*, 1885, 53). Thus dextrose or lævulose reacts with phenylglucosazone,  $C_6H_{10}O_4(N_2HPh)_2$ , a change probably to be explained by the intermediate formation of a dextrose (or lævulose) phenylhydrazine, which reacts with two molecules of phenylhydrazine to form phenylglucosazone, thus: (1)  $C_6H_{12}O_6 + PhN_2H_3 = C_6H_{12}O_5N_2HPh + H_2O$ ; and (2)  $C_6H_{12}O_5N_2HPh + 2PhN_2H_3 = C_6H_{10}O_4(N_2HPh)_2 + NH_2Ph + NH_3 + H_2O$ . The intermediate dextrose phenylhydrazine forms small, colourless crystals melting at  $144-145^\circ$ , soluble in hot water and alcohol, insoluble in chloroform and benzene. It is decomposed by acids into the hydrazine and dextrose together with humous substances; on reduction with zinc-dust and acetic acid, it yields aniline and a basic substance to be described later.

Similarly galactose forms *galactose phenylhydrazine*, crystallising in colourless needles melting at  $158^\circ$  (uncorr.), and phenylgalactosazone melting at  $193-194^\circ$ , and not at  $182^\circ$  as stated formerly.

*Phenylsorbinazone*, from sorbin and phenylhydrazine, crystallises in yellow needles melting at  $164^\circ$ ; it was formerly described as a liquid.

*Phenylmaltosazone* differs from the above azones by its greater solubility in hot water; it is insoluble in ether and benzene. In the course of its formation its anhydride,  $C_{24}H_{30}N_4O_8$ , is also obtained; this crystallises in yellow needles melting at  $223-224^\circ$ , insoluble in water, ether, and benzene.

*Phenylmaltosazone* crystallises in yellow needles sparingly soluble in water, more readily in alcohol.

It is further shown by means of the phenylhydrazine reaction that one of the products of the oxidation of mannitol with nitric acid, namely mannitose, is identical with lævulose, thus confirming Dafert's experiments. The other product combines with the hydrazine to form a substance,  $C_{12}H_{18}N_2O_5$ , melting at  $188^\circ$ , isomeric with dextrose phenylhydrazine, from which it is distinguished by its more sparing solubility in water.

In conclusion, it is remarked that a more precise definition of the word sugar is required, for in the text-books substances of the general formula  $C_6H_{12}O_6$  are classed together, all possessing to a greater or less degree the common property of sweetness, yet differing most markedly in their chemical behaviour.

V. H. V.

**Action of Nitric Acid on Sugar.** By E. MAUMENÉ (*Compt. rend.*, 104, 511).—Boutroux's failure to obtain hexepic acid was due to the employment of too small a quantity of nitric acid. Hexepic acid is absolutely identical with oxygluconic acid.

C. H. B.

**Blue Iodide of Starch.** By F. MYLIUS (*Ber.*, 20, 688—695).—The analogy between iodide of starch and iodocholic acid (this vol., p. 606), is shown by the following facts: (1) Iodine solutions which colour starch contain either hydriodic acid or one of its salts; (2) the presence of substances, such as chlorine, which decompose hydriodic acid prevents the formation of iodide of starch; (3) silver solutions decolorise solution of iodide of starch—the colour is restored by adding potassium or hydrogen iodide; (4) an aqueous solution of iodine cannot colour starch blue; the blue colour appears at once when a trace of hydriodic acid or potassium iodide is added.

When starch is added to a solution of iodine and hydriodic acid containing sulphuric acid, iodide of starch separates: the amount of iodine and hydriodic acid which has been absorbed by the starch can be readily determined by titration. The results of several experiments show that the proportion of iodine absorbed to that of the hydriodic acid is 4 : 1, and it is probable that the resulting compound has the formula  $(C_{24}H_{40}O_{20}I)_4.HI$ . From this, the author concludes that the formula of starch is  $C_{24}H_{40}O_{20}$ , which is that ascribed to it by Pfeiffer and Tollens (*Abstr.*, 1882, 490).

Iodide of starch dried in a vacuum appears to be anhydrous. The *barium compound* was analysed, and has probably the composition expressed by the formula  $(C_{24}H_{40}O_{20}I)_8.BaI_2$ . The *potassium* and *sodium compounds* are soluble, the *barium* and *zinc compounds* are insoluble.  
N. H. M.

**Reduction of Aldoximes and Acetoximes.** By H. GOLDSCHMIDT (*Ber.*, 20, 728—730; compare this vol., p. 249).—Isopropylamine is prepared by reducing 3 grams of acetoxime dissolved in 30 c.c. alcohol with 160 grams of 2.5 per cent. sodium amalgam and 14 grams of glacial acetic acid at 40°. The product is diluted with water, treated with soda solution, and distilled, the vapour being passed into dilute hydrochloric acid.

Heptylamine and ethylamine are obtained in a similar manner from œnanthaldoxime and ethaldoxime.

Salicylamine is best prepared by reducing salicylaldoxime with zinc-dust and acetic acid.

*Furfurylamine* was prepared from furfuraldoxime (m. p. 89°); it is soluble in water and boils at 143° (under 730 mm. pressure). The *hydrochloride* crystallises in thin needles, and the *platinochloride* in gold-coloured, lustrous plates.  
N. H. M.

**Action of Nitrous Acid on Acetone.** By T. SANDMEYER (*Ber.*, 20, 639—641).—When acetone is treated with an equal weight of liquid nitrous anhydride at a temperature below 30° until all blue colour has disappeared, and the product is afterwards shaken with small quantities of water, a yellow oil is obtained. This is heavier than, and moderately soluble in water, has a strong acid reaction, and decomposes after a time or when gently heated. It is probably *is-nitrosodiacetone nitrate*,  $NO_2O.CMe_2.C(OMe).NOH$ . When heated with dilute hydrochloric acid, it is decomposed into isonitrosochloracetone,  $COMe.CCl:NOH$ , together with a small quantity of hydro-

gen cyanide and acetone. On boiling a dilute aqueous solution of isonitrosodiacetone nitrate, a small quantity of a white, insoluble, feebly explosive compound separates, acetone and hydrogen cyanide distil over in small quantity, and there remains in the flask a solution containing pyruvic acid, ammonia and nitric acid.

Isonitrosochloracetone yields an *oxime*,  $\text{OH}\cdot\text{N}:\text{CMe}\cdot\text{CCl}:\text{NOH}$ , crystallising in small, white needles melting at  $171^\circ$  with decomposition. W. P. W.

**Action of Potassium Hydroxide on a Mixture of Acetone and Chloroform.** By R. ENGEL (*Compt. rend.*, 104, 688—691).—By the action of solid potassium hydroxide on acetone and chloroform, Willgerodt obtained a compound, acetone-chloroform,  $\text{C}_4\text{H}_7\text{OCl}_3$ , together with a smaller quantity of two acids,  $\text{C}_{11}\text{H}_{20}\text{O}_6$  and  $\text{C}_7\text{H}_{14}\text{O}_4$ . The author has obtained the acid  $\text{C}_{11}\text{H}_{20}\text{O}_6$  as the principal product under the following conditions:—

Acetone and chloroform in equivalent proportions are mixed with an equal volume of alcohol cooled to  $0^\circ$ , and then mixed with alcoholic potash also cooled to  $0^\circ$ , and containing twice the quantity of potassium hydroxide required to remove the whole of the chlorine. Carbonic oxide is evolved, and there is considerable development of heat. The flask is carefully cooled in the early stages of the process, but towards the end of the reaction the temperature is raised to  $60$ — $70^\circ$ . The product is acidified with hydrochloric acid, filtered, the precipitated potassium chloride washed with alcohol, the filtrate and washings mixed with water and agitated with ether. When the ethereal solution is distilled, it leaves a yellow aqueous liquid, which is converted into a lead salt and recrystallised. The majority of the salts form gummy masses, but the lead salt crystallises in prisms of the composition  $\text{PbC}_{11}\text{H}_{18}\text{O}_6 + 2\text{H}_2\text{O}$  when its solution is evaporated in a dry vacuum. The free acid volatilises in a dry vacuum, and the lead salt shows a decided tendency to become basic. The zinc salt,  $\text{ZnC}_{11}\text{H}_{18}\text{O}_6 + 2\text{H}_2\text{O}$ , crystallises in needles which lose their water when carefully heated at  $140^\circ$ . Both salts melt at about  $100^\circ$ , and begin to decompose at  $150^\circ$ . The acid,  $\text{C}_{11}\text{H}_{20}\text{O}_6$ , is formed by the condensation of three molecules of acetone with fixation of two  $\text{COOH}$  groups and loss of one atom of oxygen. It may possibly have the constitution  $\text{CMe}_2(\text{COMe}_2\text{COOH})_2$ .

Other acids are formed in the reaction, and remain in the aqueous solution after agitation with ether. C. H. B.

**Chloroformamide: Synthesis of Aromatic Acids.** By L. GATTERMANN and G. SCHMIDT (*Ber.*, 20, 858—862).—When dry carbonyl chloride is passed into ammonium chloride heated at  $400^\circ$ , chloroformamide distils over, and solidifies in long, broad needles melting at  $50^\circ$ , and distilling at  $61$ — $62^\circ$ . This substance has a peculiarly disagreeable odour. On keeping, it forms cyamelide with elimination of hydrogen chloride. By water, as also by damp air, it is decomposed into carbonic anhydride and ammonium chloride. It reacts with the amines to form monosubstituted carbanides.

Chloroformamide may be used to effect the synthesis of aromatic

acids by means of the aluminium chloride reaction, in that it yields with the hydrocarbons or ethers amides of these acids. Thus if chloroformamide is mixed with a solution of toluene in carbon bisulphide, and aluminium chloride is added, the amide of paratoluic acid is produced. In the paper, this method of synthesis is illustrated in the case of cuminic, naphthoic, anisic, and veratric acids.

V. H. V.

**Tertiary Trichlorobutyl Chloride and Ether.** By C. WILLGERODT and F. DÜRR (*Ber.*, 20, 539—540).—When solid acetone-chloroform is treated with phosphorus pentachloride at 100°, tertiary trichlorobutyl chloride and ether are obtained and can be separated by fractional distillation.

*Tertiary trichlorobutyl ether*,  $O(CMe_2CCl_3)_2$ , boils at about 156°, does not solidify in a freezing mixture, distils undecomposed with steam, and strongly attacks the mucous membrane.

*Tertiary trichlorobutyl chloride*,  $CMe_2Cl \cdot CCl_3$ , melts and boils at about 167°, has a powerful odour, is volatile with steam, and is soluble in most organic solvents, insoluble in water.

W. P. W.

**Substituted Acrylic and Propionic Acids.** By C. F. MABERY (*Amer. Chem. J.*, 9, 1—11).—*Bromotrichloropropionic acid*,  $C_3H_2Cl_3BrO_2$ , is prepared by passing chlorine into a cold chloroform solution of chlorobromacrylic acid, and is purified by recrystallisation from carbon bisulphide. It melts at 83—84°. The following salts are described:— $Ba(C_3HCl_3BrO_2)_2$ , a gummy mass;  $Ca(C_3HCl_3BrO_2)_2$  oblique prisms, and  $KC_3HCl_3BrO_2 + 2H_2O$ , rhombic plates.

*Trichloracrylic acid*,  $C_3HCl_3O_2$ , is obtained by treating the above acid with a slight excess of baryta-water in the cold. After recrystallisation from carbon bisulphide, it melts at 76°. Water at 20° dissolves 6 per cent. of the acid. The following salts are described:— $Ba(C_3Cl_3O_2)_2 + 3\frac{1}{2}H_2O$ , needles;  $Ca(C_3Cl_3O_2)_2 + 3\frac{1}{2}H_2O$ , needles;  $KC_3Cl_3O_2$ , crystalline plates; and  $AgC_3Cl_3O_2$ , which may be crystallised from hot water.

It has been supposed (Beilstein) that the dichlor- and dibrom-acrylic acids are represented by the formula  $CX_2 \cdot CH \cdot COOH$ , and not  $CHX : CX \cdot COOH$ . This view is not supported by evidence (compare Hill, *Abstr.*, 1881, 1030); it has been shown, however (*ibid.*, 1029), that the additive product of chlorine and  $\alpha$ -dibrom-acrylic acid is essentially different from the additive product of bromine and  $\alpha$ -dichloracrylic acid. On the assumption of the formula  $CHX : CX \cdot COOH$  for the disubstituted acrylic acids, these two additive products should be identical. In order to confirm these results the two acids have been treated with baryta-water, and thus converted into the corresponding bromodichloracrylic acids. Both acids yield salts which appear to be identical. The following are described:— $Ba(C_3BrCl_2O_2)_2 + 3H_2O$ ;  $Ca(C_3BrCl_2O_2)_2 + 4H_2O$ ;  $KC_3BrCl_2O_2$ ; and  $AgC_3BrCl_2O_2$ ; but the free acids differ somewhat, namely, that prepared from  $\alpha$ - $\beta$ -dichloracrylic acid melts at 85°, is dissolved by water at 20° to the extent of 2.6 per cent., and when heated with water melts before dissolving, but solidifies on cooling; that pre-

pared from  $\alpha$ - $\beta$ -dibromacrylic acid melts at  $78-80^\circ$ , is dissolved by water at  $20^\circ$  to the extent of 6.9 per cent., and with water it forms an oil which does not solidify at  $0^\circ$ .

The author explains the existence of these two bromodichloracrylic acids by supposing that in the treatment of  $\alpha$ - $\beta$ -dibromacrylic acid with chlorine the  $\beta$ -atom of bromine is substituted by chlorine, and the chlorine monobromide forms an additive product, so that two chlorine-atoms are united to the same carbon-atom ( $\beta$ ); the tri-substituted acrylic acid prepared from  $\alpha$ - $\beta$ -dibromacrylic acid would thus be  $\text{CCl}_2:\text{CBr}\cdot\text{COOH}$ , while that from  $\alpha$ - $\beta$ -dichloracrylic acid is

H. B.

**Preparation of Calcium and Potassium Tartrates.** By T. GLADYSZ (*Dingl. polyt. J.*, 263, 98—99).—The author has patented a process for extracting tartaric acid from wine yeast and other substances containing tartaric acid, based on the following facts:—When calcium tartrate is treated with water, and sulphurous anhydride introduced at the ordinary temperature, the tartrate dissolves completely. On heating the solution at  $90-100^\circ$ , sulphurous anhydride escapes, and a crystalline precipitate of calcium tartrate separates. A similar result is obtained on treating hydrogen potassium tartrate with sulphurous anhydride, a solution of hydrogen potassium sulphite and free tartaric acid being formed in the cold, whilst on application of heat sulphurous anhydride is liberated. Moreover, on adding normal or hydrogen potassium tartrate to a solution of calcium sulphite in sulphurous acid, calcium tartrate is precipitated, and a solution of hydrogen potassium sulphite is obtained.

D. B.

**Furfuraldehyde.** By H. SCHIFF (*Ber.*, 20, 540—542).—A mixture of equal volumes of xylidine and acetic acid to which some alcohol has been added can be used to detect traces of furfuraldehyde, the presence of which is rendered evident by the production of the red colour of furfuroxylidine; the test is so delicate that the amount of furfuraldehyde (about 1 per cent.) formed when 0.00005 gram of sugar is heated in a tube, can be detected by holding a slip of paper moistened with the solution in the fumes. The author finds that furfuraldehyde is formed in many culinary processes, and that it is present in very small quantities in tobacco smoke. Furfuraldehyde is also formed in very small quantities when guaiacum resin is distilled, and its formation is probably due to the presence of a trace of glucoside in the resin (Kosmann, *Jahresb.*, 1863, 557); also when calcium pyromucate is distilled either alone or with calcium formate, and when pyromucic and mucic acids are distilled. Furoïn and furil give the reaction when their vapours are exploded with air, and furfuraldehyde can be detected when furfurin and hydrofurfuramide are distilled in vessels containing air. The dry distillation of furaniline hydrochloride, of pyromucanilide, of cholic and meconic acids, and of fats and fatty acids is not accompanied with the production of furfuraldehyde.

W. P. W.

**Negative Nature of the Phenyl-group.** By V. MEYER (*Ber.*, **20**, 534—536).—When a CH- or CH<sub>2</sub>-group occurs between two CO-groups in the constitutional formula of a compound, as, for example, in that of ethyl acetoacetate, it is known that each atom of hydrogen is displaceable by a metal; the author's investigations, carried on in conjunction with his pupils, appear to prove that this property is not affected when phenyl is substituted for one of the CO-groups, and in this preliminary communication the chief results as yet obtained are briefly given. The hydrogen of the methylene-group in deoxybenzoïn, Ph·CH<sub>2</sub>·CO·Ph, is displaceable by methyl, ethyl, butyl, and benzyl, and these derivatives crystallise well and yield characteristic compounds with hydroxylamine. Dibenzylketone yields a benzyl-derivative of high melting point. Ethyl phenylacetate, however, does not react under ordinary conditions. Benzyl cyanide, when treated with benzyl chloride and sodium ethoxide, yields a well-crystallised benzyl-derivative, CH<sub>2</sub>Ph·CHPh·CN, which boils without decomposition. Ethyl dinitrophenylacetate forms a well-crystallised compound, C<sub>6</sub>H<sub>3</sub>(NO<sub>2</sub>)<sub>2</sub>·CH(COOMe)·N<sub>2</sub>Ph, with diazobenzene chloride.

The thiënyl-group exerts an influence in the molecule similar to that of phenyl: thus the ketone C<sub>4</sub>SH<sub>3</sub>·CO·CH<sub>2</sub>·Ph (?) reacts easily, like deoxybenzoïn, and yields crystalline derivatives.

W. P. W.

**Pyrogenic Reactions.** By P. FERKO (*Ber.*, **20**, 660—664).—By passing dry ethylene through gently boiling benzene, and then through an iron tube 60 cm. long, heated in a Mermet's gas furnace until all the benzene (1½ litres) was used up, a crude product was obtained from which the following hydrocarbons were isolated:—Unchanged benzene (80 grams), cinnamene (17 grams), diphenyl (300 grams), phenanthrene (10 grams), anthracene (15 grams). No naphthalene was formed.

When 1½ litres of toluene are passed through the tube (a process which takes eight hours), the following products are formed:—Benzene (150 grams), toluene (180 grams), cinnamene (7 grams), naphthalene (40 grams), diphenyl (27 grams), phenanthrene (1·5 gram), anthracene (12 grams), and an oil boiling at 270—280° (10 grams). Toluene (1¼ litres) and ethylene yielded benzene (200 grams), toluene (160 grams), cinnamene (10 grams), anthracene (20 grams), oil boiling at 270—280° (13 grams).

Naphthalene alone yielded only dinaphthyl together with unchanged naphthalene. Naphthalene (900 grams) and ethylene yielded—unchanged naphthalene (400 grams), acenaphthene (0·5 gram), phenanthrene (1 gram), and dinaphthyl (125 grams).

Ethylbenzene (500 grams) yielded—benzene (75 grams), toluene (5 grams), unchanged substance (20 grams), cinnamene (10 grams), naphthalene (11 grams), diphenyl (3 grams), phenanthrene (13 grams), and anthracene (2 grams). Azobenzene yielded only a small product, from which benzene and diphenyl were isolated.

N. H. M.

**Aromatic Lead Compounds.** By A. POLIS (*Ber.*, **20**, 716—722).—Lead tetraphenyl, PbPh<sub>4</sub>, is prepared by boiling 500 grams of

finely powdered alloy of lead and sodium (containing 8 per cent. of sodium) with 500 grams of bromobenzene and 20 c.c. of ethyl acetate for 60 hours. The liquid portion of the product is poured off, the residue extracted with hot benzene; the solutions are then mixed, and the excess of bromobenzene and benzene distilled off in a vacuum. The residue is first recrystallised from benzene in presence of animal charcoal, and then several times from warm ether. It forms small, colourless needles which melt at  $224-225^{\circ}$ , and decompose at  $270^{\circ}$ . Sp. gr. = 1.5298 at  $20^{\circ}$ . It is very sparingly soluble in alcohol, ether, and glacial acetic acid, more soluble in benzene, chloroform, and carbon bisulphide. It burns in air with a smoky flame. When heated with hydrochloric acid at  $230^{\circ}$ , lead chloride and chlorobenzene are formed.

*Lead diphenyl dinitrate*,  $\text{PbPh}_2(\text{NO}_3)_2 + 3\text{H}_2\text{O}$ , is readily obtained by gradually adding lead tetraphenyl to boiling nitric acid (sp. gr. 1.4). The acid must be kept at its boiling point. It separates on cooling in small, lustrous plates, and is recrystallised from water made acid with nitric acid. It is rather readily soluble in water and in alcohol. It detonates when heated below its melting point. When boiled with water, the liquid remains turbid owing to the formation of a *basic salt*,  $\text{OH}\cdot\text{PbPh}_2\cdot\text{NO}_3$ ; this is a white powder.

*Lead diphenyl diiodide*,  $\text{PbPh}_2\text{I}_2$ , is formed when a solution of iodine in chloroform is added to lead tetraphenyl also dissolved in chloroform. It separates in gold-coloured plates which melt at  $101-103^{\circ}$ . It is soluble in chloroform, benzene, and alcohol. The corresponding bromide is a white powder which decomposes before fusing.

*Lead tetraparatolyl*,  $\text{Pb}(\text{C}_7\text{H}_7)_4$ , is prepared similarly to the phenyl compound from 120 grams of parabromotoluene, 300 grams of alloy, 40 grams of toluene, and 4 c.c. of ethyl acetate. The heating is continued for 50 hours. It is crystallised successively from benzene and alcohol. It forms small, colourless needles which melt at  $239-240^{\circ}$ , and decompose at  $254^{\circ}$ ; sp. gr. +1.4329 at  $20^{\circ}$ . It is more readily soluble than the phenyl compound in benzene, carbon bisulphide, and chloroform.

N. H. M.

**Sulphuric Acid as an Iodine-carrier.** By G. S. NEUMANN (*Ber.*, 20, 581—582).—When equimolecular proportions of iodobenzene and sulphuric acid are heated at  $100^{\circ}$  for some hours, a mixture of paradiiodobenzene, iodobenzenesulphonic acid and benzenesulphonic acid is obtained. Ortho- and para-iodotoluene under like conditions yield diiodotoluene and triiodotoluene; whilst ortho- and para-iodophenol yield diiodophenol when treated with sulphuric acid in the cold.

W. P. W.

**Tribromophenol.** By A. PURGOTTI (*Gazzetta*, 16, 526—531).—The *calcium*-derivative of tribromophenol crystallises in white, silky needles; the *ammonium*-derivative forms minute crystals, more soluble in cold water than in hot; the *silver*-derivative is a red, insoluble powder darkening rapidly on exposure; the *lead*- and *zinc*-derivatives are white precipitates, and the *copper*-derivative a violet powder, insoluble in water, soluble in ammonia. The *ethyl*-derivative crystallises in bril-

liant prisms melting at  $69^{\circ}$ . As an antiseptic, tribromophenol seems to be superior to phenol and thymol. V. H. V.

**Manufacture of Resorcinol.** By O. MÜHLHÄUSER (*Dingl. polyt. J.*, 263, 154—157).—This substance is prepared on a large scale by fusing sodium benzenedisulphonate with sodium hydroxide. Its production from benzene involves the following operations:—(1.) Preparation of benzenesulphonic acid by treating pure benzene free from thiophen with sulphuric acid of  $67^{\circ}$  B. (2.) Conversion of the monosulphonic acid into benzenedisulphonic acid by heating with an excess of sulphuric acid at  $240^{\circ}$  for about 12 hours with constant agitation. (3.) Production of sodium benzenedisulphonate by boiling the mass out with water, liming until neutral, filter-pressing, and treating the filtrate with sodium carbonate. The mixture is again filtered, and the effluent liquid evaporated to dryness. (4.) Fusing the dried salt with soda in an open cast-iron boiler fitted with agitators. (5.) Dissolving the heated mass in water, and adding hydrochloric acid to feebly acid reaction. (6.) Extracting the resorcinol from the acid solution with amyl alcohol in an extraction apparatus. (7.) Subjecting the extract to distillation to expel the alcohol; the residue containing the resorcinol being dried in enamelled iron pans. (8.) Purification of the resorcinol by fractional distillation in a vacuum. According to this method 125 kilos. of sodium benzenedisulphonate yield from 20 to 23 kilos. of pure resorcinol. D. B.

**Constitution of Dinitroquinol and Formation of Nitrilanilic Acid.** By R. NIETZKI and J. PREUSSER (*Ber.*, 20, 797—799).—The authors find that the diacetyldiamidoquinone,  $C_6H_2O_2(NHAc)_2$ , lately described by them (*Abstr.*, 1886, 1024), is identical with the compound obtained by Bamberger (*Abstr.*, 1884, 309) by the oxidation of triacetyltriamidophenol, to which he gave the formula  $C_{20}H_{20}N_4O_8$ . The simpler formula is undoubtedly the correct one, as when reduced with stannous chloride and hydrochloric acid the acetyl-groups are eliminated and diamidoquinol is formed. The compound liquefies at  $265$ — $270^{\circ}$  without showing a definite melting point. The formation of quinol proves that the quinone-oxygens must as usual be in the para-position to one another, and the formation from triacetyltriamidophenol (prepared from picric acid), that the two amido-groups (and consequently the corresponding nitro-groups in the parent dinitroquinol) are both in ortho-positions to one of the oxygen-atoms or hydroxyl-groups respectively.

Nietzki has shown that this dinitroquinol is easily converted by nitric acid into nitrilanilic acid in which the two nitro-groups are in the para-position to each other. This and also the formation of paradinodihydroxyquinone from the same quinol, leave little doubt of the intermediate formation of a tetranitroquinol. L. T. T.

**Action of Sodium Alkoxides on Benzaldehyde.** By L. CLAISEN (*Ber.*, 20, 646—650).—When 12 grams of sodium and 150 grams of methyl alcohol are heated on a water-bath and treated with 106 grams of benzaldehyde, the whole soon solidifies to a mass of

white crystals. The product consists of benzoic acid (56 grams) and benzyl alcohol (45 grams). If the mixture, after being heated for some hours on a water-bath, is first treated with glacial acetic acid (30 grams) and then with water, the product contains only a trace of benzoic acid, and consists chiefly of benzyl benzoate boiling at 323—324°. This boiling point was confirmed by preparing the salt by another method. Methyl benzoate and benzyl alcohol are also formed.

When benzyl benzoate and sodium methoxide are heated on a water-bath, a mixture of benzyl alcohol and methyl benzoate are formed; the same products are obtained when methyl benzoate and a solution of sodium in benzyl alcohol are warmed together.

Benzyl benzoate is also obtained by dissolving 1.5 gram of sodium in benzyl alcohol, adding 200 grams of benzaldehyde and heating for some days on a water-bath. 10 grams of glacial acetic acid and then water are added, and the oil distilled. The yield of benzyl benzoate is 150 grams. N. H. M.

**Quinonedioxime and Dinitrosobenzene.** By R. NIETZKI and F. KEHRMANN (*Ber.*, 20, 613—616).—*Quinonedioxime*,  $C_6H_4(NO)_2$ , [1 : 4], is obtained when 2 parts of hydroxylamine hydrochloride and  $\frac{1}{2}$  part of hydrochloric acid are added to 1 part of quinol dissolved in the least possible quantity of cold water, and the whole allowed to remain for 12 hours. It crystallises in slender, colourless needles, decomposes at 240°, and is soluble in ether and hot water; the aqueous solution, however, undergoes partial decomposition. With dilute ammonia, it gives a greenish-yellow solution from which hydrochloric acid effects only a partial precipitation, the resulting solution yielding nitrosophenol when shaken with ether. When reduced with stannous chloride and hydrochloric acid, paraphenylenediamine is obtained.

*Paradinitrosobenzene* is formed by the oxidation of quinonedioxime in alkaline solution with potassium ferricyanide. It is a golden-yellow powder, insoluble in all neutral solvents, sublimes partially without decomposition, and is slightly volatile with steam. When boiled with a solution of hydroxylamine hydrochloride, it is reconverted into quinonedioxime. W. P. W.

**Introduction of Acid Radicles into Ketones.** By L. CLAISEN (*Ber.*, 20, 655—657).—Benzoylacetophenone is obtained by mixing sodium ethoxide (free from alcohol) with ethyl benzoate and acetophenone; the whole solidifies with development of heat to a crystalline mass. This is washed several times with water, then with dilute soda solution, and is then treated with carbonic anhydride. The yield is 50 per cent. of the acetophenone employed. In a similar manner, ethyl benzoylacetate can be prepared from acetophenone and ethyl carbonate, but the yield is less satisfactory than in the case of benzoylacetophenone.

*Nitrosoacetophenone*,  $CH_3CO : N \cdot OH$ , is readily prepared by adding acetophenone and then amyl nitrite to a well cooled solution of sodium in 20 parts of alcohol, and keeping the whole in a well closed

vessel for 12 to 24 hours at a low temperature. The reddish-brown sodium salt is freed from the liquid portion of the product by suction, washed with ether, dissolved in water and treated with acetic acid. It crystallises in prisms melting at 126—127°; the solution in sulphuric acid acquires an intense yellowish-red colour when treated with phenol. It dissolves in solutions of alkalis and alkaline carbonates, and is precipitated from the solutions slowly and incompletely by carbonic anhydride. When heated alone or with sulphuric acid, it is decomposed into benzoic and hydrocyanic acids.

The condensation products of ketones with aldehydes (Claisen and Schmidt, *Ber.*, **14**, 1459) are readily prepared by means of sodium alkoxides. Benzalacetophenone is obtained by mixing 12 grams of acetophenone with 10.5 grams of benzaldehyde, adding 3 c.c. of a 20 per cent. sodium methoxide solution, and keeping the whole for some days at a winter temperature. The yield is 90 per cent. of the theoretical.

N. H. M.

**Separation of Ortho- and Para-toluidine.** By A. WÜLFING (*Dingl. polyt. J.*, **263**, 260).—On treating a mixture of para- and ortho-toluidine with nitrous acid, the latter is first attacked and converted into an amidoazo-compound, after which the acid acts on the para-compound, forming a diazoamido-derivative. Hence by employing an amount of acid equivalent to the proportion of orthotoluidine, the para-compound remains unaltered. It is recommended to effect the conversion by treating toluidine hydrochloride with sodium nitrite. This process is of special utility in separating the paratoluidine contained in crude toluidine.

D. B.

**Manufacture of Dimethylaniline.** By O. MÜHLHÄUSER (*Dingl. polyt. J.*, **263**, 348—351).—For the production of methylaniline on a commercial scale, two processes are in vogue: (1) Treating aniline with common hydrochloric acid of 21° B. and methyl alcohol, and heating the mixture under pressure; (2) Allowing methyl alcohol to act on aniline sulphate under pressure. After the completion of the reaction, the mass is rendered alkaline with lime, and distilled with steam. The oily distillate is then treated with dried salt to remove the last traces of water. The methylaniline so obtained may be used for the preparation of "violets," whilst for the manufacture of methylene-blue and malachite-green from dimethylaniline, it is necessary to subject the oil to fractional distillation, collecting the portion which comes over between 200° and 205°.

D. B.

**Conversion of Phenols into Amines.** By V. MERZ and P. MÜLLER (*Ber.*, **20**, 544—550).—Continuing their experiments (this vol., p. 243), the authors have examined the action of mixtures of ammonium zinc bromide and ammonium bromide, and of ammonium zinc chloride and ammonium chloride on the three isomeric cresols when heated in sealed tubes for 40 hours at temperatures varying between 300° and 340°. The results are given in quantitative form, and show that under these conditions orthocresol yields about 10 per cent. of orthotoluidine and 50 per cent. of orthoditolylamine; meta-

cresol yields about 27 per cent. of metatoluidine and 50 per cent. of metaditolylamine; and paracresol yields from 25 to 45 per cent. of paratoluidine and 40 to 30 per cent. of paraditolylamine; the remainder in each case consisting of unaltered cresol, and from 2 to 6 per cent. of carbonaceous residue.

The boiling point of paraditolylamine was found to be 320—321°.

W. P. W.

### Condensation Products of Ethyleneaniline with Aldehydes.

By F. Moos (*Ber.*, 20, 732—734).—Hofmann's diethyleneaniline (diphenylpiperazine if named according to Merz and Mason's proposals, this vol., p. 498),  $C_2H_4:(NPh)_2:C_2H_4$ , is a very stable compound, and this stability is probably due to its hexatomic ring formation. The author has obtained analogous compounds of the general formula  $C_2H_4:(NPh)_2:CHR$ , containing a pentatomic ring, by the condensation of ethyleneaniline with aldehydes.

Benzaldehyde and ethyleneaniline when heated together unite, with separation of water, to form a compound,  $C_2H_4:(NPh)_2:CHPh$ , which crystallises in colourless needles, melts at 137°, and distils without decomposition. Cumaldehyde and ethyleneaniline, under like conditions, yield a compound,  $C_{24}H_{26}N_2$ , crystallising in long, white, silky needles, melting at 124—125°, and soluble in ether and absolute alcohol. Salicylaldehyde and ethyleneaniline give a compound crystallising in groups of white, silky needles. It melts at 116°, and is easily soluble in ether and absolute alcohol, less so in benzene. Anisaldehyde and ethyleneaniline form a compound crystallising in colourless prisms, soluble in benzene and alcohol; it melts at 164°, and has the composition  $C_{22}H_{22}N_2O$ . Isobutaldehyde and ethyleneaniline undergo a similar reaction, yielding a compound,  $C_{18}H_{22}N_2$ . This crystallises in large, colourless needles, melts at 95°, and is easily soluble in benzene and ether, sparingly so in water. Cēnanthaldehyde and ethyleneaniline yield the compound  $C_{21}H_{28}N_2$ , which crystallises in glistening needles, melts at 79°, and is easily soluble in ether, but sparingly so in benzene.

All these compounds, when warmed with dilute hydrochloric or sulphuric acid, are very readily reconverted into their constituents, thus differing from diphenylpiperazine. The author is now investigating the analogous compounds (containing a hexatomic ring) formed by the condensation of aldehydes with trimethyleneaniline.

L. T. T.

**Action of Carbonyl Chloride on Ethylene- and Trimethylene-diphenyldiamine.** By A. HANSEN (*Ber.*, 20, 781—785).—*Trimethylenediphenyldiamine*,  $C_3H_6(NHPh)_2$ , was prepared by heating a mixture of aniline (4 mols.) and trimethylene bromide (1 mol.) on the water-bath. It is an oil which boils with decomposition above 360°. Its *sulphate* crystallises in minute needles melting at 155—156°, and is soluble in alcohol. With sodium nitrite the sulphate yields the corresponding *dinitrosamine* crystallising in greenish scales melting at 87°. When a solution of the diamine in benzene was slowly added to a well-cooled solution of carbonyl chloride in benzene, *trimethylenediphenylcarbamide*,  $CO<\begin{smallmatrix} NPh\cdot CH_2 \\ NPh\cdot CH_2 \end{smallmatrix}>CH_2$ , and *tri-*

*methylenedicarbanilic chloride*,  $C_3H_6(NPh \cdot COCl)_2$ , were formed. The former crystallises in silky scales which are soluble in alcohol and melt at  $156^\circ$  (uncorr.). The chloride crystallises in brittle needles, sparingly soluble in alcohol and melting at  $102^\circ$  (uncorr.). An alcoholic solution of the chloride, when treated with sodium, yielded *ethyl trimethylenecarbanilate*, which forms crystals melting at  $56^\circ$ . When heated with aniline in solution in benzene, the chloride yields the corresponding *anilide* which forms hard, transparent crystals melting at  $153^\circ$  (uncorr.).

Ethylenediphenyldiamine yields with carbonyl chloride under the above conditions, *ethylenediphenylcarbamide* and *ethylenedicarbanilic chloride*. The carbamide crystallises in scales, sparingly soluble in benzene, and melting at  $206^\circ$  (uncorr.). The chloride forms glistening prisms, soluble in benzene, and melting at  $183^\circ$  (uncorr.). The corresponding *ethyl salt* crystallises from alcohol in needles melting at  $87-88^\circ$ . The chloride is more stable than that described above, and the anilide, which appears to melt at about  $170^\circ$ , could not be obtained pure, but always contained undecomposed chloride. Neither of these chlorides is attacked by boiling alkalis or dilute acids. Their formation is analogous to that of the chloride obtained by Loeb (Abstr., 1885, 1213, and this vol., p. 42) by the action of carbonyl chloride on ethenyldiphenyldiamine.

When oxidised with chromic acid, ethylenediphenylcarbamide yielded diphenylparabanic acid. L. T. T.

**The Tartrazines; a New Class of Dyes.** By J. H. ZIEGLER and M. LOCHER (*Ber.*, 20, 834—840).—Phenylhydrazine hydrochloride reacts with an equimolecular proportion of dihydroxytartaric acid to form *phenylizindihydroxytartaric acid*,

a yellow, crystalline precipitate. The compound melts at  $218^\circ$  with decomposition, is insoluble in cold, sparingly soluble in hot water, and soluble in concentrated sulphuric acid with brown coloration; it gives a brown precipitate with bleaching powder, and a red coloration with ferric chloride. It differs from dihydroxytartaric acid in its stability. Its *silver* salt forms orange-yellow leaflets, and the *barium* salt a golden precipitate. The *diphenylizindihydroxytartaric acid* formed from the above acid and phenylhydrazine hydrochloride, or directly from dihydroxytartaric acid, is an orange-yellow powder, sparingly soluble in water, soluble in alcohol. Its *ammonium* salt,  $COONH_4 \cdot C(N_2HPh) \cdot C(N_2HPh) \cdot COOH + H_2O$ , crystallises in yellow leaflets, the *sodium* salt in red needles; the lead and aluminium salts are yellow precipitates, as also the silver imide. The acid, when heated with acetic anhydride, forms an anhydride crystallising in red needles, insoluble in alcohol. The *disulphonic acid*,

is best obtained from phenylhydrazinesulphonic acid, and sodium dihydroxytartrate in presence of soda; it is an orange-yellow powder, soluble in water, insoluble in alcohol. It has been introduced into

commerce under the name of "tartrazine" as a yellow dyestuff for wools; the diphenylizindihydroxytartaric acid, owing to its insolubility in acid baths, is of no practical application. V. H. V.

**Condensation Products of Secondary Hydrazines with Dihydroxytartaric Acid.** By J. H. ZIEGLER and M. LOCHER (*Ber.*, **20**, 841—844).—The secondary, like the primary hydrazines, react with dihydroxytartaric acid to form condensation products homologous with the tartrazines. Thus, from sodium dihydroxytartrate and diphenylhydrazine hydrochloride, in presence of hydrochloric acid, there are formed simultaneously a mono- and a di-condensation product. The former of these was not obtained in a fit state for analysis; the latter,  $\text{COOH}\cdot\text{C}(\text{N}_2\text{Ph}_2)\cdot\text{C}(\text{N}_2\text{Ph}_2)\cdot\text{COOH}$ , crystallises in the prismatic form, and is soluble in chloroform and acetic acid, insoluble in water; it melts at  $177^\circ$  with decomposition. The alkali salts are soluble in water; the copper salt is a green, and the lead and silver salts white precipitates. The acid dissolves in concentrated sulphuric acid with a red coloration, changing to green on standing. On fusion with phenol, it forms variously coloured dyes; with bromine, it yields a monobromo-derivative crystallising in leaflets. When heated with an excess of acetic anhydride, the acid yields an anhydride,  $\text{O}(\text{CO}\cdot\text{C}:\text{N}_2\text{Ph}_2)_2$ , crystallising in ruby-red prisms with greenish lustre. When heated, it forms a sintered mass at  $200^\circ$ , and melts completely at  $222^\circ$ ; it dissolves in concentrated sulphuric acid with a green coloration. With ammonia, the anhydride forms a nitrogen compound, crystallising in rhombohedra which melt at  $191$ — $192^\circ$ . This is probably an imide rather than an amide, from its insolubility in alkalis and alcohol, its low melting point, and the formation of a pyrroline-derivative when it is distilled with zinc-dust. V. H. V.

**Preparation of Benzylrosanilinedisulphonic Acids.** By A. DAHL (*Dingl. polyt. J.*, **263**, 393—394).—The production of mono-, di-, and tri-benzylrosanilines may be effected according to the laws generally applicable to the introduction of alkyl- into amido-groups, the entrance of the benzyl-groups being readily effected without the application of pressure. The benzylrosanilines formed are sparingly soluble in water, dissolve with a bluish-violet colour in benzyl chloride, and assume a greenish-blue colour on treatment in alcoholic solution with hydrochloric acid. The calcium salts form readily pulverisable masses having a metallic lustre. The salts of the alkalis and alkaline earths are readily soluble in water, and form lakes with the heavy metallic oxides, especially lead oxide and the oxides of tin. The calcium salt of the mono-acid imparts a ruby-coloured shade to wool dyed in an acid bath; the corresponding derivative of the di-acid gives a bluish-red colour, and the calcium salt of tribenzylrosanilinedisulphonic acid yields a reddish-violet shade. D. B.

**Manufacture of Benzaldehyde-greens.** By O. MÜHLHÄUSER (*Dingl. polyt. J.*, **263**, 249—254; and 295—303).—1. Preparation of "Acid-green."—The formation of the leuco-base is effected by the condensation of 1 mol. of benzaldehyde and 2 mols. of ethylbenzyl-

aniline with anhydrous oxalic acid. On treating the resultant leuco-base with fuming sulphuric acid, a mixture of di- and tri-sulphonic acids of diethyldibenzyltriphenylmethane is obtained. On oxidation with lead dioxide, this yields the green acid dye, which is then converted into the sodium-derivative. 2. Preparation of "Malachite-green."—This comprises the following operations:—(a.) Formation of the pure, dry leuco-base by heating a mixture of dimethylaniline and benzaldehyde with zinc chloride. (b.) Oxidation of the base with lead dioxide and production of the green dye in a solid form, by treating the oxidised mass with zinc chloride and salting out the resultant double salt. (c.) Purification of the zinc salt by extraction with hot water and formation of the green base by the addition of ammonia to the aqueous extract. (d.) Production of the green crystals by redissolving the base in oxalic acid and reprecipitating with ammonia. 3. Preparation of "Brilliant green."—The leuco-base is obtained by heating a mixture of diethylaniline and benzaldehyde with dry oxalic acid. The product is dissolved in hydrochloric acid, treated with acetic acid, and oxidised with lead dioxide. The process used for the production of the green base and its purification is similar to the method adopted in the case of malachite-green; whilst the crystallisation is effected by dissolving the purified mass in sulphuric acid and adding ammonia.

D. B.

**Opiaurin.** By C. LIEBERMANN and P. SEIDLER (*Ber.*, 20, 873—874).—Opianic acid and phenol, when heated with concentrated sulphuric acid, yield a cherry-red dye, the aldehydic group reacting with the phenol to form a leucaurin,  $\text{COOH} \cdot \text{C}_6\text{H}_2(\text{OMe})_2 \cdot \text{CH}(\text{C}_6\text{H}_4\text{OH})_2$ , the latter being oxidised in the course of the process to an aurin,  $\text{C}_{22}\text{H}_{18}\text{O}_6$ , which it is proposed to call *opiaurin*. This compound was only obtained in an amorphous condition. It dissolves in alcohol and ether, and is insoluble in benzene and petroleum. It dissolves in alkalis with a purple-red coloration, becoming yellowish-brown when the solution is boiled, but returning, when cool, to its original tint. Similar dyes were obtained with other phenols, and the reaction can be used to detect opianic acid, as also to indicate the presence of an aldehydic group in an aromatic derivative.

V. H. V.

**Action of Aldehydes on Ammonium Thiocyanate.** By L. BRODSKY (*Monatsh. Chem.*, 8, 27—40).—When a mixture of benzaldehyde and dry powdered ammonium thiocyanate is heated between  $165^\circ$  and  $137^\circ$  for some time, *benzylidenethiobiuret*,  $\text{C}_9\text{H}_9\text{N}_3\text{S}_2$ , is formed. When crystallised from alcohol, it forms microscopic prisms, and melts at  $237^\circ$  with partial decomposition. It is quite insoluble in water, slightly soluble in cold alcohol and ether, and more so in boiling alcohol. It dissolves in dilute alkalis, and is precipitated unchanged by acids; concentrated alkalis decompose it; concentrated sulphuric acid dissolves it, and it separates unaltered on dilution with water; nitric acid decomposes it in the cold. When an alcoholic solution is treated with solutions of the salts of heavy metals, salts are thrown down; the *silver* and *lead* salts are white, amorphous powders. When boiled with excess of acetic anhydride, an *acetyl* compound is

formed, having the composition  $C_9H_7N_3S_2Ac_2$ ; it forms very brilliant, yellow, microscopic crystals melting at  $189^\circ$ .

When heated with excess of barium hydroxide solution on a water-bath, benzylidenethiobiuret is split up into benzaldehyde, barium thiocyanate, and thiocarbamide; there are also formed in small quantities, hydrogen sulphide, ammonia, and carbonic anhydride. From the above decompositions, the author concludes that the constitution of the substance is

When cinnamaldehyde is heated with ammonium thiocyanate, two substances are formed, both of which are free from nitrogen.

Isovaleraldehyde and cœnanthaldehyde, treated in the same way, give dark-red, viscous liquids, easily soluble in alcohol, ether, and acetic anhydride, and remaining unchanged on evaporation of the solvent. G. H. M.

**Additive Products of Aromatic Thiocarbimides.** By O. HELMERS (*Ber.*, 20, 786—791).—Whilst preparing isocyanic chlorides by Sell and Zierold's process (this Journal, 1875, 271), by passing a current of chlorine through solutions of thiocarbimides in chloroform, the author observed the formation of a crystalline precipitate, which, on continued passage of the chlorine, disappeared. If the passage of the chlorine through a chloroform solution of phenylthiocarbimide is stopped as soon as the solution becomes of a pale-yellow colour, a voluminous white precipitate gradually forms. The mother-liquor by further passage of chlorine yields a further crop of the substance. The compound contains chlorine, is very unstable, gives off hydrogen chloride when exposed to the air, and melts with decomposition at  $150$ — $160^\circ$ . Attempts to obtain it in a pure state proved fruitless, but from its reactions there is little doubt that its formula is  $(CS:NPh)_2Cl_2$ . When dissolved in warm, dilute alcohol or digested with water at  $100^\circ$ , it yields *phenylthiocarbimide oxide*,  $(CS:NPh)_2O$ , hydrogen chloride being at the same time formed. The oxide crystallises in yellow needles melting at  $118^\circ$ . With paratolylcarbimide, similar compounds were formed, the *oxide*,  $(CS:NC_6H_4)_2O$ , crystallising in long needles melting at  $139^\circ$ . These oxides are analogous to those obtained by Sell in a similar way from fatty thiocarbimides (this Jour., 1873, 881). When the chlorides are treated with hydrogen sulphide, the decomposition proceeds further, symmetrical diphenylthiocarbamide,  $CS(NHPh)_2$ , being formed, probably according to the equation—

When bromine is substituted for chlorine in the above reaction, a red crystalline, unstable compound,  $(CS:NPh)Br_2$ , or  $(CS:NPh)_2Br_4$ , is formed, which, on exposure to air, gradually loses bromine, yielding the compound  $(CS:NPh)_2Br_2$ ; this crystallises in glistening scales, and is more stable than the corresponding chloride. It melts with decomposition at  $190^\circ$ . The corresponding paratolyl-deri-

vative,  $(\text{CS}:\text{NC}_7\text{H}_7)_2\text{Br}_2$ , yields glistening scales melting at  $210^\circ$ . With alcohol or water, both compounds yield the corresponding oxides.

Proskauer and Sell state (this Jour., 1877, i, 67) that by the action of bromine on a chloroform solution of phenylthiocarbimide, they obtained a compound,  $(\text{CS}:\text{NPh})_2\text{SBr}_2$ , which, when acted on by alcohol or glacial acetic acid, yielded the sulphide  $(\text{CS}:\text{NPh})_2\text{S}$ . The author is, however, quite unable to corroborate this statement, as even when closely following out Proskauer and Sell's directions, he only obtained the compounds described above. L. T. T.

**Manganese Benzoate.** By K. SEUBERT (*Ber.*, 20, 791—792).—Manganese benzoate is described in text-books as crystallising in clear, stable needles of the formula  $\text{Mn}(\text{C}_7\text{H}_5\text{O}_2)_2 \cdot \text{H}_2\text{O}$ , soluble in 20 parts cold water, more easily soluble in boiling water. This description dates from the researches of John made in the early part of this century. The author finds that from a solution of equal molecular proportions of sodium benzoate and manganese sulphate, the salt  $\text{Mn}(\text{C}_7\text{H}_5\text{O}_2)_2 \cdot 4\text{H}_2\text{O}$  crystallises in flat, rose-coloured, pliant prisms. They cleave readily in the direction of their most fully developed face, and the plates so obtained are optically biaxial. The crystals are tolerably stable, but gradually lose water, becoming opaque and white; in like manner, they lose water when heated with alcohol or water. An aqueous solution, if evaporated on the water-bath, yields a crystalline mass of the constitution and properties described by John. The solution saturated at  $16^\circ$  contains in 100 parts 6.556 parts of the tetrahydrated or 5.5 parts of the monohydrated salt, a result corresponding with John's statement. L. T. T.

**Isomerism in the Cinnamic Acid Series.** By A. MICHAEL and G. M. BROWNE (*Ber.*, 20, 550—556).—Determinations of the vapour-density of the ethyl salts of the three bromocinnamic acids (*Abstr.*, 1886, 702) show that the molecular weight is 255 in each case. The authors find that in the preparation of  $\beta$ -bromocinnamic acid (m. p.  $158.5^\circ$ ) from phenylpropionic acid by the action of hydrobromic acid a fourth bromocinnamic acid is formed, and can be separated by aid of the sparing solubility of its barium salt. The acid thus obtained exhibits a great similarity to the  $\alpha$ -acid, as shown in the following table, but the authors consider them to be distinct:—

|                        | $\alpha$ -Acid.  | New acid.   |
|------------------------|--|---|
| Melting point. ....    | $130-131^\circ$ .  | $133-134^\circ$ .   |
| Crystalline form. .... | Long needles from water and chloroform.  | Long needles exhibiting end faces from water; thick rhombic prisms from chloroform.                                 |
| Solubility .....       | Readily soluble in alcohol.  | Readily soluble in alcohol and hot benzene, sparingly soluble in carbon bisulphide, hot water, and light petroleum. |
| Ammonium salt. ....    | Flat needles sparingly soluble in cold water.  | Flat needles, sparingly soluble in cold, easily soluble in hot water.   |
| Barium salt .....      | Lustrous, rhombic scales, anhydrous; solubility, 1.2 in 1000 of water at $6^\circ$ . | Lustrous, rhombic scales, anhydrous; solubility 7.76 in 1000 of water at $6^\circ$ .                                |

The concluding portion of the paper is devoted to a criticism of the hypothesis put forward by Erlenmeyer to explain the isomerism of the bromocinnamic acids (Abstr., 1886, 945), which is rejected by the authors in favour of their theory of alloisomerism (*ibid.*, 687).

W. P. W.

**Derivatives of Phenylmethacrylic Acid and of Phenylisobutyric Acid.** By L. EDELEANO (*Ber.*, 20, 616—622).—The author finds that the yields of phenylmethacrylic acid prepared by Conrad and Bischof's method (*Annalen*, 204, 188) is only slightly lessened if, instead of using sealed tubes, the materials are heated at 125—130° for 30 hours in a flask with a cooling tube attached. *Phenylmethacrylamide*,  $\text{CHPh}:\text{CMe}\cdot\text{CONH}_2$ , crystallises in prismatic scales, melts at 128°, and is sparingly soluble in ether and cold alcohol, soluble in hot water.

*Phenylisobutyramide* crystallises in needles, melts at 109°, and is readily soluble in alcohol and ether, soluble in hot water. When treated with bromine and aqueous potash, it is converted into *phenylisopropylamine*,  $\text{CH}_2\text{Ph}\cdot\text{CMeH}\cdot\text{NH}_2$ , a colourless, strongly refractive liquid boiling at 203°; its platinochloride crystallises in matted needles, and is sparingly soluble in water.

*Methyl phenylmethacrylate* is obtained when phenylmethacrylic acid is dissolved in an equal weight of methyl alcohol and the solution saturated with hydrogen chloride. It crystallises in long needles, melts at 39°, boils at 254°, and is soluble in all ordinary solvents. Two nitro-derivatives are formed when the methyl salt is treated with five times its weight of fuming nitric acid (sp. gr. = 1.52), and can be separated by crystallisation from alcohol. The less soluble compound is *methyl paranitrophenylmethacrylate*; it crystallises in rectangular scales, and melts at 115°. *Paranitrophenylmethacrylic acid*,

crystallises in rhombs, melts at 208°, and is soluble in hot alcohol and acetic acid, very sparingly soluble in all ordinary solvents in the cold. Its silver salt,  $\text{C}_{10}\text{H}_9\text{NO}_2\text{Ag}$ , crystallises in slender, white needles and is soluble in hot water. The more soluble compound is obtained by evaporation of the alcohol as a liquid, which solidifies in a freezing mixture and yields *orthonitrophenylmethacrylic acid* when saponified. This is a feebly coloured powder, melts at 164—165°, and is readily soluble in alcohol and ether, sparingly soluble in benzene and light petroleum.

When phenylmethacrylic acid is nitrated, *dinitrophenylpropylene*,  $\text{C}_6\text{H}_3(\text{NO}_2)_2\cdot\text{CH}:\text{CHMe}$ , is obtained together with other nitration products. It crystallises in pale-yellow needles, melts at 118°, and is soluble in alcohol.

W. P. W.

**Preparation of Ethyl Benzoylacetate.** By L. CLAISEN and O. LOWMAN (*Ber.*, 20, 651—654).—Ethyl benzoylacetate is prepared by heating 140 grams of sodium methoxide with 300 grams of ethyl benzoate in a water-bath until the mixture becomes solid. It is then mixed with 350 grams of ethyl acetate and heated for 15 hours in a water-bath in a reflux apparatus; 150 grams of glacial acetic acid are

added, and then water; the oil thus separated is washed with aqueous soda, dried over potash, and distilled in a partial vacuum (20 mm.). The yield of pure salt is 33 per cent. of the weight of ethyl benzoate. Ethyl acetoacetate, unchanged ethyl benzoate, and dihydrobenzoylactic acid are also obtained. Almost the same yield is obtained when the reaction is allowed to take place at the ordinary temperature.

The authors think it probable that in the formation of ethyl acetoacetate and benzoylacetate, the compounds  $\text{CMe}(\text{OEt})_2\text{ONa}$  and  $\text{CPh}(\text{OEt})_2\text{ONa}$  respectively are first formed and that these then react with ethyl acetate, yielding the acetoacetate or benzoylacetate and 2 mols. of ethyl alcohol.

N. H. M.

**Oak-tannin.** By C. BÜTTINGER (*Ber.*, 20, 761—766).—This was obtained by treating the syrupy commercial "oakwood-extract" with about 20 times its volume of water, filtering off the insoluble substance, evaporating the solution to dryness, and treating the powdered residue with acetic anhydride. The tannin was thereby converted into an acetyl-compound which was soluble in excess of the anhydride. When the acetic solution is poured into water, the acetyl-derivative  $\text{C}_{15}\text{H}_7\text{Ac}_5\text{O}_9$  is precipitated as a heavy greyish-white powder. When exposed to the air, it gradually loses its acetyl as acetic acid. The acetyl-compound is soluble in ethyl acetate, chloroform, glacial acetic acid, ethyl acetoacetate, &c., insoluble in water and cold alcohol. Boiling alcohol eliminates the acetyl-groups and then dissolves the tannin. Cold concentrated sulphuric acid acts like boiling alcohol. The free tannin is converted into an anhydride by inorganic acids. The anhydride, when heated with ethyl iodide and alcoholic potash, yields an ethyl salt which decomposes when heated. The best means of obtaining the free tannin from the aceto-derivative is to heat the latter with water at  $135^\circ$  in closed tubes. The tannin thus obtained when dried in the desiccator has the composition  $\text{C}_{15}\text{H}_{12}\text{O}_9 + 2\text{H}_2\text{O}$ . It loses 1 mol.  $\text{H}_2\text{O}$  at  $100^\circ$  and the second at  $135^\circ$ . The author has obtained from the aceto-compound two bromo-derivatives,  $\text{C}_{15}\text{H}_{10}\text{BrAcO}_9$  and  $\text{C}_{15}\text{H}_7\text{Br}_4\text{AcO}_9$ .

The author believes this oak-tannin to be a methyl salt of digallic acid.

L. T. T.

**Etherification of Opianic Acid.** By C. LIEBERMANN and S. KLEEMANN (*Ber.*, 20, 881—882).—Opianic acid is characterised by its ready susceptibility to etherification; this property may be utilised for its purification, as the ethereal salts formed are decomposed when boiled with water. The methyl salt melts at  $102^\circ$ , the ethyl salt at  $92^\circ$ , and the propyl salt at  $103^\circ$ . Possibly the above property is dependent on the constitution of opianic acid as an ortho-aldehydic acid.

V. H. V.

**Reduction of Nitro-c pianic Acid.** By S. KLEEMANN (*Ber.*, 20, 875—881).—Nitro-opianic acid, when treated with concentrated sodium methoxide, is converted into a *nitroso*-acid, crystallising in long, golden-green needles which melt at  $175$ — $176^\circ$  and decompose

at 200°. It is sparingly soluble in water, more readily in alcohol, and is distinguished from the nitro-acid in that it does not react with phenylhydrazine under the same conditions. Its *silver* salt crystallises in colourless needles, sparingly soluble in cold, readily in hot water. When reduced with stannous chloride, the nitroso- is converted into an *amido*-acid, which is crystalline, but owing to decomposition is not of definite melting point; its solution gives a green coloration with ferric chloride. Its hydrochloride, when heated with acetic anhydride and sodium acetate, yields a compound,  $C_{24}H_{24}N_2O_{11}$ , derived from the condensation of 1 mol. of the amido-acid and 1 of the anhydride with elimination of 1 mol. of water. It forms ill-defined crystals, insoluble in water, sparingly soluble in alcohol, and melts at 232—233° with decomposition. On reduction with zinc-dust and ammonia, the nitroso-acid yields an *azo*-acid,

not obtainable in a definite crystalline form; it melts with decomposition at 245°, and dissolves in alkalis with a yellow, and in concentrated sulphuric acid with a purple coloration. Its *silver* salt is a yellowish-brown, flocculent precipitate: its *ethyl* salt crystallises in small, yellow needles melting at 101°, insoluble in water, soluble in alcohol and benzene.

Meconineacetic acid (this vol., p. 47) dissolves in ammonia to form a yellow liquid, which is decolorised when boiled with zinc-dust. The acid is insoluble in water, but dissolves in alcohol with partial decomposition.

V. H. V.

**$\psi$ -Meconine.** By O. SALOMON (*Ber.*, **20**, 883—889).—As it is to be supposed that meconine stands to hemipinimide in a relation analogous to that of phthalide to phthalimide, it should be possible to convert hemipinimide into the former, but experiments showed that instead of meconine, a compound isomeric with it, called provisionally  $\psi$ -meconine, is produced.

On hydrogenation with tin and hydrochloric acid, hemipinimide yields *hemipinimidine*,  $C_{10}H_{11}O_3N$ , analogous to phthalimidine; this crystallises in leaflets melting at 181°, soluble in benzene. With nitrous acid, it yields a nitroso-derivative,  $C_{10}H_{10}NO_3 \cdot NO$ , crystallising in silky needles which melt at 156° with decomposition, sparingly soluble in cold, more readily in hot water. On treatment with dilute soda, this compound yields  $\psi$ -meconine or dimethoxyphthalide,

a formula which may explain the isomerism of this compound with meconine, which contains the  $CH_2$  and  $CO$  groupings in the reverse positions.  $\psi$ -Meconine crystallises in long, colourless needles which melt at 123—124°, soluble in benzene, alcohol, and ether. With fuming nitric acid, it yields a nitro-derivative,  $C_{10}H_9O_4NO_2$ , crystallising in yellow needles which melt at 166°; on further treatment with nitric acid, oxalic acid is produced. On reduction, an amido-derivative is formed, a yellowish substance melting at 165°, and distinguished

from amido-meconine (m.p.  $171^{\circ}$ ) by its melting point, the difference in solubility in benzene, and the more marked basic properties of the former. *Bromo- $\psi$ -meconine* is a white flocculent precipitate, which melts at  $141-142^{\circ}$ , and is soluble in benzene, insoluble in petroleum.

The isomeric meconines are also distinguished by their behaviour towards oxydising agents; thus with manganese dioxide and sulphuric acid meconine yields opianic acid almost in quantitative proportions, whilst  $\psi$ -meconine is, for the most part, unaltered. With nitric acid (sp. gr. = 1.14),  $\psi$ -meconine yields, besides the nitro-derivative, nitro-hemipinic acid; but meconine, under the same conditions, yields nitromeconine. It is further shown that hemipinic anhydride when hydrogenised yields  $\psi$ -meconine.

V. H. V.

**Action of Potassium Cyanide on Meconine.** By W. BOWMAN (*Ber.*, 20, 890-891).—Another method of distinguishing the two isomeric meconines described in the preceding Abstract is their behaviour with potassium cyanide;  $\psi$ -meconine remains unaltered while meconine is converted into normethylmeconine, first isolated by Matthiessen and Foster. The change is probably to be explained by the alkaline nature of the potassium cyanide which, at the high temperature, effects the removal of the methyl-group.

V. H. V.

**Orthotolylphthalimide.** By M. KUHARA (*Amer. Chem. J.*, 9, 51-58; comp. Abstr., 1881, 1039).—According to v. Gerichten, phthalyl chloride is either  $\text{C}_6\text{H}_4\langle\text{CCl}_2\text{CO}\rangle\text{O}$  or a mixture of this substance with the normal chloride. By treating phthalyl chloride with ammonia, a substance isomeric with phthalimide was on one occasion obtained, but its preparation could not be repeated (*loc. cit.*). By substituting orthotoluidine, a similar result is obtained, only one substance being produced, and hence it is probable that phthalyl chloride is not a mixture of two substances. The substance produced is—

*Orthotolylphthalimide*,  $\text{C}_6\text{H}_4:(\text{CO})_2\cdot\text{N}\cdot\text{C}_6\text{H}_4\text{Me}$ , melting at  $182^{\circ}$ , and identical with Froelich's phthalorthotoluide, obtained from phthalic anhydride and orthotoluidine.

*Orthotolylphthalamic acid*,  $\text{COOH}\cdot\text{C}_6\text{H}_4\cdot\text{CO}\cdot\text{NH}\cdot\text{C}_6\text{H}_4\text{Me}$ , is obtained by boiling the imide with ammonia, and acidifying; it crystallises in needles. The two lead salts and silver salts, as well as the normal barium salt, are described.

*Methyl-derivatives of Orthotolylphthalamic Acid.*—The above acid was treated with sodium in presence of xylene and then with methyl iodide, and finally with water in the presence of the excess of sodium used; the methylated compound was thus saponified, and yielded phthalic acid and dimethylorthotoluidine, which is formed most probably from the decomposition of the methiodide of sodium methyl-orthotolylphthalamate,  $\text{COONa}\cdot\text{C}_6\text{H}_4\cdot\text{CO}\cdot\text{NMe}_2(\text{C}_7\text{H}_7)\text{I}$ . Neither this compound nor sodium methylorthotolylphthalamate,

could be properly purified, as they do not crystallise readily.

The existence of the salts described is held to be in favour of the symmetrical formula for phthalyl chloride.

H. B.

**Syntheses of the Ethyl Salts of Ketonic Acids.** By W. WISLICENUS (*Ber.*, 20, 589—595).—An almost theoretical yield of ethyl oxalacetate (this vol., p. 234) can be obtained by employing twice the weight of sodium indicated by theory, inasmuch as one-half of the metal enters into combination to form sodium ethoxide. When ethyl acetate (2 mols.) is slowly added to a solution of ethyl oxalate (1 mol.) in ether to which sodium wire (4 atoms) has been added, and the well-cooled product is treated with water, the aqueous layer yields ethyl ketipate (this vol., p. 362) on acidification.

*Ethyl phenylloxalacetate*,  $\text{COOEt}\cdot\text{CHPh}\cdot\text{CO}\cdot\text{COOEt}$ , is prepared by dissolving 10 grams of ethyl oxalate in 40 grams of ether, adding 3.2 grams of sodium wire, and then gradually adding 12 grams of ethyl phenylacetate; the product is decomposed by dilute sulphuric acid, and the compound extracted from the ethereal layer by means of aqueous soda. It is a very viscous oil, decomposes on distillation, is insoluble in water, readily soluble in alkalis, ether, and alcohol. The alcoholic solution gives an intense red coloration with ferric chloride. When boiled with 10 per cent. sulphuric acid, it decomposes with evolution of carbonic anhydride and formation of phenylpyruvic acid.

*Phenylpyruvic acid*,  $\text{CH}_2\text{Ph}\cdot\text{CO}\cdot\text{COOH}$ , crystallises in lustrous scales, melts at  $153^\circ$  with a feeble evolution of gas, and is readily soluble in ether and alcohol, soluble in hot chloroform and benzene, sparingly soluble in hot water, and insoluble in cold water and light petroleum. The alcoholic solution gives a dark-green coloration with ferric chloride. The *phenylhydrazide* crystallises in small, yellowish needles, melts at  $160$ — $161^\circ$  with evolution of gas, and is insoluble in water and light petroleum, sparingly soluble in ether, soluble in alcohol, chloroform, and benzene. It is probably identical with the phenylhydrazide of Plöchl's phenylglycidic acid (this vol., p. 142).

Ethyl phthalate is not attacked by sodium at  $100^\circ$ , but when ethyl acetate is gradually added a reaction occurs, resulting in the formation of an acid of the composition  $\text{C}_9\text{H}_6\text{O}_2$ . This crystallises in small, lustrous, yellow needles, melts at  $130$ — $132^\circ$ , and is soluble in alcohol, ether, and benzene. Its salts have generally an intense yellow coloration, the *iron* salt is dark-red. When treated with nitrous acid, it yields a yellow nitroso-derivative; the *phenylhydrazide*,  $\text{C}_9\text{H}_6\text{O}(\text{N}_2\text{HPh})$ , crystallises in microscopic needles, melts at  $162$ — $163^\circ$  with decomposition, and is readily soluble in alcohol, ether, and benzene. When the acid is boiled with water, an acid of the composition  $\text{C}_{18}\text{H}_{10}\text{O}_3$  is obtained in microscopic scales; this is insoluble in all solvents, melts at  $206$ — $208^\circ$  with complete decomposition, and yields salts showing an intense coloration; thus the salts of the alkaline metals are intensely violet, the *silver* salt is dark-red, the *zinc* salt intensely violet-blue, and the *copper* salt deep-blue.

W. P. W.

**Synthesis of Ethyl Trimesate.** By A. PIUTTI (*Ber.*, 20, 537—539).—Ethyl sodacetate does not react with formic acid either in the cold or on heating, and when treated with ethyl formate yields only sodium ethoxide, carbonic oxide, and ethyl acetoacetate. If, however, a mixture of ethyl acetate and ethyl formate in equimolecular pro-

portions is treated with sodium, hydrogen and carbonic oxide are evolved and ethyl trimesate is obtained. The yield amounts to 6 to 7 per cent. on the ethyl formate used; at the same time ethyl acetoacetate is also formed in some quantity. When mixtures in equimolecular proportions of methyl formate and ethyl acetate, and of ethyl formate and methyl acetate are respectively treated with sodium, a mixture of ethyl and methyl trimesate is obtained in both cases; this melts at 105—110° after one crystallisation from alcohol.

*Methyl trimesate* crystallises in small, silky needles melting at 143°, and a mixture of it and ethyl trimesate in equal proportions melts at 105—110°. W. P. W.

**Rosindole.** By E. FISCHER and P. WAGNER (*Ber.*, 20, 815—818).—Methylketole when heated with benzoic chloride in presence of zinc chloride yields, in addition to a benzoyl-derivative, the hydrochloride of a base,  $C_{25}H_{20}N_2$ . This salt, which may be completely separated from its aqueous solution by the addition of sodium chloride, forms green iridescent crystals, resembling in appearance rosaniline hydrochloride; on adding an alkali, the free base is obtained in reddish-yellow, prismatic crystals, which change colour at 250° and fuse completely at 270°. With acids, it forms salts which are soluble in water and alcohol, and dye silks and wools of a red colour; it appears also to form unstable salts with alkalis, readily decomposed by water. When the alcoholic solution of the base is treated with zinc-dust and ammonia, it is decolorised with formation of benzylidenemethylketole, a change analogous to the formation of leucaniline from rosaniline. From the similarity in colour, dyeing properties, and chemical reactions of the above base with those of rosaniline, it is proposed to call it *dimethylrosindole*; it is probably the anhydride of a carbinol,  $CPh(C_9H_8N)_2 \cdot OH$ .

*Benzoylmethylketole* crystallises in glistening leaflets, melting at 82°, and is moderately soluble in ether and alcohol, sparingly soluble in water. V. H. V.

**Methylation of Indole-derivatives.** By E. FISCHER and A. STECHE (*Ber.*, 20, 818—820).—When methylketole is heated with methyl alcohol and iodide, it yields the hydriodide of a basic compound,  $C_{11}H_{13}N$ , crystallising in prisms, and from which the base itself is obtained as a colourless oil boiling at 243°. This compound is not an indole-derivative in that it gives neither the pine-wood reaction nor the red picrate; also it is unaltered by nitrous acid, and differs from the indoles by its strongly basic character. It is probably a dimethyldihydroquinoline, containing a methyl-group attached to the nitrogen, and another in the quinoline residue; but of this view no proof is given. Of its salts, the sulphate crystallises in leaflets soluble in alcohol, and the *picrate* in golden-yellow leaflets; the *hydrochloride* forms a compound with ferric chloride.

In like manner, dimethylindole yields a base,  $C_{12}H_{15}N$ , boiling at 244°, and dimethyl- $\beta$ -naphthindole yields a compound,  $C_{15}H_{15}N$ , probably a methyldihydronaphthaquinoline, which crystallises in colourless leaflets, melts at 115°, and is readily soluble in mineral acids forming crystalline salts. V. H. V.

**Derivatives of Diphenyl.** By P. ADAM (*Compt. rend.*, 104, 691—693).—*Diphenyl-diphenyl ketone*,  $\text{CO}(\text{C}_6\text{H}_4\text{Ph})_2$ , is obtained in almost theoretical quantity, when a mixture of diphenyl, 15 parts, carbon bisulphide, 20 parts, and carbonyl chloride, 10 parts, is added to 15 parts of aluminium chloride. There is an immediate evolution of hydrogen chloride, and towards the end of the reaction the flask is placed in tepid water. The carbon bisulphide is distilled off, and the residue washed with dilute alkali, then with pure water, dried, and recrystallised from boiling benzene or acetone. Diphenyl-diphenyl ketone forms white needles which melt at  $229^\circ$ , and are somewhat soluble in acetone, benzene, and chloroform, but almost insoluble in benzene and light petroleum. It is reduced with great difficulty. When dissolved in a mixture of alcohol and benzene, and treated with a large quantity of sodium amalgam, it yields diphenylbenzhydrol,  $\text{CH}(\text{C}_6\text{H}_4\text{Ph})_2\cdot\text{OH}$ , which crystallises readily, melts at  $151^\circ$ , and is very soluble in alcohol.

The action of carbonyl chloride on diphenyl in presence of aluminium chloride, with the aid of heat, but without carbon bisulphide, also produces the ketone, but the yield is smaller. The use of carbon bisulphide has advantages in the case of acid chlorides, but not with haloid derivatives of hydrocarbons.

Acetic chloride acts readily on diphenyl in presence of aluminium chloride, whether carbon bisulphide is present or not. The product is diphenyl methyl ketone, or diphenylacetyl,  $\text{C}_6\text{H}_4\text{Ph}\cdot\text{COMe}$ ; this forms white, flexible, nacreous crystals, readily soluble in alcohol or acetone; it melts at  $121^\circ$ , and boils at  $325\text{--}327^\circ$ . C. H. B.

**Condensation of Diphenic and Orthodiphenylcarboxylic Acids.** By C. GRAEBE and C. AUBIN (*Ber.*, 20, 845—848).—Anschütz has shown that diphenic acid yields an anhydride with acetic chloride or acetic anhydride, but Mensching and Graebe, by the action of concentrated sulphuric acid, obtained a substance of the same composition, but of higher ( $7^\circ$ ) melting point. In this paper, these experiments are repeated; in the latter case, *diphenyleneketonecarboxylic acid*,  $\text{<}\overset{\text{CO}}{\text{C}_6\text{H}_4}\text{>C}_6\text{H}_3\text{COOH}$ , is produced, which crystallises in needles melting at  $227^\circ$ ; its salts are also crystalline; the *ethyl* salt crystallises in needles melting at  $103^\circ$ , and the *methyl* salt at  $132^\circ$ . The acid combines with hydroxylamine to form a colourless acetoxime, and with phenylhydrazine it yields a condensation product. The potassium salt is reconverted into the salt of diphenic acid by fusion with alkali. On vaporisation, the acid is decomposed into carbonic anhydride and diphenylene ketone. In like manner, orthodiphenylcarboxylic acid is converted into diphenylene ketone by heating with concentrated sulphuric acid. The diphenic anhydride, isomeric with the above acid, crystallises in pyramidal needles melting at  $217^\circ$ , and sparingly soluble in alcohol and ether. When boiled with solutions of alkalis, it is converted into the potassium salt of diphenic acid.

V. H. V.

**Formula of Diphenic Acid.** By C. GRAEBE (*Ber.*, 20, 848—850).—In this paper, the question is discussed whether the diphenic acid

$\text{COOH} \cdot \text{C}_6\text{H}_4 \cdot \text{C}_6\text{H}_4 \cdot \text{COOH}$  [ $\text{COOH} : \text{COOH} = 1 : 1'$ ] is isomeric or identical with the acid, [ $\text{COOH} : \text{COOH} = 1 : 6'$ ]. If the two benzene nuclei were in the same plane, these two acids would be identical; but if they were situated in different planes, it is possible that the acids might be isomeric. At present, the evidence is insufficient to decide the question.

V. H. V.

**Preparation of  $\beta$ -Nitronaphthalene.** By E. LELLMANN (*Ber.*, 20, 891—893).—The following method has been found to be the most practicable for the preparation of  $\beta$ -nitronaphthalene; the mixture of the ortho- and para-nitroacetanaphthalide is boiled with a 14 per cent. potash solution in presence of alcohol, and the mixture of the ortho-aceto-compound and para-nitronaphthalene is treated with ethyl nitrite, when the diazo-amido-derivative of para-nitronaphthylamine separates as a brown precipitate. This is filtered off, and the orthonitroacetanaphthalide crystallises out, and, after purification, is best decomposed by an alcoholic solution of hydrogen chloride. The orthonitronaphthylamine thus obtained serves for the preparation of the nitronaphthalene.

V. H. V.

**$\beta$ - $\alpha$ -Azonaphthalene.** By R. NIETZKI and J. GÖTTIG (*Ber.*, 20, 612—613).— $\beta$ - $\alpha$ -Amidoazonaphthalene,  $\text{C}_{10}\text{H}_7\text{N}_2\text{C}_{10}\text{H}_6\text{NH}_2$ , is prepared by diazotising  $\beta$ -naphthylamine (1 mol.), adding  $\alpha$ -naphthylamine hydrochloride (1 mol.), and subsequently precipitating the base with soda; it crystallises in yellowish-brown needles, melts at  $152^\circ$ , and is soluble in alcohol. Its solution in concentrated sulphuric acid has a violet coloration.

$\beta$ - $\alpha$ -Azonaphthalene,  $\text{C}_{10}\text{H}_7\text{N}_2\text{C}_{10}\text{H}_7$ , is obtained by adding 3 parts of sulphuric acid to a solution of 1 part of  $\beta$ - $\alpha$ -amidoazonaphthalene dissolved in 50 parts of alcohol, diazotising, boiling the whole for some time, and afterwards precipitating with water. It crystallises in dark-brown scales with steel-blue iridescence, melts at  $136^\circ$ , and is more soluble in alcohol, acetic acid, &c., than the corresponding  $\alpha$ - $\alpha$ -derivative (*Abstr.*, 1886, 245). It dissolves in sulphuric acid yielding a violet solution.

W. P. W.

**New Method of Preparing Azines.** By O. N. WITT (*Ber.*, 20, 571—577).—When diazobenzenesulphonic acid (1 mol.) is gradually added to phenyl- $\beta$ -naphthylamine (1 mol.) dissolved in acetic acid at  $50^\circ$ , and the mixture afterwards treated with potassium carbonate, iridescent, blood-red needles of *sulphobenzeneazophenyl- $\beta$ -naphthylamine*,  $\text{NHPh} \cdot \text{C}_{10}\text{H}_6\text{N}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{SO}_3\text{H}$  [ $\text{N}_2 : \text{NHPh} = 1 : 2$ ], are obtained. These dissolve readily in water, and the solution, even when dilute, solidifies in the cold to a transparent, red jelly. Concentrated sulphuric acid produces a cherry-red colour; whilst stannous chloride in acid solution decolorises the compound with formation of phenylorthonaphthylenediamine. Sulphobenzeneazophenyl- $\beta$ -naphthylamine is the lowest member of a series of beautiful, ponceau-red dyes, which have great tinctorial power, but are extremely sensitive to light; sunlight rapidly producing the same change that is brought about when the dyes are boiled with dilute mineral acids.

*Naphthaphenazine*, [1 : 2]  $\text{C}_{10}\text{H}_6 \begin{array}{c} \text{N} \\ \diagdown \quad \diagup \\ | \\ \diagup \quad \diagdown \\ \text{N} \end{array} \text{C}_6\text{H}_4$  [1 : 2].—Sulphobenzene-

azophenyl- $\beta$ -naphthylamine, when boiled with dilute sulphuric acid, decomposes quantitatively into sulphuric acid and naphthaphenazine. This crystallises in lustrous, citron-yellow needles or prisms, melts at  $142.5^\circ$ , sublimes at about  $200^\circ$  in long, flat needles, and boils above  $360^\circ$  with slight decomposition. It is readily soluble in hot benzene, very sparingly in alcohol and ether, and dissolves in concentrated sulphuric acid with a brownish-red colour. With mineral acids, naphthaphenazine forms crystalline salts which are decomposed by water, and show a peculiar dimorphism. The two *sulphates* are respectively obtained in cinnabar-red tufts of needles or garnet-red, compact, twinned prisms; the *nitrates* are very sparingly soluble, one forms orange-yellow and the other brick-red aggregates of needles; the *hydrochloride* obtained by dissolving the azine in hydrochloric acid forms long, reddish-yellow needles, and when heated at  $150^\circ$  is converted into the second form, which crystallises in needles; the two forms of each salt are convertible into one another. Stannous chloride reduces the azine to the corresponding hydro-compound, crystallising in violet needles. Naphthaphenazine can also be obtained by the action of  $\beta$ -naphthaquinone (1 mol.) on orthophenylenediamine (1 mol.) in 50 per cent. acetic acid at  $0^\circ$ , and by oxidising a mixture of orthophenylenediamine and  $\beta$ -naphthol in equimolecular proportions with potassium ferricyanide in alkaline solution.

W. P. W.

**Constitution of the Isomeric Tolunaphthazines.** By O. N. WITT (*Ber.*, 20, 577—581).—Inasmuch as naphthaphenazine (comp. preceding Abstract) is a 1 : 2-derivative of naphthalene, the tolunaphthazine (m. p. =  $179.8^\circ$ ) obtained by the simultaneous oxidation of  $\beta$ -naphthol and orthotoluylenediamine (*Trans.*, 1886, 404), must have a similar constitution. Hinsberg's tolunaphthazine (m. p. =  $139$ — $142^\circ$ ), from its method of preparation (*Abstr.*, 1885, 909), must also be a 1 : 2-derivative of naphthalene, and to assign to each its constitutional formula (in other words to determine the position of the methyl-group in the benzene nucleus) sulphobenzeneazoparatolyl- $\beta$ -naphthylamine was prepared from paratolyl- $\beta$ -naphthylamine and diazobenzenesulphonic acid, and afterwards decomposed by boiling with dilute sulphuric acid (comp. preceding Abstract). The *tolunaphthazine* so obtained, however, crystallises from benzene in needles and prisms, and from alcohol, in which it is very sparingly soluble, in lustrous, citron-yellow scales; it melts at  $169^\circ$ , and forms well-crystallised salts. The solution in sulphuric acid is dark cherry-red in colour, and the *sulphate* crystallises in long, orange-yellow, lustrous needles. The same tolunaphthazine can be prepared from "wool-black," a dye obtained by the action of diazobenzenedisulphonic acid on paratolyl- $\beta$ -naphthylamine, by boiling it with dilute sulphuric acid. The author finds that when equal weights of the tolunaphthazines melting at  $169^\circ$  and  $179.8^\circ$  respectively, are mixed and crystallised from alcohol, a compound melting at  $139$ — $142^\circ$ , and undistinguishable

from Hinsberg's modification, is obtained. The following are the constitutional formulæ assigned to the isomeric tolunaphthazines:—

M. p. = 169°.

M. p. = 179·8°.

*Paratolyl-β-naphthylamine*, obtained by heating paratoluidine hydrochloride with β-naphthol for eight hours at 200°, crystallises in snow-white scales, melts at 104°, and is soluble in alcohol, benzene, ether and acetic acid, the solutions showing a beautiful violet-blue fluorescence.

W. P. W.

**Acenaphthene.** By C. GRAEBE (*Ber.*, **20**, 657—659).—In oxidising acenaphthene to naphthalic acid, a compound of the formula  $C_{24}H_{14}O_2$  is formed. The latter sublimes when heated (at 269°) in red needles which melt at 260°. It is sparingly soluble.

When acenaphthene, dissolved in glacial acetic acid, is oxidised with chromic acid, a compound is obtained which crystallises in reddish-yellow needles melting at 230°. Analyses of the compound, after prolonged treatment with sodium carbonate solution, point to the formula  $C_{10}H_6<\overset{CO}{\underset{CO}{\text{C}}}>$ ; when oxidised, it is converted into naphthalic acid.

N. H. M.

**Derivatives of Acenaphthene.** By F. QUINCKE (*Ber.*, **20**, 609—611).—*Nitracenaphthene*,  $C_{12}H_9\cdot NO_2$ , is obtained when fuming nitric acid is added to a solution of acenaphthene in acetic acid. It crystallises in yellow, matted needles, melts at 102°, and is soluble in alcohol, ether, light petroleum, acetic acid, and hot water. When it is reduced with tin and hydrochloric acid *amidoacenaphthene*,  $C_{12}H_9\cdot NH_2$ , is formed. This is a white, asbestos-like compound, melts at 96°, is volatile with steam, and yields a crystalline hydrochloride.

W. P. W.

**Dimethylantragaolol.** By W. BIRUKOFF (*Ber.*, **20**, 870—873).—*Dimethylantragaolol*,  $C_{14}H_3Me_2O_2(OH_2)$  [ $Me_2 : (OH)_3 = 1 : 3 : 1' : 2' : 3'$ ], is obtained, in like manner to the trimethyl-derivative, by heating metaxylic and gallic acids with concentrated sulphuric acid; it crystallises in golden-red needles; it resembles anthragaolol as regards its solubility in alkalis and its absorption-spectrum. On distillation over zinc-dust, it yields a dimethylantracene, melting at about 220°, and yielding on oxidation a quinone crystallising in white needles melting at 112°. These compounds are isomeric, therefore, with those which Gresly obtained melting at 202° and 180° respectively.

V. H. V.

**Trimethylantragallol.** By H. WENDE (*Ber.*, 20, 867—870).—*Trimethylantragallol*,

is obtained by heating a mixture of 2 parts of gallic acid, 3 parts of durylic acid, and 30 parts of concentrated sulphuric acid. The crude product is finally exhausted with benzene, which dissolves the trimethylantragallol, leaving the rufgallie acid. The former crystallises in glistening, brown needles, melting at  $244^\circ$ , soluble in alcohol, sparingly soluble in benzene; it dissolves in concentrated sulphuric acid with a violet-red coloration; it resembles anthragallol in its absorption-spectrum and dyeing properties. Its *triacetyl*-derivative,  $\text{C}_{14}\text{H}_2\text{Me}_3\text{O}_2(\text{OAc})_3$ , crystallises in pale-yellow, rhombic tables, melting at  $174^\circ$ . Trimethylantragallol, on distillation over zinc-dust, yields a solid trimethylantracene, identical probably with that obtained by Gresly, together with a liquid hydrocarbon which, though not fully examined, is considered to be a dihydride of trimethylantracene.

V. H. V.

**Hydroxyanthraquinone Dyes.** By C. LIEBERMANN and W. WENSE (*Ber.*, 20, 862—866).—Liebermann and Kostanecki have shown that only those hydroxyanthraquinones which contain the hydroxyl-groups in the alizarin-position can be mordanted on fabrics. In order to confirm this view, a compound, at once an alizarin and a quinazin, has been prepared from hemipinic acid and quinol by heating a mixture of the two with concentrated sulphuric acid. There is thus formed a *dimethyl ether* of a *quinalizarin*,  $\text{C}_{14}\text{H}_4(\text{OMe})_2(\text{OH})_2\text{O}_2$   $[(\text{OMe})_2 : (\text{OH})_2 = 1 : 2 : 1' : 4']$ , which crystallises in brown-red minute leaflets, melting at  $225$ — $230^\circ$ , soluble in alkalis with violet coloration and in concentrated sulphuric acid with a blue coloration. With mordants, it gives but a faint colour. Its *acetyl-derivative* crystallises in small needles melting at  $210$ — $211^\circ$ , sparingly soluble in cold alcohol and acetone, but more readily in hot. *Quinalizarin*,  $\text{C}_{14}\text{H}_4(\text{OH})_2\text{O}_2$ , obtained from the above by heating it with hydrochloric acid, crystallises in deep-red needles, exhibiting no signs of fusion at  $275^\circ$ . Its reactions with alkalis and with concentrated sulphuric acid are similar to those of the dimethyl ether; its *barium* and *calcium* salts are insoluble in water. It possesses strong dyeing powers, resembling those of alizarin. On distillation with zinc-dust at  $210^\circ$ , it yields anthracene. Its *tetracetyl-derivative*,  $\text{C}_{14}\text{H}_4(\text{OAc})_4\text{O}_2$ , crystallises in needles melting at  $201^\circ$ , soluble in chloroform, less soluble in alcohol.

V. H. V.

**Substituted Anthracene- $\gamma$ -carboxylic Acids; Behaviour of Carbon Oxychloride towards Anthracene Dihydride.** By G. BEHLA (*Ber.*, 20, 701—708; compare *Abstr.*, 1886, 248).— $\gamma$ -*Chloranthracene- $\gamma$ -carboxylic acid*,  $\text{C}_{14}\text{H}_8\text{Cl}\cdot\text{COOH}$ , is obtained by heating 3 grams of anthracene with 5—6 grams of carbon oxychloride for 6—7 hours at  $240$ — $250^\circ$ ; the product is extracted with boiling sodium carbonate solution, precipitated with hydrochloric acid, dried, and recrystallised from benzene, from which it separates in long, greenish-yellow, lustrous needles. It sublimes at  $155^\circ$ , and melts at  $258$ — $259^\circ$ , with evolution of carbonic anhydride. It dissolves in alcohol, ether,

acetone, &c., sparingly in benzene and chloroform. The solutions have a blue fluorescence. Potassium permanganate and dilute nitric acid oxidise it to anthraquinone. Fuming sulphuric acid dissolves it with formation of a compound, crystallising in long, yellow needles, soluble in water; this is probably the disulphonic acid. *Potassium  $\gamma$ -chloranthracenecarboxylate*,  $C_{14}H_8Cl \cdot COOK$ , forms very slender, yellow needles; the *barium salt* crystallises in lustrous, yellow prisms. The *methyl salt* crystallises in tufts of slender, yellow needles, which melt at  $123^\circ$ ; it is insoluble in water, soluble in alcohol, ether, and chloroform.

*Methyl anthracene- $\gamma$ -carboxylate*,  $C_{14}H_9 \cdot COOMe$ , forms yellow prisms, melting at  $111^\circ$ ; it resembles the chlorinated derivative in its solubility.

$\gamma$ -Chloranthracene- $\gamma$ -carboxylic acid can be obtained by passing dry chlorine through a solution of anthracene- $\gamma$ -carboxylic acid in chloroform; by the action of a second molecule of chlorine in the product, dichloranthracene, melting at  $209^\circ$ , is obtained.

$\gamma$ -Bromanthracene- $\gamma$ -carboxylic acid is prepared by adding the calculated amount of bromine to a solution of anthracene- $\gamma$ -carboxylic acid in glacial acetic acid; the product is treated with water, filtered, and the precipitate warmed with sodium carbonate solution; it is again filtered, precipitated with hydrochloric acid, dried, and crystallised successively from benzene and alcohol. It forms greenish-yellow, lustrous needles, which sublime at  $160^\circ$ , and melt at  $266^\circ$ , with evolution of gas. It is almost insoluble in water, soluble in ether, alcohol, and glacial acetic acid. The solutions show a blue fluorescence. It dissolves in fuming sulphuric acid, forming a reddish-yellow solution with green fluorescence; a yellow crystalline substance is formed, probably a disulphonic acid. *Potassium- $\gamma$ -bromanthracene- $\gamma$ -carboxylate* forms very slender, long, yellow needles; the *barium* and *silver salts* crystallise respectively in lustrous needles and microscopic prisms; both are yellow.

*Anthracene- $\gamma$ -carboxylic acid monosulphonic acid*,  $COOH \cdot C_{14}H_8 \cdot SO_3H$ , is obtained by keeping a solution of the carboxylic acid in concentrated sulphuric acid surrounded by ice for 12 hours, and precipitating with water. It is purified by means of the barium salt. The free acid crystallises from alcohol in microscopic, slightly yellow prisms, which do not melt at  $360^\circ$ ; it dissolves readily in water and alcohol, and is insoluble in ether and benzene. The aqueous solution shows a blue fluorescence. The *barium salt* is very readily soluble in water.

The *disulphonic acid*,  $COOH \cdot C_{14}H_7(SO_3H)_2$ , is prepared by dissolving the carboxylic acid in fuming sulphuric acid, and precipitating with water. It forms prisms, readily soluble in water and alcohol. The aqueous solution shows hardly any fluorescence; the solution in sulphuric acid has a yellowish-green fluorescence. The *barium salt* is very sparingly soluble.

When anthracene dihydride (Liebermann and Topf, this Journal, 1877, i, 86) is heated with carbon oxychloride at  $200^\circ$  for four hours, anthracene is regenerated; when the temperature is raised to  $240^\circ$ , and the heating continued for four hours, anthracenecarboxylic chloride and chloranthracenecarboxylic chloride are formed. N. H. M.

**Nitrogen-derivatives of Terebenthene.** By C. TANRET (*Compt. rend.*, 104, 791—794).—The mother-liquor from terpin and the liquid hydrates formed from terebenthene by the action of nitric acid diluted with alcohol, were washed with water, neutralised, and distilled in a current of steam. The distillate consists of unaltered terebenthene, mixed with a continually increasing proportion of hydrate as the temperature rises. The nitrogen-derivatives are found in the last portions of the distillate. The liquid thus obtained is neutral to litmus, and colourless. With alcoholic potash, it yields potassium nitrite. A similar product is obtained by the action of nitric oxide on terpene hydrates, and hence it would seem that the compound is of the same nature as nitroethane, but less stable. When heated at  $100^{\circ}$ , it becomes acid, and decomposition increases as the temperature rises, and becomes rapid at  $150^{\circ}$ , nitrogen, nitric oxide, and water-vapour being given off.

The liquid product of the reaction is agitated with dilute soda, and the latter is treated with sulphuric acid and agitated with chloroform. When the chloroform is distilled, and the residue treated with boiling water to remove tarry matter, a crystalline substance is obtained, which is recrystallised from alcohol. Direct treatment of the washed and neutralised mother-liquor in the same way yields the same product.

The solid product is a mixture of two isomerides of the composition  $C_{10}H_{17}NO_2$ , which can be separated by means of ether. The  $\alpha$ -compound is comparatively insoluble in ether, and requires 30 parts of this liquid for solution. It dissolves in 6 parts of alcohol of  $90^{\circ}$ , 20 parts of water at  $100^{\circ}$ , and 68 parts at  $13^{\circ}$ , and is very soluble in chloroform. It melts at  $210^{\circ}$ , boils at  $283^{\circ}$  with partial decomposition, and crystallises in long, brittle, opaque, flattened prisms with a rhomboidal base. The  $\beta$ -derivative crystallises in bulky, transparent, quadratic prisms, which begin to melt at  $110^{\circ}$ , are completely liquid at  $114^{\circ}$ , and boil at  $274^{\circ}$ . It appears to be a mixture of two isomerides. It dissolves in 7 parts of ether, 2.5 parts of alcohol, 7 parts of water at  $100^{\circ}$ , and 42 parts at  $13^{\circ}$ .

The rotary power of the  $\alpha$ -compound is  $[\alpha]_D = +69^{\circ}$ , of the  $\beta$ -compound  $[\alpha]_D = +18.4^{\circ}$ . Both are neutral to litmus, but have a distinctly acid function. They are not affected by strong sulphuric acid, nor by a solution of potassium hydroxide, but when fused with caustic alkalis they yield an alkaline carbonate and cyanide. When heated with soda-lime, only 76 per cent. of the nitrogen is evolved as ammonia.

With ferric salts, they give a deep violet coloration, owing to the formation of a compound  $(C_{20}H_{34}N_2O_4)_3(Fe_2O_3)_2$ , which can be isolated. It dissolves in water, forming a reddish-brown solution which changes to red on addition of a trace of an organic acid.

If an excess of calcium saccharate is added to a solution of the  $\alpha$ -compound, the salt  $(C_{10}H_{16}NO_2Ca)_2 \cdot 3H_2O$  is obtained in slender crystals, only very slightly soluble in water. C. H. B.

**Terpenes and Ethereal Oils.** By O. WALLACH (*Annalen*, 238, 78—89).—Schmidt (*Arch. Pharm.* [2], 141, 1) and Ogialoro (this

Journal, 1876, ii, 642) have pointed out that oil of cubebs contains two sesquiterpenes,  $C_{15}H_{24}$ , one of which yields a crystalline hydrochloride,  $C_{15}H_{24}2HCl$ , melting at  $117-118^{\circ}$ . The author has succeeded in obtaining this hydrochloride from oil of cubebs, patchouli (b. p.  $270-280^{\circ}$ ), oil of galbanum, *Oleum cadinum*, and *Oleum sabinæ*. It is best obtained by distilling *Oleum cadinum* in a current of steam, and treating the distillate with potash to remove phenols. The purified oil is distilled over potash, and the portion boiling between  $260^{\circ}$  and  $280^{\circ}$  is diluted with ether and saturated with hydrogen chloride. The hydrochloride can be recrystallised from ethyl acetate. It is deposited from ether in rhombic prisms,  $a : b : c = 0.61379 : 1 : 0.41432$ . The solution is lævogyrate. The terpene is easily obtained by heating the hydrochloride with anhydrous sodium acetate and acetic acid. The sesquiterpene boils at  $274-275^{\circ}$ . Its sp. gr. at  $16^{\circ} = 0.921$ . It has a great tendency to resinify. The hydrochloride, hydrobromide, and hydriodide are conveniently prepared by adding the corresponding acid to an acetic acid solution of the terpene.  $C_{15}H_{24}2HBr$  melts at  $124-125^{\circ}$ .  $C_{15}H_{24}2HI$  melts with decomposition at  $105-106^{\circ}$ . A solution of the terpene in a large excess of chloroform or acetic acid, gives on the addition of strong sulphuric acid first a green, and then a blue coloration. Attempts to prepare the sesquiterpene from isoprene were unsuccessful.

W. C. W.

**Ethereal Oils.** By E. WEBER (*Annalen*, **238**, 89—108).—Oil of rosemary not only contains camphor, borneol and a terpene, but also cyneol,  $C_{10}H_{16}O$ , which was discovered by Wallach and Brass in *Oleum cynæ* (Abstr., 1885, 171).

Oil of cardamoms begins to boil at  $164^{\circ}$ , and the temperature gradually rises to  $220^{\circ}$ . A small quantity of a crystalline compound, which melts at  $60-61^{\circ}$ , is left in the retort. The liquid distilling over below  $170^{\circ}$  consists of water, acetic and formic acids.

The oil contains *terpinene*, boiling at  $179-182^{\circ}$ , and another terpene, which boils at  $180-183^{\circ}$  (probably limonene or dipentene), and yields a hydrochloride which melts at  $52^{\circ}$ . The portion of the distillate coming over between  $205^{\circ}$  and  $220^{\circ}$  contains the compound  $C_{10}H_{16}O$ , which is probably identical with Wallach's *terpineol* (Abstr., 1886, 71).

W. C. W.

**Active Camphene and Ethyl-borneol.** By G. BOUCHARDAT and J. LAFONT (*Compt. rend.*, **104**, 693—695).—The monohydrochloride,  $C_{10}H_{17}Cl$ , with a rotatory power  $[\alpha]_D -28^{\circ} 30'$ , obtained from French essence of terebenthene, was heated in sealed tubes at  $150^{\circ}$  with somewhat less than its own weight of fused potassium acetate dissolved in very strong alcohol. After 48 hours, the product was precipitated with water, fractionated in a vacuum, and the unaltered hydrochloride was again subjected to the same treatment, twice at  $150^{\circ}$ , and finally at  $175^{\circ}$ . The rotatory power of the camphene obtained at each operation was—

|                        | $[\alpha]_D$ |          |
|------------------------|--------------|----------|
|                        | 155—158°     | 158—161° |
| First treatment .....  | 77° 30'      | —80° 37' |
| Second treatment ..... | —67 21       | —69 8    |
| Third „ .....          | —60 35       | —59 40   |
| Fourth „ .....         | —30 30       | —34 30   |

At a high temperature the potassium acetate and acetic acid either render part of the camphene altogether inactive, or diminish the general activity of the whole. The effect of temperature is very marked; the reduction in rotatory power was only 9—10° in the first two operations at 150°, whilst it was 30° in the last operation at 175°.

In addition to the camphene, a certain quantity of some substance is formed which distils over with the hydrochloride. This is *ethylborneol*,  $C_{10}H_{17}EtO$ , isomeric with the compound obtained by Baubigny by the action of ethyl iodide and potassium hydroxide on borneol. It boils at 205—208° under ordinary pressure; sp. gr. at 0° = 0.9495; vapour-density, 5.8; rotatory power,  $[\alpha]_D = +26^\circ 3'$ . It is not affected by potash, but if treated at 0° with a saturated solution of hydrochloric acid it forms a buttery mass, which when compressed yields a solid camphoraceous substance mixed with borneol and borneol hydrochloride. When heated at 100° with ten times its weight of saturated hydrochloric acid, ethylborneol is completely converted into ethyl chloride and inactive camphene hydrochloride. It is rapidly oxidised by ordinary nitric acid, with formation of camphor. C. H. B.

**Determination of Position in the Pyrroline Series.** By G. CIAMICIAN and P. SILBER (*Ber.*, 20, 698—700); compare Abstr., 1886, 938).—When tribromacetylpyrroline, methyl tribromocarbopyrrolate, dibromacetylmethylpyrroline, and dibromodiacetylpyrroline are treated with nitric acid, dibromomaleïnimide is formed. In these compounds, the acetyl, methyl, or carboxyl must be attached to the carbon-atom next to nitrogen in the pyrroline-ring.

When brominated pyrroline dimethyl diketone is heated with fuming nitric acid, dibromomaleïnimide is at once formed; if the reaction is allowed to take place at the ordinary temperature, *dibromomononitracetylpyrroline*,  $NO_2 \cdot C_4NHBr_2Ac$ , is obtained. This crystallises in long needles melting at 206°. When dissolved in a mixture of sulphuric and fuming nitric acids at —18°, and precipitated with water, dibromodinitropyrrroline,  $C_4NHBr_2(NO_2)_2$  is formed, which changes at the ordinary temperature into dibromomaleïnimide. These reactions can only be explained by assuming that the acetyl-group is directly substituted by the nitro-group. N. H. M.

**Tetraiodopyrroline.** By G. CIAMICIAN (*Gazzetta*, 16, 543—548).—Tetraiodopyrroline, sold commercially under the name of “iodole,” is readily obtained by the direct action of iodine on pyrroline; it forms yellow crystals, insoluble in water, sparingly soluble in alcohol. Its presence may be recognised by the action of concentrated sulphuric acid; this produces an intense green coloration, which after some

time turns to a dirty violet. Its alcoholic solution yields an intense red coloration with nitric acid. Its physiological and therapeutic actions resemble those of iodoform, over which it has the advantage of being odourless and less poisonous. It has been successfully applied in venereal, ulcerous, and suppurative lesions. V. H. V.

**Reaction of Acetone with Pyrroline.** By M. DENNSTEDT and J. ZIMMERMANN (*Ber.*, **20**, 850—857).—When acetone and pyrroline are heated in presence of zinc chloride, *isopropylpyrroline*,  $C_4NH_3Pr^{\beta}$ , is formed (compare Abstr., 1886, 1043) together with a subsidiary product. This compound, best purified by means of its potassium-derivative, is a colourless oil boiling at  $173-175^{\circ}$ , it has the odour of the substituted pyrrolines, and gives the pine-wood reaction. The isopropyl-group is attached to one of the carbon-atoms. Like ethyl pyrroline, it yields an *acetyl*-derivative,  $C_4NH_3Pr^{\beta}Ac$ , which crystallises in the monoclinic system;  $a : b : c = 1.7304 : 1 : 0.5009$ ; it melts at  $64^{\circ}$ , and boils at  $251^{\circ}$ ; its *silver*-derivative is a white crystalline mass. Isopropylacetylpyrroline, when heated with benzaldehyde, yields a *cinnamyl*-derivative,  $C_4NH_3Pr^{\beta} \cdot CO \cdot CH : CHPh$ , melting at  $142-143^{\circ}$ , and crystallising in the rhombic system;  $a : b : c = 0.7002 : 1 : 0.3833$ . Potassium isopropylpyrroline, when fused with potash, yields the corresponding salt of a carbopyrrolic acid, which melts with decomposition at  $166^{\circ}$ , and is readily soluble in water, alcohol, and ether; its *methyl* salt crystallises in silky, colourless needles, melting at  $129^{\circ}$ . Isopropylpyrroline resembles the 1 : 4 dimethylpyrroline as regards its reaction with hydrochloric acid, in which the salt of a new base is produced; attempts, however, to prepare the compound in a fit state for analysis were unsuccessful. V. H. V.

**Synthesis of Pyridine Bases.** By J. PLÖCHL (*Ber.*, **20**, 722—723).—Pyridines are formed by the action of aldehydes on concentrated solutions of ammonium chloride at a high temperature. Collidine was obtained from paraldehyde, and parvoline from propaldehyde. The reactions are analogous to those by means of which quinoline-derivatives are obtained from the hydrochlorides of primary amines and aldehydes, ketones, &c. N. H. M.

**Cinchonic Acid.** By W. MUTHMANN and J. U. NEF (*Ber.*, **20**, 636—638).—Inasmuch as the crystallographic measurements of the crystals of cinchonic acid obtained by the oxidation of  $\alpha$ - and  $\beta$ -3'-phenolquinoline did not agree with Ditscheiner's data (*Annalen*, **173**, 84), the authors compared the specimens with cinchonic acid prepared by the oxidation of cinchonine and of monobromapocinchene, and found them to be identical. Cinchonic acid crystallises from hot concentrated solutions with 1 mol.  $H_2O$ , but when a dilute solution is allowed to evaporate spontaneously, crystals with 2 mols. of  $H_2O$  are obtained. The latter are triclinic;  $a : b : c = 0.74653 : 1 : 0.81749$ ;  $\alpha = 81^{\circ} 37'$ ,  $\beta = 120^{\circ} 2'$ ,  $\gamma = 86^{\circ} 37'$ . The following faces were observed:  $\infty P \infty$ ,  $\infty \bar{P} \infty$ ,  $0P$ ,  $\infty P'$ ,  $\bar{P}' \infty$ , the pinacoids usually predominating. Ditscheiner's observations are therefore erroneous. W. P. W.

**Condensation Products of Acetone and Acetophenone with Aniline and Ammonia.** By P. RIEHM (*Annalen*, 238, 1—29).—When acetone and aniline hydrochloride in the proportion of 2 mols. of the former to 1 mol. of the latter are heated at 180° in sealed tubes, marsh-gas is evolved, water is eliminated, and  $\alpha$ - $\gamma$ -dimethylquinoline and a tertiary base are produced. The dimethylquinoline has been previously described by the author (*Abstr.*, 1885, 1246). The tertiary base,  $\text{NPh} : \text{CMe}_2$ , is a colourless liquid boiling between 227° and 229°. On exposure to air and light, it darkens in colour. Most of the salts of this base are very soluble in water and in alcohol.

A small quantity of a crystalline base which melts at 340°, and yields crystalline salts, is obtained by the action of acetophenone on aniline.

$\beta$ -*Collidine* is formed together with marsh-gas and water, by the action of acetone on ammonium chloride in sealed tubes at 265°.

In the presence of zinc chloride, acetone acts on carbamide at 110—140°, yielding  $\beta$ -collidine and a base (probably  $\text{C}_{16}\text{H}_{19}\text{N}$ ). The base forms colourless monoclinic needles. It melts at 119°, and boils about 320°. It is soluble in alcohol, ether, benzene, chloroform, and light petroleum. The salts of the base do not as a rule crystallise well. Their solutions are fluorescent.

*Triphenylpyridine*,  $\text{C}_{23}\text{H}_{17}\text{N}$ , is formed by the action of ammonia on acetophenone, in the presence of phosphoric anhydride. The base melts at 135°, and yields a crystalline platinochloride.

W. C. W.

**4'-Phenylquinoline and the Derived Diquinolylys.** By W. KOENIGS and J. U. NEF (*Ber.*, 20, 622—636).—When 4'-phenylquinoline (*Abstr.*, 1886, 1045) is treated with nitric acid of sp. gr. 1.5, and the whole allowed to remain for 12 hours, the nitrates of three nitrophenylquinolines are obtained, termed  $\alpha$ ,  $\beta$ , and  $\gamma$  respectively; from these, after liberation of the bases, the  $\alpha$ -derivative can be separated by fractional crystallisation from alcohol, in which it is the least soluble, and the separation of the  $\beta$ - from the  $\gamma$ -derivative can be effected by converting them into sulphates, and crystallising out the less soluble  $\beta$ -sulphate. The yield of the  $\alpha$ -base is 50 to 60 per cent., that of the  $\beta$ -base 35 to 45 per cent., and that of the  $\gamma$ -base 5 per cent.

$\alpha$ -*Nitro-4'-phenylquinoline*,  $\text{C}_9\text{NH}_6 \cdot \text{C}_6\text{H}_4 \cdot \text{NO}_2$ , crystallises in snow-white flocks, melts at 187°, and is sparingly soluble in cold alcohol and ether. Its salts crystallise well, and are sparingly soluble in water. When reduced with stannous chloride and hydrochloric acid, it yields  $\alpha$ -*amido-4'-phenylquinoline*; this crystallises in colourless glistening scales, melts at 150°, is volatile with decomposition, and dissolves readily in benzene, chloroform, and hot alcohol, but very sparingly in ether, the ethereal solution showing a violet-blue fluorescence. It forms two series of salts which are distinguished by their colour, the di-acid salts being colourless, whilst the monacid salts are intensely yellow, and have considerable tinctorial powers.  $\alpha$ -*4'-Phenolquinoline*,  $\text{C}_9\text{NH}_6 \cdot \text{C}_6\text{H}_4 \cdot \text{OH}$ , is formed when the  $\alpha$ -amido-derivative is diazotised. It crystallises in flat needles or prisms,

melts at  $243^{\circ}$ , is volatile without decomposition, and dissolves readily in alcohol and chloroform, very sparingly in benzene, and is almost insoluble in ether. The *potassium* and *sodium* salts are precipitated by a slight excess of alkali in colourless, glistening prisms, and give yellow solutions with water. Oxidation with chromic acid converts it into cinchonic acid. When fused with potassium hydroxide,  $\alpha$ -4'-phenolquinoline yields a compound, probably a phenol-oxyquinoline, which melts above  $317^{\circ}$ , shows no basic properties, and is sparingly soluble in all solvents.

$\beta$ -Nitro-4'-phenylquinoline crystallises in colourless, hard needles, melts at  $117$ — $118^{\circ}$ , and is readily soluble in alcohol, very sparingly soluble in ether.  $\beta$ -Amido-4'-phenylquinoline crystallises in pale-yellow, four-sided prisms, melts at  $198^{\circ}$ , volatilises without decomposition and is soluble in chloroform, sparingly soluble in alcohol and benzene, and almost insoluble in ether, the ethereal solution showing a characteristic bluish-violet fluorescence. The monacid salts are intensely yellow, and have considerable tinctorial powers, whilst the di-acid salts are colourless.  $\beta$ -4'-Phenolquinoline, obtained by diazotising the  $\beta$ -amido-derivative, is granular, melts at  $235^{\circ}$ , volatilises without decomposition, and is sparingly soluble in alcohol, chloroform, and ethyl acetate, almost insoluble in ether. Aqueous potash and soda do not precipitate the corresponding salts. Oxidation with chromic acid converts  $\beta$ -4'-phenolquinoline into cinchonic acid. When fused with potassium hydroxide,  $\beta$ -4'-phenol-oxyquinoline,  $C_9NH_6O \cdot C_6H_7 \cdot OH$ , is obtained; this crystallises in pale-yellow needles, melts at  $305^{\circ}$ , sublimes unchanged, is readily soluble in alcohol and acetic acid, sparingly soluble in ethyl acetate, and is destitute of basic properties.

$\gamma$ -Nitro-4'-phenylquinoline forms tabular crystals, melts at  $135^{\circ}$ , and is readily soluble in alcohol, sparingly soluble in ether. Its salts are readily soluble in water. The *amido*-derivative melts at  $115^{\circ}$ , and the corresponding *hydroxy*-derivative melts at  $205^{\circ}$ .

$\alpha$ -4'-Diquinolyl is prepared from  $\alpha$ -amido-4'-phenylquinoline by Skraup's reaction. It crystallises in pale-yellow forms, melts at  $122^{\circ}$ , volatilises without decomposition, and is readily soluble in alcohol, soluble in chloroform, benzene, and ethyl acetate, very sparingly soluble in ether. Its salts are mostly readily soluble in water; the *platinochloride*,  $C_{18}H_{12}N_2 \cdot H_2PtCl_6$ , forms granular crystals, and is insoluble in water.

$\beta$ -Diquinolyl is obtained by Skraup's reaction from  $\beta$ -amido-4'-phenylquinoline. It forms colourless, tabular crystals, melts at  $116$ — $117^{\circ}$ , volatilises without decomposition, and is readily soluble in alcohol, soluble in chloroform, benzene, and ethyl acetate, very sparingly soluble in ether. Its salts are mostly readily soluble in water; the *platinochloride*,  $C_{18}H_{12}N_2 \cdot H_2PtCl_6$ , crystallises in yellow needles, and is insoluble in water. The mode of formation of these diquinolyls shows that each must have one of the four possible formulæ 4' : 1, 2, 3, or 4.

The marked similarity in the properties of apocinchene (Abstr., 1882, 224) and the 4'-phenolquinolines renders it probable that the former is also a 4'-phenolquinoline, and the conjecture is further

strengthened by the fact that oxyapocinchene, obtained by fusing apocinchene with sodium hydroxide (*Ber.*, 18, 2385), and the 4'-phenoxoxyquinolines show similar properties. W. P. W.

**Ortho- and Meta-quinolinesulphonic Acids.** By O. FISCHER (*Ber.*, 20, 731).—Referring to La Coste and Valeur's paper (this vol., p. 379) the author points out that he and Bedall did not state that the solubility of ortho- and meta-quinolinesulphonic acids was identical, but merely that the difference was not sufficient to enable them to be thoroughly separated by simple crystallisation. He also states that as the meta-acid has recently been found to yield a quinolinecarboxylic acid with the carboxylic-group in the ana-position, it should now be called anaquinolinesulphonic acid. L. T. T.

**Synthetical Experiments by means of Ethyl Acetoacetate.** By L. KNORR (*Annalen*, 238, 137—219).—Many of the compounds obtained by the action of ethyl acetoacetate and its derivatives on the primary aromatic hydrazines have already been described by the author as *quinizines* (*Abstr.*, 1884, 302, 1153, 1377, 1380, and 1381). The author now regards these substances as *pyrazolones*. Phenylmethylpyrazolone has the constitution  $\text{PhN} \begin{smallmatrix} \text{CO} \cdot \text{CH}_2 \\ \text{N} : \text{CMe} \end{smallmatrix} >$ .

The *hydrochlörider*,  $\text{C}_{10}\text{H}_{10}\text{N}_2\text{O} \cdot \text{HCl} + \text{H}_2\text{O}$ , melts at  $96^\circ$ , and the *platinochloride*,  $(\text{C}_{10}\text{H}_{10}\text{N}_2\text{O})_2 \cdot \text{H}_2\text{PtCl}_6 + 4\text{H}_2\text{O}$ , crystallises in prisms melting at  $110^\circ$ . The addition of silver nitrate to an aqueous solution of phenylmethylpyrazolone precipitates a crystalline double salt of the composition  $\text{C}_{10}\text{H}_9\text{AgN}_2\text{O} + \text{C}_{10}\text{H}_{10}\text{N}_2\text{O}$ .

By the action of methyl iodide on the sodium salt of phenylmethylpyrazolone two atoms of hydrogen may be successively displaced by methyl, but *antipyrine* is formed when methyl iodide acts on a solution of phenylmethylpyrazolone in methyl alcohol at  $100^\circ$ . The constitution of antipyrine is  $\text{CO} \begin{smallmatrix} \text{CH} = \text{CMe} \\ \text{NPh} \cdot \text{NMe} \end{smallmatrix} >$ .

*Phenyldimethylpyrazolone* does not yield a nitro- or a nitroso-derivative. Nitrous acid oxidises this substance and converts it into *disphenyldimethylpyrazolone*,  $\text{C}_{22}\text{H}_{22}\text{N}_2\text{O}$ . Phenylmethylethylpyrazolone and its derivatives have been previously described (*loc. cit.*, p. 1380). *Phenyltrimethylpyrazolone*,  $\text{Ph} : \text{Me} : \text{Me}_2 = 1 : 3 : 4$ , formed by the action of phenylhydrazine on ethylic dimethylacetoacetate, melts at  $55\text{--}56^\circ$  and boils at  $300\text{--}303^\circ$ . It is soluble in alcohol, ether, benzene, and chloroform and in strong acids. From the acid solutions, it is precipitated on dilution with water. It is distinguished from its isomeride methylantipyrine by its volatility in a current of steam. Phenyltrimethylpyrazolone is converted into a base (probably phenyltrimethylpyrazoline) by treatment with sodium and alcohol. The dilute acid solution of the product yields an intense carmine coloration with a drop of ferric chloride.

The preparation of dis-phenylmethylpyrazolone and its conversion into *di-antipyrine* and *pyrazol-blue* has already been described (*loc. cit.*, 1379).

*Dis-phenyldimethylpyrazolone*,  $\text{C}_{22}\text{H}_{22}\text{N}_4\text{O}_2$  [1 : 3 : 4 : 5], is prepared by adding a solution of a nitrite to phenyldimethylpyrazolone dissolved in sulphuric acid. It crystallises in prisms and melts at  $164^\circ$ . It is soluble in alcohol and acetic acid. *Dis-phenylmethylethylpyrazolone*, [1 : 3 : 4 : 5]  $\text{C}_{24}\text{H}_{24}\text{N}_4\text{O}_2$ , melts at  $160^\circ$ .

On the addition of bromine to an acetic acid solution of phenylmethylpyrazolone [1 : 3 : 5], a monobromo-derivative is obtained. It melts at  $128\text{--}130^\circ$  and dissolves freely in chloroform and acetic acid. The alcoholic solution soon deposits pyrazol-blue, even at the ordinary temperature. The dibromo-derivative  $\text{C}_{10}\text{H}_8\text{N}_2\text{OBr}_2$  melts at  $80^\circ$ ; it is soluble in alcohol, ether, chloroform, and acetic acid. It is not attacked by oxidising agents, but is reduced by hydriodic acid or by tin and hydrochloric acid, yielding phenylmethylpyrazolone.

The dichloro-derivative  $\text{C}_{10}\text{H}_8\text{N}_2\text{OCl}_2$  is best prepared by the action of phosphorus pentachloride on phenylmethylpyrazolone. It melts at  $61^\circ$ , and decomposes on boiling.

Benzaldehyde acts on phenylmethylpyrazolone, forming *phenylmethylbenzylidenepyrazolone*,  $\text{C}_3\text{N}_2\text{MePhO} : \text{CHPh}$ . This substance crystallises in orange-coloured prisms; it melts at  $106\text{--}107^\circ$ . *Phenylmethylcinnimenepyrazolone*,  $\text{C}_3\text{N}_2\text{MePhO} : \text{C}_3\text{H}_3\text{Ph}$ , melts at  $139^\circ$ . *Phenylmethylisopropyleneepyrazolone*,  $\text{C}_3\text{N}_2\text{MePhO} : \text{CMe}_2$ , forms yellow needles which melt at  $117^\circ$ . It is soluble in ether, benzene, chloroform, alcohol, and strong acetic acid. *Phenylmethylpyrazoloneazobenzene* is obtained in orange-coloured needles when diazobenzene chloride is added to a cold solution of phenylmethylpyrazolone in acetic acid. The compound melts at  $155^\circ$ . The preparation of *phenylmethylisonitrosopyrazolone*,  $\text{C}_3\text{N}_2\text{MePhO} : \text{NOH}$ , has been previously described (*loc. cit.*, p. 1378). It melts at  $157^\circ$ . On careful oxidation with nitric acid, it is converted into *phenylmethylnitropyrazolone* (m. p.  $127\text{--}130^\circ$ ). On reduction with zinc and acetic acid, both these compounds yield phenylmethyramidopyrazolone,  $\text{C}_3\text{N}_2\text{HPhMeO} \cdot \text{NH}_2$  [1 : 3 : 4]. The *hydrochloride*,  $\text{C}_{10}\text{H}_{12}\text{N}_3\text{O} \cdot \text{HCl}$ , forms colourless crystals. In solution, this salt rapidly oxidises to rubazonic acid. The *benzylidene*-derivative,  $\text{C}_{17}\text{H}_{15}\text{N}_3\text{O}$ , melts at  $186^\circ$  and dissolves in alcohol and chloroform with an intense yellow coloration.

oxidation of phenylmethyramidopyrazolone and also by boiling pyrazol-blue with dilute ammonia. It is insoluble in water and dilute acids, but dissolves freely in benzene, ether, and chloroform. It dissolves in alkalis with a deep-violet coloration. The alkali salts are

soluble in water but insoluble in solutions of caustic alkalis. The violet-colour changes to yellow when the alkaline solutions are boiled, and phenylmethylketopyrazolone and diphenylhydrazineacetylglyoxylic acid are probably formed. The latter compound melts at  $212^{\circ}$ , dissolves in alkalis, and dyes silk yellow. Phenylhydrazinephenylmethylketopyrazolone is formed when equivalent quantities of rubazonic acid and phenylhydrazine are boiled together in acetic acid. The compound crystallises in golden needles and melts at  $155^{\circ}$ .

On distillation with zinc-dust, phenylmethylpyrazolone yields aniline, benzene, ammonia, methyl cyanide, and phenylmethylpyrazine,  $C_3N_2HPhMe$  [1 : 3]. *Antipyrine*,  $C_3N_2HPhMe_2O$  [Ph : Me<sub>2</sub> = 1 : 2 : 3], has been already described (Abstr., 1884, 1153, 1378). The *picrate* melts at  $188^{\circ}$ . The *ferrocyanide* and the *platinochloride*,  $(C_{11}H_{12}N_2O)_2, H_2PtCl_6 + 2H_2O$ , crystallise in prisms. Ferric chloride gives a deep brownish-red coloration with a neutral solution, and sodium nitrite gives an intense emerald coloration with a slightly acid solution of antipyrine. The formation of *methylantipyrine*,  $C_3N_2PhMe_3O$  [1 : 2 : 3 : 4], has already been mentioned. This substance melts at  $82-83^{\circ}$ , and boils at  $286^{\circ}$  under 153 mm. pressure. The base is freely soluble in water, alcohol, and chloroform. The aqueous solution gives a violet-red coloration with ferric chloride and a white precipitate with potassium ferrocyanide. The *picrate* melts at  $94^{\circ}$ . *Di-antipyrine*,  $C_3N_2PhMe_2O - C_3N_2PhMe_2O$ , prepared by the action of methyl iodide and methyl alcohol on *dis-phenylmethylpyrazolone*, melts at  $245^{\circ}$  and dissolves freely in chloroform. The *picrate* is deposited from alcohol in needles and melts at  $161^{\circ}$ ; the *hydrochloride*,  $C_{22}H_{22}N_4O_2, 2HCl + 2H_2O$ , forms monoclinic crystals. The *platinochloride* crystallises in prisms and melts about  $232-236^{\circ}$  with decomposition.

The nitroso-, nitro-, and benzylidene-compounds have been previously described (*loc. cit.*). *Antipyrine dibromide*,  $C_{11}H_{12}N_2OBr_2$ , is formed when bromine is added to a solution of antipyrine in chloroform. It is unstable and easily loses hydrobromic acid, forming bromantipyrine. It is soluble in alcohol and chloroform and melts about  $150^{\circ}$ . *Bromantipyrine*,  $C_3N_2PhMe_3OBr$ , is deposited from hot water in needles, and is soluble in alcohol, chloroform, and hot toluene. The compound melts at  $117^{\circ}$ . W. C. W.

**Alkaloids.** By O. DE CONINCK (*Compt. rend.*, 104, 513—515).—Equal volumes of sparteïne, alcohol, and ethyl iodide heated together in sealed tubes at  $100^{\circ}$  for several hours yield needles of the ethylspartylammonium iodide,  $C_{15}H_{17}EtN_2I_2$ , described by Mills. The corresponding methyl-derivative forms white crystals. If either of these compounds is dissolved in a slight excess of warm alcohol, the solution rapidly becomes rose-coloured, but if some drops of potassium hydroxide solution of  $45^{\circ}$  are now added, no deep coloration is produced. It follows that sparteïne differs from the pyridines and dipyridines.

Nicotine reacts readily with ethyl iodide and yields a yellow, translucent solid which dissolves in warm, absolute alcohol, forming a deep-brown solution. If this is mixed with potash of  $45^{\circ}$ , and heated on a water-bath for 10 hours, a garnet-red coloration is produced which

afterwards changes to carmine. When the solution is mixed with an excess of hydrochloric acid and is poured into acidified water, there is no change of colour and no fluorescence, but after 24 hours the liquid becomes yellow.

It is evident from this behaviour that nicotine is related to the pyridic and dipyridic alkaloids. C. H. B.

**Strychnine.** By C. STÖHR (*Ber.*, **20**, 810—814).—In order to obtain evidence on the view of Hanssen that strychnine contains a phenylpyridine-group as well as a quinoline-group (this vol., p. 505), the author has distilled strychnine with alkali and obtained, in addition to a hydride of pyridine, not fully examined,  $\gamma$ -picoline, identified by analyses of its auro- and mercurio-chlorides, and crystalline form, as also by the melting point of the latter. Experiments to obtain methyl chloride as a product of the decomposition of strychnine were unsuccessful. It is shown that strychnine does not contain a hydroxyl-group, in that by treatment with phosphorus pentachloride the atoms of oxygen remain intact, whilst three hydrogen-atoms are displaced by chlorine to form a *trichloro*-derivative,  $C_{21}H_{19}Cl_3N_2O_2$ , the hydrochloride and sulphate of which crystallise in leaflets.

V. H. V.

**Phenylpiperidine.** By E. LELLMANN (*Ber.*, **20**, 680—681).—*Phenylpiperidine*,  $C_5NH_{10}Ph$ , is obtained by heating bromo- or iodobenzene with piperidine (3 mols.) at 250—270° for several hours. Piperidine hydrobromide (or hydriodide) is formed at the same time. Phenylpiperidine is slightly heavier than water and reacts strongly alkaline.

*Dinitrophenylpiperidine* is readily prepared by the action of orthoparadinitrochlorobenzene on piperidine. It crystallises from alcohol in orange-coloured needles melting at 92°. From nitroparadichlorobenzene a compound, probably chloronitrophenylpiperidine, is obtained; it forms small red plates which melt at 51°.

*Paranitrophenylpiperidine*,  $C_5NH_{10} \cdot C_6H_4 \cdot NO_2$ , is prepared by heating parachloronitrobenzene (1 mol.) with piperidine (2 mols.) at 120° in a reflux apparatus. The product is treated with moderately strong hydrochloric acid, filtered, and precipitated with ammonia. It crystallises from hot alcohol in very large, yellow plates melting at 105°. The *platinochloride* was prepared. *Amidophenylpiperidine*,  $C_5NH_{10} \cdot C_6H_4 \cdot NH_2$ , is obtained by reducing the nitro-compound with tin and hydrochloric acid. It is obtained from its ethereal solution as a crystalline mass melting at 40°.

N. H. M.

**Berberine Salts.** By C. SCHILBACH (*Arch. Pharm.* [3], **25**, 155—164).—The results obtained by the analysis of various berberine salts confirm the observations of previous investigators as to the composition of the alkaloid and its salts, except in the case of the hydrochloride, which is shown to have the composition indicated by the formula  $C_{20}H_{17}NO_4 \cdot HCl + 4H_2O$ .

J. T.

**Action of Potassium Permanganate on Berberine.** By E. SCHMIDT and C. SCHILBACH (*Arch. Pharm.* [3], **25**, 164—170).—Berberine, under the action of concentrated nitric acid, yields a tribasic

nitrogenous acid, berberonic acid,  $C_5H_2N(CO\cdot OH)_3$ , as has been shown by Weidel, and again by Fürth. It is remarkable that the principal effect of the action of potassium permanganate on berberine should be the production of a non-nitrogenous acid analogous to hemipinic acid, as J. Court has shown in an investigation instigated by one of the authors. The authors in supplementing this investigation, conducted the oxidation in an alkaline solution, and in general followed the course taken by Court. A hot dilute solution of berberine was treated with aqueous potash and then with hot potassium permanganate solution. The slight excess of permanganate was decomposed by a few drops of alcohol. Preliminary tests indicated the formation of only very minute quantities of oxalic acid. On the contrary, carbonic anhydride was freely evolved on adding excess of sulphuric acid, and a strong odour of nitric acid was perceptible. The filtrate from the manganese oxide was neutralised with sulphuric acid, evaporated to dryness, powdered, well shaken with ether, and treated with excess of moderately dilute sulphuric acid. On distilling off the ether, a brown liquid remained which deposited a considerable quantity of crystals when placed over sulphuric acid. To avoid loss, the brown liquid was dissolved in water and the contained acids were precipitated by means of a slight excess of lead acetate. The well-washed precipitate was treated with hydrogen sulphide, the lead sulphide and excess of hydrogen sulphide removed, and the liquid evaporated and set to crystallise over sulphuric acid. The filtrate from the lead precipitate was freed from acetic acid by repeated evaporation and again treated with lead acetate, when a further crop of crystals was obtained. The lead acetate treatment gave crystals much purer than those obtained by direct crystallisation of the ether extract. These crystals, dried at  $100^\circ$ , have a constant melting point of  $160$ — $162^\circ$ , and amount to about 30 per cent. of the original berberine. A small quantity of nitrogenous, nodular crystals was obtained by treating the mother-liquor of the ether extract with water, dissolving the precipitate obtained in hot water, and purifying with the aid of lead acetate. No other well characterised compounds were isolated. A considerable portion of the nitrogen of berberine was evidently converted into nitric acid during the oxidation. Another portion appeared in the form mentioned above. A further portion was converted into ammonia, or at least into compounds which gave ammonia on distillation with potash. The copious oxidation product melting at  $160$ — $162^\circ$ , obtained as above, was compared with hemipinic acid, specially prepared by Schilbach from narcotine, and the two compounds were shown to be identical.

J. T.

**Lactucerin.** By G. KASSNER (*Annalen*, 238, 220—228).—Lactucerin can be obtained in a pure state by treating the ethereal solution with an aqueous solution of potassium hydroxide. Alcohol is then added to the ethereal extract, until a small precipitate forms. On the addition of water to the filtrate, lactucerin is deposited in white, microscopic, needle-shaped crystals. Lactucerin purified in this manner melts at  $200^\circ$ , but after it is purified by sublimation in an atmosphere of carbonic anhydride it melts at  $210^\circ$ . The results of

analyses agree with the formula  $C_{28}H_{44}O_2$  more closely than they do with Hesse's formula  $C_{20}H_{32}O_2$  (Abstr., 1886, 1020). On fusion with potash, hydrogen is evolved and *lactucol*,  $C_{13}H_{20}O$ , is formed according to the equation  $C_{28}H_{44}O_2 + 2H_2O = C_2H_4O_2 + 2C_{13}H_{19}OH + 2H_2$ . Lactucol melts at  $160-162^\circ$ , and crystallises in needles. The acetate melts at  $198-200^\circ$ . Solutions of the alcohol and of the acetate in ether, chloroform, and carbon bisulphide are dextrogyrate. These results differ in some important respects from those of Hesse (*loc. cit.*). W. C. W.

**Cholic Acid.** By F. MYLIUS (*Ber.*, **20**, 683—688; comp. Abstr., 1886, 480, 952).—*Iodocholic acid*,  $(C_{20}H_{40}O_5I)_4KI + xH_2O$ , is obtained by adding a concentrated aqueous solution of 1 gram of potassium iodide to a solution of 2 grams of cholic acid and 0.8 gram of iodine in 40 c.c. of alcohol. The mixture is gradually diluted with water until the blue substance separates. This is then collected and washed with water. It forms a matted mass of a bronze-like lustre. When suspended in water (500 c.c.), an indigo-blue liquid is produced. When the latter is heated, it becomes yellow and cholic acid separates; when a few drops of the blue liquid are poured into water, the blue colour disappears in a few moments, and the solution is found to contain free iodine. The substance is therefore decomposed by excessive dilution. Sulphurous acid decolorises the liquid with separation of cholic acid. The solution is also decolorised by adding a few drops of soda solution, with formation of sodium cholate, iodide, and iodate; on adding hydrochloric acid, the blue compound is re-formed. When iodocholic acid is dried in a vacuum, a dark, lustrous, crystalline powder is obtained which dissolves in ether containing alcohol, yielding a yellow solution; this, when evaporated, leaves a yellow, amorphous substance which is anhydrous iodocholic acid. The latter becomes blue in presence of water.

The compound  $(C_{24}H_{40}O_5I)_4HI$  is prepared by adding a small quantity of hydriodic acid to the brown solution of cholic acid and iodine. The liquid at once becomes blue. The compound is isolated in a manner similar to the potassium compound which it completely resembles. The *barium compound*,  $(C_{24}H_{40}O_5I)_8BaI_2$ , and the zinc, cadmium, and ammonium compounds are obtained by using corresponding iodides in the place of potassium or hydrogen iodides.

N. H. M.

**Bile Acids.** By C. SCHOTTEN (*Zeit. physiol. Chem.*, **11**, 268—276).—The author has previously suggested (Abstr., 1886, 565) that the smaller solubility of the salts of cholic acid obtained from human bile as compared with those from the ox, was due to an admixture of choleates. Further researches have led to the conclusion that the second acid in human bile is neither choleic acid,  $(C_{25}H_{42}O_4)$ , nor the desoxycholic acid  $(C_{23}H_{40}O_4)$  of Mylius (Abstr., 1886, 480), although both of these resemble the second acid of human bile in the insolubility of their barium salts, but a previously undescribed acid of the formula  $C_{23}H_{40}O_4$ , and to which the name *felic acid* is given. The insoluble barium precipitate was decomposed by boiling with sodium carbonate, the filtered solution shaken with ether, and then the free

acid obtained by means of hydrochloric acid. The barium salt,  $(C_{23}H_{39}O_4)_2Ba$ , contains 4 mols.  $H_2O$ , and is soluble in about 700 or 800 times its weight of water; the magnesium salt,  $(C_{23}H_{39}O_4)Mg + 2\frac{1}{2}H_2O$ , was also prepared; from both of these salts, the free acid was obtained. Fellic acid is not homologous with cholic or choleic acid, the nature of its relations to lithofellic, hyocholic, and chenocholic acids, requires further investigation. In the dry condition, it is strongly electrical, as shown by rubbing it with a pestle. With Pettenkofer's reaction, it gives a red but not a violet colour. It melts at  $120^\circ$ . By heating strongly, it yields a turpentine-like residue. Its taste is bitter.

In opposition to Mylius (Abstr., 1866, 952), the author adheres to the statement he previously made that cholic acid does not give an acetyl compound.

W. D. H.

**The Behaviour of Hydrogen Peroxide to Albumin.** By C. WURSTER (*Ber.*, 20, 263—267).—Egg albumin is not affected by hydrogen peroxide when in an alkaline or neutral solution, but in an acid solution in the presence of sodium chloride, hydrogen peroxide causes the albumin in a few minutes or hours to be changed into a proteid, insoluble in water. The rate at which this coagulation occurs varies directly with the fresh condition of the albumin, the concentration of the liquid, and especially the temperature, the most favourable temperature being from  $37^\circ$  to  $40^\circ$ , the mixture being kept in an incubator. For the precipitation, an equal volume of hydrogen peroxide is well shaken with the white of egg, and 1 to 2 c.c. of commercial lactic acid, and 1 to 2 grams of sodium chloride, or 20 c.c. of a 5 per cent. solution added for every 100 c.c. of albumin. The cold mixture remains clear, becomes cloudy when held in the hand, and after 12 hours in the incubator has set into a firm cheesy mass. It is not necessary to use so large an excess of hydrogen peroxide; 3 to 5 c.c. will often suffice, but 1 c.c. to the 100 of albumin does not cause complete coagulation. The mother-liquor has a greenish-yellow colour like whey; on evaporating it an acid syrup is obtained, which after repeated drying and heating is found to contain hydrogen peroxide. Alcohol precipitates a peptone-like substance from this syrup. The precipitate caused by the peroxide reminds one more of acid albumin than casein. On digestion with artificial gastric juice, it is rapidly and very completely peptonised. It is soluble in solutions of sodium carbonate; on neutralising this solution with acetic acid, a proteid is precipitated, which blackens an alkaline lead solution, and is insoluble in sodium acetate or tartrate, and is, therefore, not the oxyproteo-sulphonic acid of Brücke and Maly. It is insoluble in salt solutions and in water, soluble in hot alcohol, for the greater part soluble in sodium carbonate solution and in concentrated acids in the cold, wholly soluble in sodium carbonate solution and dilute acids at a temperature of  $70$ — $80^\circ$ . It is soluble with ease in caustic alkalis, especially in ammonia.

The precipitate caused by hydrogen peroxide is stated to be a mixture of gelatinous acid albumin with a large quantity of a proteid very similar to casein.

In order to obtain the precipitate, acid, sodium chloride, and hydrogen peroxide must all be present, but acetic, phosphoric, or sulphuric acids may be substituted for lactic acid.

Lactic acid and sodium chloride are both present in sweat, and hydrogen peroxide can also be shown to be present by the tetramethylparaphenylenediamine paper test; as it is also in certain tissues; the question arises whether the deep cutaneous tissues are able by this means to cause coagulation of proteïds circulating in the lymph; this and the questions whether the coagulation of blood and of muscle plasma and the formation of casein in milk may be similarly explained, are not yet considered proven.

W. D. H.

**Deterioration of Diastase by the Action of Heat.** By E. BOURQUELOT (*Compt. rend.*, 104, 576—579).—A solution of diastase is heated at 68° for several hours, and is then allowed to act on potato starch. The enfeebled diastase, even when employed in large excess, has lost the power of carrying the hydration of the starch to its utmost limit, but accomplishes the first stages of the alteration with practically the same rapidity as natural diastase. It would seem that it is not the quantity of the ferment which is diminished, but its quality which is altered. It may, however, be supposed that natural diastase is a mixture of two or more soluble ferments, which are successively destroyed by the action of heat.

## Physiological Chemistry.

---

**Specific Gravity of Human Blood.** By E. L. JONES (*J. Physiol.*, 7, 1—14).—The observations were made by Roy's method (*Proc. Physiol. Soc.*, 1884). A drop of blood is introduced into a mixture of glycerol and water of known specific gravity; if the drop tends to rise or sink it is assumed that it is of lower or higher specific gravity respectively than the liquid in which it is placed. By having ready to hand a number of solutions of glycerol and water of different specific gravities, it was not difficult to find one in which the drop of blood neither rose nor sank, and as its specific gravity was known, the specific gravity of the blood examined was thus found. Fermentation changes are prevented in the standard solutions by adding to them either thymol or mercuric chloride.

The principal results obtained were as follows:—

1. The specific gravity is highest at birth, at a minimum between the second week and the second year, and rises gradually to a point attained in the male between the ages of 35 and 45, in the female after the climacteric.

2. The specific gravity of the blood tends to be higher in the male than in the female; and in the latter pregnancy diminishes it to a slight extent.

3. The immediate effect of mixed food is to cause a fall in specific gravity; but if alcohol is taken this effect is not observed.

4. Exercise if gentle causes a fall; if violent leading to perspiration, it causes a rise in specific gravity.

5. The specific gravity of the blood in a passively congested part of the body is higher than elsewhere.

6. Diurnal variation. The specific gravity of the blood tends to fall during the day and to rise during the night. W. D. H.

**Causes of the Alteration of Blood in Contact with Air, Oxygen, and Carbonic Anhydride.** By A. BÉCHAMP (*Compt. rend.*, 104, 587—589).—Separate quantities of blood were treated with (1) a current of ordinary air, (2) a current of air washed with water, (3) a current of pure, washed oxygen, and (4) the air was expelled by means of carbonic anhydride, and the vessel closed.

In no case, even after a month, did the blood acquire a disagreeable odour, although, as in the first experiment, it contained a large number of bacteria. Between 20° and 25° the blood in contact with air remains red, and deposits no crystals; that in contact with oxygen at 24—26° deposits some crystals after the second day, and their number slowly increases. The blood in contact with carbonic anhydride deposits no crystals at 20—28°, and the blood becomes dark-red; at 33—40° crystals appear, and the blood becomes brown. Addition of one-fourth the volume of a 0·2 per cent. solution of phenol accelerates the formation of these crystals. The destruction of the corpuscles is evidently not due to the action of oxygen, since it takes place most readily in presence of carbonic anhydride. The formation of the crystals and destruction of the corpuscles in presence of carbonic anhydride is a function of the temperature, and this is probably true also in presence of air or oxygen.

Other experiments show that none of the substances separated from blood, such as hæmoglobin and albumin, alter under the conditions described, and the changes observed in blood by Pasteur and by the author can only be due to the activity and influence of the microzymes in the blood. C. H. B.

**A First Product of Gastric Digestion.** By K. HASEBROEK (*Zeit. physiol. Chem.*, 11, 343—360).—When fresh fibrin is employed in experiments on artificial gastric digestion, it is found that previous to the formation of parapeptone or syntonin, and propeptone and peptones, there is a substance present which is a globulin. It is soluble in weak saline solutions, precipitable on dilution with water, by saturation with sodium chloride or magnesium sulphate, and can be separated by fractional heat coagulation into two proteïds which coagulate respectively at the temperatures 55° and 72°. Supposing fibrin to be formed from fibrinogen and serum globulin (Schmidt), the conclusion is drawn that the first effect of gastric juice or fibrin is to separate it into two substances, one of which corresponds exactly with one of the components of fibrin (serum globulin), and the other only differs from the other component of fibrin (fibrinogen) in

having lost the power of coagulating under the influence of the fibrin ferment.

If boiled fibrin be employed, no such globulins are formed in gastric digestion.

One experiment only was made with fibrin that had been kept under alcohol; from it a small amount of globulins was obtained by the action of artificial gastric juice; as, however, the fibrin had only been under alcohol for two days, it is probable that some uncoagulated fibrin was still present. Experiments with egg albumin coagulated either by heat or by alcohol, showed that no globulin was yielded by gastric digestion. Lastly, it was found by using a pure solution of trypsin, or at least one which contained no globulins, and subjecting fibrin freed from adherent globulins by washing it with a solution of ammonium chloride, to its action in an alkaline medium, that the first effect of tryptic digestion was exactly the same as that of gastric digestion.

W. D. H.

**Intestinal Digestion in the Horse.** By H. GOLDSCHMIDT (*Zeit. physiol. Chem.*, **11**, 286—305).—The reaction of the contents of the small intestine of the horse was usually as follows:—At the duodenal end the reaction was acid; then after the first 15 to 20 inches neutral or weakly alkaline; in the remainder of the small intestine it was alkaline, and towards the end of the ileum strongly alkaline. The consistency was slimy, especially in the duodenum, the sliminess seeming to depend on the presence of starch; the colour depends on the food, but the colour of the intestinal juice is dark yellow, becoming darker brown down the intestine. The contents give the reactions of proteids, peptones, and sugar, especially the latter; the amount present being on the average 0.5 to 1.5 per cent.

The digestion in the small intestine is in the horse not so important as in the stomach. Whilst in the stomach about 55 per cent. of the albuminous and about 40 per cent. of the non-nitrogenous constituents are digested, about 20 and 25 per cent. respectively represent digestion in the small intestine. During inanition an extraordinarily large quantity of fluid (4 to 6 litres) is present in the small intestine. With regard to the movement of the food, it was found that the first portions reached the colon about 8 to 12 hours after it was eaten. Digestion in the large intestine of the horse is not described.

W. D. H.

**Oxidation in the Animal Body.** By C. WURSTER (*Ber.*, **20**, 256—263).—Certain amines being well adapted to the study of oxidation processes, the following experiments were performed:—

Tetramethylparaphenylenediamine was injected subcutaneously and into the veins of certain warm-blooded animals (rabbits, guinea-pigs, and pigeons), and soon caused the death of the animal after violent convulsions. Post-mortem examination gave in most cases a negative result; the base could not be discovered in the skin or muscles, as it had been oxidised to form a colourless substance. The liver and bile contained traces. Freshly captured frogs also oxidise the base quickly if its hydrochloride is employed. By using the acetate or sulphate subcutaneously, the muscles under the skin are seen during life to be

blue-violet. This colour is formed more quickly in the presence of air. The skin also contains the pigment, but appears to oxidise the colouring matter more slowly. After frogs have been kept a long time without food, their tissues burn the tetramethylparaphenylenediamine with greater difficulty, but better if muscular movements are brought about, and if a weak solution of sugar be added to the hydrochloride of the base. After intravenous injection of such a mixture into a frog, the unchanged substance is found after death in the liver, blood, bile, certain muscles, and the central nervous system, and the free base can be obtained by treating with sodium hydroxide and subsequent shaking with ether; treatment of the tissues with a solution of copper sulphate or of iodine gives a blue-violet coloration.

The liver in the air became deep-blue violet; certain muscles, especially of the trunk, also became violet, and darkened on exposure in the air; the muscles of the lower extremity which continued to move longest were free from colour, which they had probably oxidised. In the alimentary canal, the mucous membrane was colourless, marking it off sharply from the muscular coat, which became violet in the air. These facts show that protoplasm, although itself reducing, can on access of air bring about powerful oxidation, and that even after the death of the animal, further oxidation processes will go on in the cells which still retain vital power. Moreover, the organs which during life form glycogen, namely, the liver and resting muscles, produce oxidation only to a certain extent, whilst the acting muscles, the glands of the alimentary tract, and the skin, cause still further oxidation, resulting in the formation of a colourless compound from the amine.

Dimethylparaphenylenediamine behaves similarly to the tetra-compound, but as its oxidation occurs more slowly, the effects on warm-blooded animals can be observed better. 20 to 40 c.c. of a  $\frac{1}{2}$  to 3 per cent. solution of the hydrochloride causes in warm-blooded animals violent convulsions and death, the symptoms much resembling those described by Brieger as the result of poisoning by tetanine. Weaker solutions do not kill so quickly; the muscles in certain cases became violet during life; and in these the base is no longer present as such; but as a rule in the muscles in the neighbourhood of the injection, and in certain cases in the tears and peritoneal fluid the base could be detected after treatment with sodium hydroxide and ether, or by the red colour produced by chromic and glacial acetic acids. In the lung, the blue oxidation product caused mottling, and both this organ and the muscle darkened as in the case of the tetra-compound on exposure to air. The blood contains the unaltered amine. Experiments on frogs gave confirmatory results. Muscle which had undergone heat rigor no longer produced oxidation changes; this is analogous to fibrin, which, as Scherer (*Annalen*, 40, 15) showed, does not decompose hydrogen peroxide after it had been boiled. The general conclusions drawn are: (1) That during life oxidation processes go on in the body, corresponding with the effect produced by ordinary oxidising agents on di- and tetra-methylparaphenylenediamine, which, causing them to take up 1 atom of oxygen, produces a blue-violet colour; or they may undergo still further oxidation, 6 atoms of oxygen being used to form carbonic anhydride from two methyl-groups, and

so convert the amine into a colourless derivative; (2) the oxidation of the amines occurs not in the blood, but in the tissues; (3) the secretions of the body are also strongly oxidising, in virtue of the hydrogen peroxide they contain; (4) the rapidity with which dimethylparaphenylenediamine is burnt in the tissues, as compared with what occurs in laboratory experiments or in the secretions, points to oxidation in the tissues as being brought about by atomic oxygen, which is probably produced, as Hoppe-Seyer suggests, by the action of nascent hydrogen (Abstr., 1886, 120).

Many of the foregoing experiments and conclusions run counter to those of Ehrlich (*Das Sauerstoffbedürfniss des Organismus*, Berlin, 1885). Ehrlich's methods are criticised by the author. W. D. H.

### The Fate of certain Chlorine Compounds in the Organism.

By A. KAST (*Zeit. physiol. Chem.*, 11, 277—285).—Certain results of Mylius, showing the influence of the administration of chloroform on the amount of chlorine in the urine of the dog, which have not been hitherto published, are first given. The following example will illustrate the result arrived at:—

| Day. | Amount of urine. | Specific gravity. | NaCl. |
|------|------------------|-------------------|-------|
| 1    | 700 c.c.         | 1010              | 0.1   |
| 2    | 950 „            | 1009              | 0.13  |
| 3    | 1050 „           | 1011              | 1.48  |
| 4    | 570 „            | 1012              | 0.44  |
| 5    | 570 „            | 1012              | 0.25  |

On the second day, 10 grams of chloroform were given; the next day's urine shows a great increase of sodium chloride. Ether given in similar amount produced no such change.

This research was now pursued further; the effect of the inhalation of chloroform was first tried on a dog. The following table shows the results obtained:—

| Day.    | Quantity of urine. | Specific gravity. | NaCl. | Remarks.                          |
|---------|--------------------|-------------------|-------|-----------------------------------|
| 1 ..... | 170                | 1035              | 0.11  | Chloroform narcosis for 4½ hours. |
| 2 ..... | 290                | 1038              | 0.25  |                                   |
| 3 ..... | 290                | 1039              | 0.89  |                                   |
| 4 ..... | 210                | 1033              | 0.24  |                                   |
| 5 ..... | 270                | 1036              | 0.26  | Deep ether narcosis for 4½ hours. |
| 6 ..... | 160                | 1037              | 0.18  |                                   |
| 7 ..... | 240                | 1036              | 0.26  |                                   |
| 8 ..... | 260                | 1036              | 0.20  |                                   |

The effect in the increase of chlorides is thus seen to be very marked after chloroform narcosis; whilst ether produces no effect.

During the progress of the experiment, the animal was kept on a

constant diet containing as few chlorides as possible. Following out a similar experiment on man, it was found that chloroform narcosis here also produced an increase in the urinary chlorides.

Chloral was next investigated, and it was found to have no such effect in producing an increase in the chlorides of the urine; Mering has previously shown that this substance leaves the body as urochloralic acid, and does not part with its chlorine. Similar investigations with carbon tetrachloride, methyl chloride, and ethyl dichloracetate also gave negative results, but ethyl trichloracetate, on the other hand, produced a very decided increase in the output of chlorides.

W. D. H.

**Formation of Xanthocreatinine in the Organism.** By A. MONARI (*Gazzetta*, 16, 538—543).—In the course of investigations on the changes produced by fatigue in the chemical composition of muscle, it was observed that the quantity of creatinine was one-third to one-half greater than that of creatine, and that the compound of creatinine with zinc chloride was precipitated in pale-yellow, acicular crystals. In the course of working up an extract of flesh, a yellow flocculent mass was obtained soluble in water and alcohol, from which it may be recrystallised. This substance was shown by analysis and by its physical and physiological properties to be identical with the xanthocreatinine isolated by Gautier.

The same substance was also extracted, together with creatinine, from the urine of soldiers after a march of several hours. Considerable difficulty was experienced in the complete separation of the xanthocreatinine from creatine.

V. H. V.

**Invertebrate Chromatology.** By C. A. MACMUNN (*Proc. Physiol. Soc.*, 1887, 11—12).—Chlorophyll is present in nine specimens of sea-water sponge in addition to the fresh water sponge, the presence of chlorophyll in which was shown by Ray Lankester. A histohæmatin soluble in glycerol was found in seven species; in some reddish sponges this is replaced by tetronerythrin or allied pigments. In most sponges, various lipochromes are present.

Hæmatoporphyrin occurs in all parts of the body of the mollusc *Solecurtus strigillatus*, except where it is attached to the shell. It is curiously distributed in the epidermis, being laid down at the margins of the cells, which are serrated, and reminding one of pavement epithelium stained with silver nitrate.

In *Anthea cereus*, chlorophyll is present, but in this case is due to the presence of symbiotic algæ. In *Flustra foliacea*, chlorophyll is present in the "brown bodies," which Moseley says are due to the atrophy of the zooids. As these "brown bodies" contain diatoms, &c., eaten by the zooid, it is possible that chlorophyll may in this case be derived from food products. Its spectrum, however, resembles that of enterochlorophyll.

W. D. H.

**Analysis of Nitrogenous Metabolites in Fæces.** By A. STUTZER (*Zeit. physiol. Chem.*, 11, 361—364).—The author has previously described (Abstr., 1886, 377) a method of separating the nitrogenous

constituents of fæces due to metabolism from those which are not, by means of artificial gastric juice, or better still by the successive action of gastric and pancreatic ferments. Pfeiffer has stated that the fæces must be used in the fresh, not in a dried condition, as the process of drying converts some of the nitrogenous constituents of the fæces into such a condition as to be indigestible. The fæces used in Pfeiffer's work had, however, been under alcohol for two years, and therefore it was deemed advisable to repeat the experiment. The fæces of the cow and horse were used, and the result of nitrogen estimations confirms the accuracy of Pfeiffer's statement as is shown by the following numbers:—

|                             | Nitrogen left after<br>peptic digestion. | Nitrogen left after<br>peptic and pancreatic<br>digestion. |
|-----------------------------|--|--|
| Cow's fæces (fresh).....    | 50 per cent.                             | 45 per cent.   |
| Ditto (dry) .....           | 69    "                                  | 51    "  |
| Horse's fæces (fresh) ..... | 47    "                                  | 30    "  |
| Ditto (dry).....            | 49    "                                  | 34    "  |

W. D. H.

**Proteïds of Cerebrospinal Fluid.** By W. D. HALLIBURTON (*Proc. Physiol. Soc.*, 1887, 14).—A few specimens of fluids obtained from meningocœles and from cases of chronic hydrocephalus were examined. It was found that all the proteïds were precipitable by saturation with magnesium sulphate. Serum albumin was therefore absent. The precipitate was redissolved and found to consist of a small quantity of serum globulin, but the greater part consisted of proto-albumose. In one case, a variety of albumose was present, which was not precipitable by magnesium sulphate or sodium chloride (deutero-albumose). In cases of acute hydrocephalus, the total quantity of proteïds in the cerebrospinal fluid was greater than normal, and the fluid contained serum albumin as well as serum globulin and albumose. The question as to whether a proteolytic ferment exists in the fluid has not as yet been investigated. A number of specimens of hydrocele, pericardial, peritoneal and pleuritic fluids were also examined for albumoses, but with negative results. Several specimens of human blood, and the blood of other mammalian animals were also examined, but no albumose was found in any of them.

This peculiarity of the proteïds of cerebrospinal fluid, together with the previously known facts of the existence of a substance in it which reduces alkaline solutions of cupric hydrate, and of the excess of potassium over sodium salts in the fluid, shows that effusions into the cerebrospinal cavity differ considerably from the other so-called serous effusions.

W. D. H.

**Therapeutic Action of Colchicine.** By A. MAIRET and COMBEMALE (*Compt. rend.*, 104, 515—517).—Experiments on men, dogs, and cats show that colchicine acts either as a diuretic or a purgative

according to the dose administered, and acts by irritating the kidneys and digestive canal. The effects are the same whether the drug is administered hypodermically or by ingestion, but the action is more rapid in the former case, and the effects are produced by smaller doses. Man is three times more sensitive to its action than are cats and dogs. A dose of 2 to 3 mgrms. is sufficient to produce the diuretic, and 5 mgrms. to produce the purgative action. Colchicine increases the excretions and produces congestion at the articulations and in the bony cartilage. Its tendency to accumulate in the organism, and its great toxic power, make it essential to use the greatest care in administering it.

## Chemistry of Vegetable Physiology and Agriculture.

---

### Changes Induced in Water by the Development of Bacteria.

By T. LEONE (*Gazzetta*, 16, 505—511).—The author has already demonstrated that the number of micro-organisms, in a typically pure water, such as the Mangfall near Munich, although at first small, yet on standing gradually increase to a maximum, and afterwards rapidly decrease. The development of bacteria induces certain chemical changes in the water; thus the quantity of oxidisable organic matter gradually decreases, whilst the proportion of ammonia increases to a maximum, and then decreases owing to its oxidation into nitrites and nitrates; on this account, the time which elapses between the taking of a sample and its analysis is an important factor. The consequent changes are divisible roughly into two distinct periods: the first, in which the organic matter is decomposed with production of ammonia; and the second, in which this is subsequently oxidised. It is further shown, on the other hand, that certain micro-organisms seem to act as reducing agents, reconverting the nitrates into ammonia, and even the same organisms, according to the conditions, may have either an oxidising or a reducing function. In the first phase, when the nutritive matter is readily oxidisable and assimilated, the micro-organisms thrive at its expense, the process of nitrification being materially assisted by atmospheric oxygen; in the second phase, on the other hand, the necessary oxygen is derived from the nitrates; thus a change, seemingly of reduction, is induced.

V. H. V.

**Formation of Albumin in Plants.** By A. EMMERLING (*Landw. Versuchs-Stat.*, 1887, 1—180).—This long paper is a report of a series of experiments made by the author in order to determine the locality in which, and the mode by which, vegetable albumin is formed: they are a continuation of previous experiments of his own, and a kind of test of those made by Kellner, Schultze, Hornberger, and others, abstracts of whose researches will be found in this Journal, 1879, 819; 1880, 279, 493, 731; 1883, 491; 1885, 1087.

Observers have adopted two hypotheses to account for the phenomena of the production of amido-compounds in plants. One that they are formed synthetically in the plant from inorganic nitrogenous matter and organic substances brought into contact with it; the second, that they are formed from the decomposition of albumin already existing in the plant.

Growing plants are rich in amido-acids, the quantity diminishes as the plants grow older, and young cells cease to be produced, the amides being specially their nutriment. Schultze (Abstr., 1883, 493) thinks that there is a constant process of decomposition and reformation. Hornberger, in his studies on the growth of the maize plant (Abstr., 1883, 491), and on that of *Sinapis alba* (Abstr., 1885, 1087) has thrown very great light on the subject; he is of the opinion that amido-compounds are formed according to the first hypothesis, but does not indicate the locality of their production.

The results of the author's experiments are given in tables which cover 46 pages. The plants used were the common bean, and the estimations comprised—total dry substance, total nitrogen, nitrogenous combinations soluble in aqueous potash, nitrogen existing as legumin, albumin, ammonia, amido-acids, amides, carbamides, and nitrates respectively, sulphur as sulphuric acid, and in organic combination.

There is an intimate and striking connection between the development of the leaves and the fruit of plants; when the leaf is growing, the production of nutrient matter is very active, but it is consumed by the leaf itself. When it has ceased growing, the same active production continues, but it is for the benefit of the seed or fruit, which only develops when the leaf is fully formed; the author believes that the leaf is the principal centre of albumin formation from whence it is diffused throughout the plant, the roots and stems playing a subordinate part in the process. In all parts of the plant, amido-acids are found, and it would seem that there are several centres of production.

The formation of new cellular matter in the first case is at the cost of the nitrogen stored in the seeds, and as the plant grows the quantity contained in the stem and roots sensibly diminishes.

The results of researches hitherto made are not decisive, however, although the author believes that the weight of probability is in favour of the synthesis of amido-compounds from inorganic and organic nitrogenous matter; he considers the difficulties of the alternate hypothesis too great, as it requires a regressive metamorphosis in presence of a most active production of the very matter which is being decomposed. The question, however, must still be considered an open one, as in recent experiments of Borodin and Schultze they observed that on many occasions cut plants placed in water for some time produced considerable quantities of asparagine and other amido-compounds which arise from the decomposition of albumin. J. F.

**American Barley.** By C. RICHARDSON (*Amer. Chem. J.*, 9, 16—22). Märcker found that the finest grain contained not more than 8 per cent. of albuminoids, and consisted of at least 80 per cent. mealy kernels. Of 12 typical specimens of the Canadian crop, none

were below 9 per cent. of albuminoïds, the average being 9·83, and only 6 contained 60 per cent. of kernels mealy or half mealy in structure. The average amount of albuminoïds in the barley of the United States, 11·50 per cent., is still higher. The average of 127 specimens from all parts of the world is given by Koenig as 11·14 per cent. Winter grown barley contains less albuminoïds than spring-grown, namely, 10·05 as against 11·42 per cent. H. B.

**Destruction of the Nematoids of Beetroot.** By A. GIRARD (*Compt. rend.*, 104, 585—587).—When the nematoids have not been long established and the area infected is limited, carbon bisulphide is an efficacious remedy, but must be applied in considerable quantity. Very satisfactory results were obtained by injecting it into the soil at a depth of 0·25 metre in the proportion of 300 grams per metre. Potassium thiocarbonate is of very little value as a remedy.

C. H. B.

**Direct Absorption of Free Nitrogen from the Atmosphere by Vegetable Soils which are Supporting Vegetation.** By BERTHELOT (*Compt. rend.*, 104, 625—630).—The experiments were made with soils in which *Amarantus pyramidalis* was being grown. The nitrogen in the soil and in the roots of the plants were estimated at the outset, and the nitrogen existing in the rain-water and the ammonia in the atmosphere during the course of the experiments were also determined. The nitrogen in the water which drained from the soil was estimated, and at the close of the experiments the nitrogen existing in the plants and in the soil was determined. In all cases there was a very decided gain of nitrogen, which could only have been derived from the gaseous nitrogen of the atmosphere.

The increase of nitrogen whilst the soil is supporting vegetation is less than in the case of the same soil on which nothing is being grown. The plants consume a considerable part of the nitrogen, and it would seem that the life of higher plants like that of higher animals causes an incessant loss of combined nitrogen. Further experiments are, however, required before this last conclusion can be regarded as placed beyond doubt.

C. H. B.

**Incompatibility of Nitrates and Superphosphates.** By A. ANDOUARD (*Compt. rend.*, 104, 583—585).—Mixtures of nitrates with superphosphates very rapidly lose their nitric nitrogen in the form of nitrogen oxides, and therefore still more rapidly when exposed on the surface of the soil to direct solar radiation. At the same time, there is some loss of organic nitrogen, and if the manure also contains ammonium salts there is likewise a loss of ammoniacal nitrogen.

C. H. B.

## Analytical Chemistry.

---

**Behaviour of Alkaline Solutions of Phenolphthaleïn in the Presence of Alcohol.** By H. N. DRAPER and C. DRAPER (*Chem. News*, 55, 133—134; 143—144).—The authors have investigated the conditions influencing the decolorisation of slightly alkaline solutions of phenolphthaleïn by the addition of alcohol; it would appear that dissolved carbonic acid is in the main the cause of the phenomenon. D. A. L.

**Apparatus for Estimating Hydrogen in the Presence of Methane.** By F. HOPPE-SEYLER (*Zeit. physiol. Chem.*, 11, 257—267).—This is a modification (figured) of Winkler's apparatus, in which (1) the mixture of gases is collected over mercury; (2) the portion of gas which has been freed from hydrogen by the action of palladium is transferred without loss to a eudiometer for further investigation. After this, the apparatus is ready for a fresh analysis.

W. D. H.

**New Method of Standardising Iodine Solutions and of Estimating Sulphurous Acid in the Presence of Thiosulphuric Acid.** By W. KALMANN (*Ber.*, 20, 568—570).—If sodium sulphite is employed instead of hydrogen sulphide in titrating iodine solutions (*Abstr.*, 1886, 579), the objections to the method arising from the use of the gas and the deposition of finely divided sulphur are removed. The sodium sulphite must be free from sodium hydrogen sulphite and from sodium carbonate, and a solution containing 15 grams in the litre is a convenient strength to employ. This is added to the iodine solution until it is just decolorised, and the hydriodic acid formed is titrated with decinormal soda, methyl-orange being used as an indicator.

Sodium sulphite may be estimated in the presence of sodium thiosulphate, by titrating with  $\frac{1}{20}$  normal iodine, inasmuch as sodium iodide results from its action on the latter; so that the amount of hydriodic acid formed, titrated as above, is a measure of the sodium sulphite present.

W. P. W.

**Volumetric Estimation of Sulphides.** By F. WEIL (*Ber.*, 20, 695—697).—A reply to Friedheim's criticism (this vol., p. 396) of the author's method for determining hydrogen sulphide in sulphides which are decomposed by hydrochloric or sulphuric acid (*Abstr.*, 1886, 918). Analyses of stibnite were made in the following way: the finely powdered mineral, wrapped in filter-paper, was put into a flask with 50 c.c. of hydrochloric acid, heated in a sand-bath, and the evolved hydrogen sulphide passed into 50 c.c. of a modified Fehling solution, which was diluted with about 100 c.c. of distilled water containing 7 to 8 grams of soda; the filtered solution was made up to 300 c.c., and a portion (25 c.c.) treated with 60 to 70 c.c. of hydro-

chloric acid, and titrated with stannous chloride. The numbers obtained in these analyses were: S = 28·38, 28·18, and 28·59 per cent.  
N. H. M.

**Manganese in Steel and Iron.** By H. C. BABBITT (*Amer. Chem. J.*, 9, 58—60).—The method is as follows: 5 grams of the sample is dissolved in 50 c.c. of nitric acid (1·20 sp. gr.) and 1 to 2 grams of red lead added together with about an equal bulk of hot water, when it may be boiled for some minutes. After a time, the liquid is decanted, and the residue boiled with fresh portions of hot dilute nitric acid (20 to 25 per cent.) so long as the decanted liquid is coloured by the permanganate formed. The united liquids are filtered through asbestos and the permanganate determined as usual. The presence of lead nitrate does not interfere, and the results obtained are very satisfactory.  
H. B.

**Decomposition of Chrome Iron Ore.** By E. DONATH (*Dingl. polyt. J.*, 263, 245).—The finely pulverised ore is mixed with five times its weight of barium dioxide and heated for half-an-hour in a porcelain crucible over a Bunsen burner. A greenish-yellow mass results, which is completely soluble in cold water acidified with hydrochloric acid. The solution contains the whole of the chromium in the form of chromic acid.  
D. B.

**Bacteriological Examination of Water.** By C. W. FOLKARD (*Chem. News*, 55, 124—125).—A bent tube drawn out at one end and of 1 c.c. capacity is adapted by a cotton-wool plug to a test-tube containing the nutrient jelly; the whole being then sterilised. The sealed capillary end of the bent tube is then passed through a hole in the wall of an india-rubber tube through which the water to be examined is running under slight pressure, the point is broken, and as soon as the bent tube is filled, it is withdrawn, the point sealed in a flame and the water transferred to the test-tube by shaking.  
A. J. G.

**Determination of Organic Carbon and Nitrogen in Waters.** By C. A. BURGHARDT (*Chem. News*, 55, 121—123).—250 c.c. of the water is mixed with 100 c.c. of a standardised solution containing about 10 grams of chromic acid per litre, and 10 c.c. of strong sulphuric acid. The mixture is boiled for  $\frac{1}{2}$  hour, diluted to 1000 c.c., and the excess of chromic acid titrated in 100 c.c. by means of standard ferrous sulphate solution; from these data, the carbon is calculated. For the nitrogen determination, part of the oxidised solution is treated with soda and distilled, the ammonia being collected in a receiver containing acidified water. The method, although only in a preliminary stage, appears to work well.  
D. A. L.

**Decolorising Power of Bone-black.** By G. LAUBE (*Arch. Pharm.* [3], 25, 133).—Good animal charcoal, from which defective pieces have been rejected, is powdered, dried at 110°, and preserved as "normal charcoal." 50—100 grams of caramel (as obtained from liqueur manufacturers) is dissolved in an equal quantity of water, 100 c.c. of alcohol is added, and the volume is made up to a litre;

after standing some days the liquid is filtered and marked "normal colour." 5 grams of the normal charcoal is heated to boiling with 200 c.c. of water; 10 c.c. of the normal colour is added, and after 10 minutes' gentle boiling in a reflux apparatus, the liquid is filtered through a double-folded filter. 200 c.c. of water is now measured off and normal colour is added from a pipette until the tint is the same as that of the filtrate. If, for example, 2.1 c.c. of normal colour is required, the charcoal is equivalent to  $10 - 2.1 \text{ c.c.} = 7.9 \text{ c.c.}$  Any other sample of charcoal can now be compared with the normal charcoal. If a sample indicates 5.5 c.c. of the normal colour, its decolorising power in comparison with the normal charcoal will be 70 per cent. J. T.

**Quantitative Estimation of Wood in Paper.** By C. WURSTER (*Ber.*, 20, 808—810).—Inasmuch as crude wood shavings have been introduced into the paper manufacture, and the paper prepared from them turns after some time yellow and then brown, and finally becomes unsightly, an estimation of the proportion of wood present becomes desirable.

Dimethylparaphenylenediamine imparts a magenta coloration to paper containing wood, but no change is produced with paper prepared from linen or cotton fibre. In order to make this change quantitative, the paper to be examined is moistened, tested with the reagent, and the tint given is compared with those of standard papers tinted and arranged according to scale. As then the oxidation of the dimethylparaphenylenediamine to the red dye-stuff is quantitative, these standard papers can be prepared and estimated by some titrated oxidising solution, such as iodine. A few such estimations are given as examples. V. H. V.

**Investigation of Acetyl-compounds; New Method for the Analysis of Fats.** By R. BENEDIKT and F. ULZER (*Monatsh. Chem.*, 8, 41—48).—The authors use a modification of Köttstofer's process for the determination of the saponification value of fats. The process is carried out by boiling the acetyl-compounds with strong standard alcoholic potash for 15 minutes, the excess of potash is then titrated with standard hydrochloric acid, about half normal. The amount of potash required for the decomposition is expressed as the "saponification-value," that is, the number of milligrams of potassium hydroxide required for the saponification of 1 gram of the acetyl-compound. If the substance under investigation is an acid, a portion of the potash is used up in neutralising the acid; in such cases the "saponification-value" is the sum of the "acid-value" and "acetyl-value." The former must be determined by a separate titration with standard potash. This method is applied to the determination of the molecular weights of the higher fatty alcohols and hydroxy-acids; the substances are first converted into acetyl-derivatives and then saponified as above. The authors have also applied the method to the examination of fats, and state that where the fats principally contain hydroxy-acids, it is possible to identify the acid and in some cases to detect adulterations, both qualitatively and quantitatively. The fat

is first saponified to obtain the fatty acid, and this is then treated as above. G. H. M.

**Analysis of Fats.** By B. RÖSE (*Chem. Centr.*, 1887, 234).—In order to avoid the imperfections of the methods of Oudemans (*J. pr. Chem.*, 96, 407) and Kremel (*Pharm. Centr.*, 5, 337), for determining acids of the oleic and linoleic series in presence of solid fatty acids, the author has studied the action of lead oxide on mixtures of these acids in ethereal solution. At the boiling point of ether, an excess of lead oxide rapidly neutralises the acids and even partially converts the liquid acids into basic salts, which remain with the insoluble lead stearate and palmitate. The amount of basic salt formed increases with the time. At ordinary temperatures, however, no basic salt is formed, even during a contact of some weeks; whilst the presence of the solid fatty acids does not hinder the complete neutralisation of the oleic acid by the lead oxide. The soluble lead oleate can, therefore, be accurately separated and determined. M. J. S.

**Examination of Butter Colours.** By H. B. CORNWALL (*Chem. News*, 55, 49).—The solution of fat in ether is shaken with a solution of potash or soda of such dilution as to be only just alkaline when separated from the fatty layer after a few hours. Annatto and saffron may be looked for in this extract. With sulphuric acid, annatto strikes first a blue or violet-blue, then a green, and finally brownish or somewhat violet colour. These changes of colour are important, as pure butters have been known to give a green coloration, but always without the preceding blue. Turmeric is easily recognised by the action of the alkaline solution. D. A. L.

**Estimation of Uric Acid by Potassium Permanganate.** By C. BLAREZ and G. DENIGÉS (*Compt. rend.*, 104, 789—790).—If the solution of uric acid is too strong, the action of potassium permanganate varies with the strength of the solution and the proportion of free acid.

If the solution contains not more than 1 gram of uric acid in 8000 c.c. the action of the permanganate is regular and is independent of the degree of dilution and the proportion of free acid. 1 c.c. of decinormal permanganate is equivalent to 0.0074 gram of uric acid. The results are the same in hot solutions as in cold. The quantity of uric acid should not exceed 0.1 gram, and the quantity of free sulphuric acid should be about 3.5 grams. The amount of permanganate required to produce the end reaction with the same volume of water containing the same quantity of free acid should be subtracted.

C. H. B.

**Volumetric Estimation of Acids in Salts of the Alkaloids.** By P. C. PLUGGE (*Arch. Pharm.* [3], 25, 45—59).—By using litmus as indicator, the acids in narcotine, papaverine, and narceine salts can be directly titrated with standard soda solution, and in this respect these feeble bases differ from the strong opium bases. Equally good results are obtained with phenolphthaleïn as indicator. In

general, the salts of the alkaloïds can be titrated directly with phenolphthaleïn as indicator, excepting the salts of the volatile bases, conine and nicotine. In the cases of brucine, morphine, and thebaine, however, a red coloration makes its appearance before the end of the reaction, but a little experience surmounts this difficulty. In solutions of alkaloïd salts (excepting those of the feeble bases), the amount of free acid can be determined by titration with litmus, and the total quantity of acid by titrating with phenolphthaleïn. The difference gives the quantity of acid combined with the alkaloïd, and from this the amount of alkaloïd can be calculated. Sundry examples of the application of the foregoing principles are given, in which the purity or otherwise of various compounds is determined. J. T.

**Assay of Opium.** By — ADRIAN and E. GALLOIS (*J. Pharm.* [5], 15, 193—197).—In 1867, Guilbermond proposed to estimate the morphine in an aliquot part of the extract obtained from the opium. More recently Doux proposed to modify Regnault's process in the same direction. He treats 50 grams of opium with 200 c.c. of alcohol at 70°, and takes 105 c.c. of the filtrate as representing accurately 25 grams of opium. The authors hold that to arrive at accurate and comparable results, it is indispensable to take into account, in every case, the amount of water and of soluble constituents contained in the opium. They consider the opium as being composed of water, material soluble in alcohol at 70°, and insoluble residue. The sample for assay is pounded in a mortar; 5 grams is extracted with 50 c.c. of alcohol at 70°, with which it is kept in contact for 12 hours; the residue is then filtered off, dried, and weighed on a tared filter. The loss gives the amount of water and soluble matter, and the amount contained in the portion taken for the morphine estimation is of course deduced. 50 grams of the sample is placed in a tared and stoppered flask with a wide neck, treated with 200 grams of alcohol at 70°, placed in a bath of 25—30°, and frequently agitated. When the estimation of water and soluble constituents is finished, the flask is carefully weighed, and alcohol is added to make up the liquid contents of the flask exactly to 250 grams. After filtering, 200 grams of this liquid exactly contain the morphine from 40 grams of opium; this morphine is precipitated by ammonia, washed with alcohol at 40°, dried, treated with chloroform, and dried again as in Regnault's process, but taking care to wait 36 hours before collecting the deposit. The method requires somewhat more time than Regnault's, but it has the advantage of being applicable to all opiums whatever their composition, and it gives exact results. J. T.

**Estimation of Morphine in Opium and its Preparations.** By O. SCHLICKUM (*Arch. Pharm.* [3], 25, 13—32).—The method recommended is founded on that proposed by Dietrich, and depends on the fact that if a not too concentrated solution of morphine salts is mixed with a slight excess of ammonia and half its weight of alcohol, and is boiled down to one-half the volume of the mixture, no precipitation of morphine follows when the original volume of solution is made up by adding water. The perfectly neutral solution thus

obtained remains quite clear and free from morphine crystals. For opium, 3 grams is frequently shaken with a mixture of 15 grams dilute alcohol and 15 grams water and digested during 12 hours. The filtrate is made faintly alkaline with ammonia, and evaporated to half its volume. The solution is made up to its original weight and filtered. 21.25 grams of this filtrate is treated with 5 grams of ether and 0.4 of gram ammonia, and shaken round occasionally during five or six hours. The ethereal layer is taken off with a pipette and passed through two equal filters, on which the morphine is collected and washed twice with 2 c.c. of water each time. After drying at 100°, the morphine is weighed, one paper serving as tare. Of opium extract, 1.5 grams is treated with 10.5 grams of dilute alcohol, and 10.5 grams of water without heat, and filtered. The weighed filtrate rendered slightly alkaline by ammonia is boiled down to one-half, made up to its original weight with water, and filtered. 15 grams of the filtrate is treated with ether and ammonia as above. Of *Tinctura opii simplex* or *crocata*, 25 grams is taken, made slightly alkaline with ammonia, and treated as above. J. T.

**Estimation of Cinchonidine in Quinine Sulphate.** By L. SCHÄFER (*Arch. Pharm.* [3], 25, 64—72).—After reviewing several methods, the author gives one for estimating 1 per cent. or less of cinchonidine in quinine sulphate, based on the extremely slight solubility of quinine oxalate in water in presence of a small excess of potassium oxalate, and the relatively easy solubility of cinchonidine oxalate in such a solution. 2 grams of quinine sulphate is dissolved in a small tared flask in 55 c.c. of boiling water, and 0.5 gram of neutral, crystallised potassium oxalate in 5 c.c. of water is added. The liquid is made up to 625 grams and cooled for half an hour in water at 20°, with occasional shaking to and fro, and then filtered. If on the addition of one drop of officinal aqueous soda to the filtrate no turbidity appears, the quinine sulphate contains less than 1 per cent. of cinchonidine sulphate. In the presence of 1 per cent. of the latter salt, a turbidity or a precipitate of cinchonidine appears. Quantitatively, 5 grams of quinine sulphate is taken, and an aliquot part of the filtrate is treated with aqueous soda; the cinchonidine is collected. Since a certain amount of cinchonidine remains in solution, and a little also goes down with the quinine oxalate, it is necessary to apply a slight correction to the amount found. Numerous experiments show that this correction should be 0.04 gram cinchonidine for each 100 c.c. of solution originally taken. Further, if more than 4 per cent. of cinchonidine is present, a more dilute solution should be employed, as the process is expressly intended for small quantities only. The test also indicates small quantities of quinidine and cinchonine sulphate when present; indeed, the conditions are more favourable in the case of these compounds, as they are not carried down by the oxalate precipitate. J. T.

**Testing Quinine Sulphate.** By O. SCHLICKUM (*Arch. Pharm.* [3], 25, 128—129).—Employing De Vrij's chromate method (this vol., p. 404), the author finds that not only quinine but also cinchonine

forms a chromate soluble in 2000 parts of water at moderate temperatures, whilst quinidine and cinchonidine chromates are much more soluble in water. On precipitating a quinine solution by means of normal potassium chromate, and allowing it to remain four or more hours, the filtrate remains unchanged on the addition of soda if the quinine salt is pure. If the quinine salt contains cinchonine, quinidine, or cinchonidine in not too minute traces, the soda produces a turbidity either at once or after some time. The method detects cinchonine sulphate to  $\frac{1}{2}$  per cent., and cinchonidine or quinidine sulphate to 1 per cent. In testing other neutral quinine salts it is not necessary to convert them into sulphate. Acid quinine salts require conversion into neutral ones, say by evaporation to dryness with ammonia. J. T.

**Colour Reactions of Picric Acid and Dinitrocresol (Victoria-yellow).** By H. FLECK (*Chem. Centr.*, 1887, 99).—When solutions of these substances are evaporated in a porcelain dish, and the residue moistened with a little 10 per cent. hydrochloric acid, a small piece of pure zinc added, and the dish allowed to remain for some hours without warming, a fine blue colour is developed in the case of picric acid and a bright blood-red with dinitrocresol. These reactions are useful for examining artificially-coloured farinaceous foods, the alcoholic extract of which should be employed. G. H. M.

**Determination of Tannin in Sumach.** By J. MACAGNO (*Chem. Centr.*, 1887, 125).—The author has compared Löwenthal's method for the determination of tannin with those of Davy and Gerland. He finds that Davy's method, which consists in precipitating the tannin with gelatin, drying, and weighing the precipitate, and multiplying the weight by the factor 0.4, gives results both with pure tannin and also with sumach which stand in the ratio to results obtained by Löwenthal's method as 53.34:100; whilst Gerland's method (precipitation of the tannin with tartar emetic solution in the presence of ammonium chloride; the reagent is prepared by dissolving 2.611 grams dry tartar emetic in a litre of water, 1 c.c. equals 0.005 gram tannin) gives results which, when compared with Löwenthal's method, stand in the ratio of 2 : 3. G. H. M.

---

## General and Physical Chemistry.

---

**Absorption-spectrum of Liquid Oxygen and of Atmospheric Air.** By K. OLSZEWSKI (*Monatsh. Chem.*, **8**, 73—77).—Liquid oxygen, examined with a thickness of 12 mm. and at a temperature of  $-181.4^{\circ}$ , gives absorption-bands, the middle of which correspond with the wavelengths 628, 577, 535, and  $480\mu$ ; the band 628 is characterised by its width (634—622), and the band 577 by its intensity: the bands 535 and 480 do not appear to be present in the solar spectrum.

Liquid air was examined at  $-191^{\circ}$ , and with a thickness of 12 mm. No other absorption-bands besides those of oxygen were observed, but bands 628 and 577 were not so strong as with pure oxygen.

G. H. M.

**Red Fluorescence of Alumina.** By L. DE BOISBAUDRAN (*Compt. rend.*, **104**, 824—826).—The author has previously found (this vol., p. 538) that alumina prepared from pure aluminium chloride shows no phosphorescence even in the phosphoroscope. An aqueous solution of the chloride was left exposed to the air in a glass vessel for several days, and was then evaporated to dryness, and the residue strongly heated. The alumina thus obtained gave no fluorescence in a vacuum, and only a very feeble tint in the phosphoroscope.

Alumina from aluminium chloride, which has been very strongly heated and shows no phosphorescence in the phosphoroscope, shows a brilliant red phosphorescence when mixed with a very small quantity of chromium.

In order to ascertain whether the fluorescence shown by alumina from alum is due to the presence of impurities, ammonia alum was recrystallised seven times from a slightly acid solution. Alumina prepared from the seventh crystallisation, and very strongly heated, gave no red fluorescence in a vacuum, but a moderately intense violet fluorescence, becoming indigo with a weaker current. In the phosphoroscope, it showed a very feeble greenish phosphorescence with a tendency to become red at some points. Alumina from the fifth crystallisation gave no red in a vacuum, but a somewhat marked pale green fluorescence, becoming violet with a weaker current. The alumina from the third crystallisation gave the red fluorescence, and the mother-liquor gave the spark spectrum of chromium.

Alumina precipitated from the seventh crystallisation by ammonia, and very strongly heated, showed no trace of the red fluorescence in a vacuum, but gave a mixture of a feeble green and a still feebler violet fluorescence. If this alumina is mixed with 0.0000186 of its weight of chromium oxide, it shows a beautiful rose-red fluorescence.

The author considers that these facts, together with those previously described, show that the red fluorescence is really due to the presence of minute quantities of chromium.

C. H. B.

**Molecular Refraction of Carbon Compounds of High Dispersive Power.** By R. NASINI (*Gazzetta*, 17, 48—55, and 55—64).—In these papers the author criticises Brühl's conclusions regarding the relations between molecular refraction and chemical constitution. The papers are mainly controversial, and contain neither fresh determinations nor conclusions.

V. H. V.

**Formation of the Electric Arc without Contact of the Electrodes.** By G. MANEUVRIER (*Compt. rend.*, 104, 967—969).—The electrodes are enclosed in an air-tight glass vessel provided with a three-way stopcock, the electrodes being connected with a source of alternating currents by means of platinum wires fused into the glass. The apparatus is attached to an air-pump, and the pressure inside reduced until a violet silent discharge takes place between the poles. The stopcock is then turned so as to admit a small quantity of air, and under the influence of the sudden increase of pressure, the silent discharge between the poles is transformed into an arc. When the arc has formed, the stopcock is closed, and in this way an arc is obtained in what is practically a vacuum, and thus many of the causes which interfere with the constancy of the arc are eliminated; there is, for example, no combustion of the carbons. The silent discharge passes when the pressure in the globe is 5—6 mm., and the arc is formed at pressures between 30 and 150 mm.

C. H. B.

**Thermic Expansion of Liquids at Various Pressures.** By G. P. GRIMALDI (*Gazzetta*, 17, 18—31).—In continuation of experiments on the expansion of liquids at various pressures (Abstr., 1886, 498), the author gives determinations for chloroform at temperatures varying from 0—80° and pressures of 1 to 15·5 metres, and of pentane between 1 and 100°, and pressures of 1 to 22 metres. The equation expressing the expansion in terms of temperature is of the form  $\Delta = at + bt^2 + ct^3$ , and the values for the constants  $a$ ,  $b$ ,  $c$  are given for chloroform and pentane at pressures of 1 and 15·5 metres and 12 and 22 metres respectively.

The various formulæ, expressing the dilatation in terms both of temperature and pressure, which have been proposed by Duprè, Heen, and van der Waals are fully discussed. The formula most in accordance with the results is a modification of Duprè's, and is expressed thus:

$$K = \frac{T\alpha V}{\beta}, \text{ in which } K = \alpha\Delta^2 \text{ when } t = 0^\circ, T \text{ is the absolute temperature, } \alpha \text{ the time coefficient of dilatation at pressure } p, \beta \text{ the coefficient of compressibility at } T, \text{ and } K \text{ a constant dependent on the nature of the liquid examined.}$$

The difference between the observed and calculated values is most marked at the extreme limits of temperature, at which the determinations are least exact, and it is noted that a small error in the experimental value for the expansion influences to a considerable degree the value for the constants  $\alpha$  and  $\beta$ . The coefficients calculated according to Heen's equation give results lower than those observed, and these differences rapidly increase with increase of temperature.

V. H. V.

**Latent Heat of Vaporisation of Certain Volatile Substances.** By J. CHAPPUIS (*Compt. rend.*, 104, 897—900).—The apparatus consists of a cylindrical glass reservoir closed at the bottom, and containing the liquid to be evaporated. This receiver terminates in a serpentine capillary tube united to an ordinary delivery tube, and to the free end of this a steel stopcock with a lateral tubulus is cemented.

The receiver containing the liquid under examination is weighed and placed in a Bunsen's ice-calorimeter, in which both it and the serpentine tube are completely surrounded by mercury. The stopcock is then opened, and the vapour is allowed to escape very slowly so that the reduction of pressure which is essential to vaporisation may be kept as small as possible. After the usual readings have been made, the apparatus is again weighed. The loss of weight gives the difference between the weight of the liquid which has been volatilised and the weight of its saturated vapour which occupies the same volume; from this, the weight of the liquid evaporated is readily calculated. The following results were obtained:—

|                            |       |
|----------------------------|-------|
| Methyl chloride.....       | 96·9  |
| Sulphurous anhydride ..... | 91·7  |
| Cyanogen .....             | 103·7 |

Further experiments, which will be described in a subsequent paper, show that the rate of vaporisation exerts considerable influence on the results, but if it does not exceed 8 to 16 mgrms. per minute, the latent heat of vaporisation is constant. Within the same limits, the temperature of the apparatus in which evaporation takes place is not reduced below 0·3°.

C. H. B.

**The Calorimetric Bomb.** By BERTHELOT and RECOURA (*Compt. rend.*, 104, 875—880).—The calorimetric bomb (*Abstr.*, 1886, 756) consists of three metals, platinum (interior), steel, and brass (stopcock). Its water value may be calculated from the weight of these metals and their specific heats, or may be directly determined by one of three methods, namely: (1) by burning in the bomb in the calorimeter two different weights of the same substance, one being twice or three times as great as the other; the thermometric measurements give equations which contain the value of the unknown quantity; (2) by introducing into the water of the calorimeter containing the bomb a known quantity of water at a definite temperature; (3) by introducing into the water of the calorimeter a known weight of concentrated sulphuric acid, a previous experiment being made with the same quantity of water and sulphuric acid, but without the bomb in the calorimeter. Direct determination gave 343·9 grams; whilst the calculated water value was 344·7 grams.

Ten minutes after compressing the gas, or allowing it to escape, the rate of cooling of the apparatus resumes its normal value. The compressed oxygen from the pump is passed through a copper tube heated to redness in order to oxidise any organic matter, and is cooled to the ordinary temperature before entering the bomb.

Three of these bombs are in existence, and a comparison of the heat

of combustion of naphthalene made by means of the bombs in three separate laboratories, will give some idea of the accuracy of the method—

|                             | Per gram.   |
|-----------------------------|-------------|
| Berthelot and Vieille ..... | 9·718       |
| Louguinine .....            | 9·763       |
| Recoura .....               | 9·664       |
|                             | <hr/> 9·715 |

The variations only amount to 0·5 per cent., and with greater experience in the manipulation of the apparatus still greater accuracy will be attained.

C. H. B.

**Dependence of Chemical Affinity on Temperature.** By W. MÜLLER-ERZBACH (*Ber.*, 20, 1152—1153).—If  $t_1$  and  $t_2$  be the temperatures at which a hydrated compound and pure water respectively exert the same vapour-tension, the author speculates that  $t_1 - t_2$  may be a measure of the firmness of union of the chemically combined water. For all solid hydrated salts hitherto examined,  $t_1 - t_2$  diminishes with rise of temperature; but for aqueous solutions of these salts it increases slightly with the temperature (Wüllner, Tamman) up to 100°. For dilute sulphuric acid also,  $t_1 - t_2$ , calculated from Regnault's experiments, increases regularly with the temperature, but more rapidly for the stronger acids.

Hence the author concluded that, for example, hydrated cupric sulphate and dilute sulphuric acid, enclosed in the same space, could be in equilibrium as regards affinity for water, only at some definite temperature. And, in fact, when the hydrate  $\text{CuSO}_4 + 3$  to  $4\frac{1}{2} \text{H}_2\text{O}$  and sulphuric acid of 1·418 sp. gr. are enclosed in the same vessel, but not in direct contact, the weight of the copper salt increases in the course of a day at 12°, but at 50° it diminishes perceptibly in a few hours. With acid of 1·427 sp. gr., the changes are of the same kind, but slower, and the action is reversed at about 32°. Below this, the affinity of the copper salt for water is the more powerful, above it that of the acid prevails. Further experiments are promised.

CH. B.

**Thermal Study of Solutions of Hydrobromic Acid, and of the Solid Hydrate,  $\text{HBr} \cdot 2\text{H}_2\text{O}$ .** By H. W. B. ROOZEBOOM (*Rec. Trav. Chim.*, 5, 323—334. See Abstr., 1886, 117 and 414). The following are the specific heats,  $C$ , of solutions containing  $n$  molecules of water to one  $\text{HBr}$ .

| $n$ .    | $C$ .  | $n$ . | $C$ .  | $n$ . | $C$ .  |
|----------|--------|-------|--------|-------|--------|
| $\infty$ | 1·0000 | 7·01  | 0·5397 | 2·92  | 0·3742 |
| 200      | 0·9688 | 5·69  | 0·5005 | 2·72  | 0·3608 |
| 100      | 0·9402 | 4·92  | 0·4711 | 2·48  | 0·3524 |
| 50       | 0·8876 | 4·85  | 0·4694 | 2·0   | 0·3553 |
| 20·12    | 0·7641 | 4·65  | 0·4640 | 1·84  | 0·3827 |
| 10       | 0·6154 | 4·013 | 0·4310 | —     | —      |

The molecular heats calculated from this table are almost identical with the values found by Marignac and Thomsen for solutions of hydrochloric acid. The specific heat and the molecular heat for  $\text{HBr}, n\text{H}_2\text{O}$  reach minimum values for  $n = 2$ . When the molecular heat is calculated for  $n'\text{HBr}, 100\text{H}_2\text{O}$ , the value is a minimum for  $n' = 8$ . These results do not point to the hydrates of  $\text{HCl}$  and  $\text{HBr}$ , supposed to exist by Berthelot (*Ann. Chim. Phys.* [5], 4, 488). The author rather supposes the solutions to contain several molecular groupings in dynamical equilibrium, the composition and quantity of these groupings varying with the temperature and concentration. Similar views as to the constitution of solutions of sulphuric acid are held by Mendeléeff (*Abstr.*, 1886, 413).

The author has also determined the heat of dilution of the *liquid* hydrate,  $\text{HBr}, 2\text{H}_2\text{O}$ , and finds it = 5880 cal. at  $10^\circ$ . Its value increases with the temperature by about 40 cal. for  $1^\circ$ . The heat of solution of the *solid* hydrate,  $\text{HBr}, 2\text{H}_2\text{O}$ , at  $-15.5^\circ$ , when dissolved in about 150 mols. of water at  $10^\circ$ , = 1778 cal. The difference between this and the heat of dilution of the liquid hydrate at the same temperature gives heat of fusion of  $\text{HBr}, 2\text{H}_2\text{O} = 3045$  cal. Finally, heat of formation of solid  $\text{HBr}, 2\text{H}_2\text{O}$  at  $-15^\circ = 1692$  cal.

By means of these tables, the *heat of transformation* of the solid hydrate, that is, the heat necessary to convert 1 mol. of hydrate partly into solution, partly into gas, or into solution of greater concentration, may be calculated. These numbers are extensively used in the following papers. CH. B.

**Conditions of Equilibrium of Two Substances in the Three States, Solid, Liquid, and Gaseous.** By H. W. B. ROOZEBOOM (*Rec. Trav. Chim.*, 5, 335—350).—The following investigation is due to van der Waals. Gibbs's thermodynamic equation  $dp/dt = dy/dv$  ( $y$  = entropy) or  $Tdp/dt = Q/dv$ , for a system of  $n + 1$  coexistent phases of  $n$  substances, may be applied to the case of the solid hydrate of a gas, in presence of a solution and of the free gas.  $Q$  may be expressed as the heat of transformation (see last Abstract) of a molecule of the solid hydrate,  $\text{H}_2\text{O} + c$  mols. gas, into a solution  $\text{H}_2\text{O} + x$  mols. gas, and  $c - x$  mols. gas; and  $d/v$  as the increase of volume due to this transformation. The curve  $dp/dt$  ( $t$  = abscissæ,  $p$  = ordinates) is then the curve of equilibrium for the three coexistent phases. It is shown, that when  $c > x$ ,  $Q$  and  $dp/dt$  are positive; when  $c = x$ ,  $dp/dt$  is either very great or infinite; when  $c < x$ , either  $Q = +$  and  $dp/dt = -$ , or  $Q = -$  and  $dp/dt = +$ .

The curves ( $p, t$ ) for different concentrations ( $x$ ) of the coexistent solution may be similarly calculated. In this case,  $Q$  = heat necessary to expel 1 mol. of gas from a solution of supposed constant composition. The values  $dp/dt - (\partial p/\partial t)_x$  indicate the relative directions of the curve of equilibrium, and the curves ( $x$ ). These values necessarily have the same sign as  $dx/dt$ . An expression for  $dx/dt$  involving  $(\partial x/\partial p)_T$ , heat of fusion, and heat of dilution =  $Q$  diss. of the hydrate, and  $(c - x)$  is then arrived at, and it is shown that  $dx/dt$  is  $+\infty -$ , accordingly as  $c > = < x$ .

From the combined results, three branches of the curve of equilibrium may be distinguished, for which the following relations hold.

1.  $c > x$ .  $Q = +$ ,  $dp/dt = +$  :  $Q \text{ diss.} = +$ ,  $dx/dt = +$ .
2.  $c < x$ .  $Q = +$ ,  $dp/dt = -$  :  $Q \text{ diss.} = +$ ,  $dx/dt = -$ .
3.  $c < x$ .  $Q = -$ ,  $dp/dt = +$  :  $Q \text{ diss.} = +$ ,  $dx/dt = -$ ,

and for the points of transition between the branches,

$$1 \text{ and } 2. \ c = x. \ Q = Q \text{ fus.}, \ dp/dt = \infty : Q \text{ diss.} = Q \text{ fus.}, \ dx/dt = \infty$$

$$2 \text{ and } 3. \ c < x. \ Q = 0, \ dp/dt = 0 : Q \text{ diss.} = +, \ dx/dt = -.$$

The first point of transition represents the highest temperature, the second, the highest pressure at which the three phases can coexist.

The author then constructs a typical curve of equilibrium for the three coexistent phases of two substances. CH. B.

**The Hydrate  $\text{HBr}, 2\text{H}_2\text{O}$ .** By H. W. B. ROOZEBOOM (*Rec. Trav. Chim.*, **5**, 351—362).—The author discusses the experimental results already obtained (Abstracts, 1886, 117 and 414) in connection with van der Waals' formula. The curve of equilibrium, constructed from direct observation, consists of three branches, for the first of which  $dp/dt$  is positive, for the second negative, and for the third again positive. For the two lowest branches, the agreement with theory is very satisfactory, as the author shows by calculating  $\frac{dp}{p}/dt = \frac{d \log p}{dt}$  for different points. The third or upper branch cannot, however, be the continuation of the curve of equilibrium for  $\text{HBr}, 2\text{H}_2\text{O}$ ; for although  $dp/dt$  is here positive, as theory requires (see last Abstract),  $dx/dt$  is also positive, whereas it should be negative; and again,  $Q$  should here be negative, whereas the thermal data (last Abstract but one) show that it is positive. Although, then, along this part of the experimental curve a solid hydrate still exists, this cannot be  $\text{HBr}, 2\text{H}_2\text{O}$ . The experimental results are, however, explicable by assuming a hydrate to be formed at high pressures, richer in  $\text{HBr}$  than the coexistent liquid, whereby a new system is introduced. The author's experiments (next Abstract) have confirmed this prediction in a remarkable way.

When the pressure is such that the gas can be removed, the number of phases is reduced to two; and in the simplest case, when the hydrate has the same composition as the solution, the transformation of the hydrate is perfectly analogous to the fusion of a simple substance. Accordingly  $dt/dp = Tdv/Q$  expresses the rise of melting point with pressure. Putting  $dp = 1$  atmosphere, and  $Q =$  heat of fusion of one equivalent in kilograms of the hydrate, in gravitation measure,  $dv =$  difference in cubic metres of the volumes of the solid and melted hydrate (Tables, *Rec. Trav. Chim.*, **3**, 344), and  $T = 261.7^\circ =$  melting point of hydrate under  $3/4$  atm. pressure,  $dt = 0.0135^\circ$ . Experimenting at pressures up to 200 atmospheres, the author finds  $dt = 0.012, 0.013, 0.016$ .

The author then shows how the change of melting point may be calculated, when the concentration of the solid and coexistent liquid

are different,  $Q$  and  $dv$  being differently expressed. Interesting geometrical relations are traced between the curves of fusion, the curve of equilibrium, &c.

CH. B.

**New Hydrate of Hydrobromic Acid,  $\text{HBr}, \text{H}_2\text{O}$ .** By H. W. B. ROOZEBOOM (*Rec. Trav. Chim.*, 5, 363—379).—When the hydrate  $\text{HBr}, 2\text{H}_2\text{O}$  in contact with gaseous  $\text{HBr}$  is submitted to pressure, no absorption of gas takes place so long as the temperature is below  $-15.5^\circ$ , whatever be the pressure. Above  $-15.5^\circ$ , fusion of the hydrate and absorption of gas take place as already described. At  $-14^\circ$ , the hydrate may be completely fused under a pressure of two atmospheres. Absorption of gas by the liquid then continues up to a pressure of three atmospheres, when the new solid hydrate  $\text{HBr}, \text{H}_2\text{O}$  appears. Any attempt to increase the pressure beyond this point increases the amount of the solid.

For higher temperatures, the relations of pressure, temperature, and concentration of the coexistent liquid are those of the third branch of the curve of equilibrium attributed to  $\text{HBr}, 2\text{H}_2\text{O}$  (last Abstracts and 1886, 117 and 414). Tables are now given showing the conditions of equilibrium for this hydrate in contact with a solution down to  $-18^\circ$ , and for the hydrate both alone and in contact with solid  $\text{HBr}, 2\text{H}_2\text{O}$  and gas, down to  $-28^\circ$ . Since the tension of the new hydrate at  $-30^\circ$  is less than one atmosphere, the author has been able to collect it for analysis, at this temperature.

The application of van der Waals' theory to the curves of equilibrium of this compound is also discussed.

CH. B.

**Combinations of Ammonium Bromide with Ammonia.** By H. W. B. ROOZEBOOM (*Rec. Trav. Chim.*, 5, 387—392).—The author discusses the curves of equilibrium of the compounds  $\text{NH}_4\text{Br}, \text{NH}_3$  and  $\text{NH}_4\text{Br}, 3\text{NH}_3$ , in contact with ammonia (Abstr., 1886, 500), in connection with van der Waals' theory. These compounds are strictly analogous to the hydrates  $\text{HBr}, 2\text{H}_2\text{O}$  and  $\text{HBr}, \text{H}_2\text{O}$  (previous Abstracts). No new experimental results are given. In the first paper, the equilibrium curves are incorrectly spoken of as curves of tension of the solid and liquid compounds.

CH. B.

**Influence of Concentration on the Vapour-tension of Ethereal Solutions.** By F. M. RAOULT (*Compt. rend.*, 104, 976—978).—For concentrated solutions,  $D$ , the diminution of vapour-tension resulting from the solution of 1 mol. of the substance in 100 mols. of ether, ceases to be constant (this vol., p. 207), and diminishes as the quantity of dissolved matter increases, finally becoming *nil*.

If  $y = D \times 10000$  and  $x$  = the number of molecules of the substance dissolved in 100 mols. of ether, and curves are constructed having the values of  $y$  for ordinates and the values of  $x$  for abscissae, it is found that the curves representing the behaviour of different substances are of the same general character, and coincide more or less completely at their extremities, and in some cases even throughout their whole length. A mean curve can therefore be readily con-

structed, and the first part of this curve, which includes the values of  $x$  between 10 and 100, is represented by the equation—

$$y = 100 - 1.105x + 0.0053x^2,$$

whilst the second part, comprising the values of  $x$  from 100 to 700, is given by the expression—

$$y^3x^2 = 760000000.$$

The differences between the observed and calculated values vary with the nature of the substance, but never exceed one-thirtieth, and are frequently much less. When the value of  $x$  is very large, the differences disappear, and the two equations furnish simple laws sufficiently exact to be of value for the determination of molecular weights.

There is evidence that other liquids which act as solvents behave in a manner analogous to ether. C. H. B.

**Apparatus for Determining Vapour-densities.** By W. BOTT and D. S. MACNAIR (*Ber.*, **20**, 916—922).—The apparatus is similar in principle to that described by Dyson (this vol., p. 431), and in addition results obtained by its use are given which agree well with the numbers required by theory. A simple device is also described by which the movement of a piece of soft iron suspended by two thin platinum wires, when attracted by a magnet outside, is made to bring about the fall of the experimental bulb into the hot chamber of the apparatus. W. P. W.

**Variation of Solubility with Variations in the Heat of Solution.** By G. CHANCEL and F. PARMENTIER (*Compt. rend.*, **104**, 881—882).—A reply to Le Chatelier (this vol., p. 548).

**Effect of Nitric Acid on the Solubility of Nitrates.** By R. ENGEL (*Compt. rend.*, **104**, 911—913).—Each molecule of nitric acid up to about the thirtieth precipitates practically 1 mol. of sodium nitrate, a result identical with that obtained with hydrochloric acid and the chloride. At first, the sum of the molecules is somewhat higher and afterwards somewhat lower than it should be if the law were absolutely true.

Whilst the quantity of acid added is small, the action remains purely physical, and the amount of salt precipitated is proportional to the quantity of acid added. According to Van t'Hoff, equilibrium under these conditions results from equality of the osmotic forces of the liquids. The numbers calculated on this assumption are practically identical with the numbers actually observed, and since the same law holds good in the case of the chlorides, it is highly probable that a simple relation exists between the osmotic forces of saturated solutions of metallic chlorides, and consequently between their vapour-tensions.

When the proportion of acid becomes large, chemical action intervenes, and soon predominates over the physical action. This change consists of the formation of acid salts. The acid nitrates of potas-

sium and ammonium have been isolated by Ditte. Nitric acid at first precipitates ammonium nitrate from its solution molecule for molecule, then a minimum of solubility is passed, and afterwards the solubility increases with the amount of acid. In the case of potassium nitrate, the minimum of solubility is very quickly passed, and the influence of the chemical change is in fact perceptible at the outset.

C. H. B.

**Critical Remarks on the Avidity Formula.** By G. A. HAGEMANN (*Ber.*, 20, 556—562).—Thomsen's theory of the avidity of acids (*Thermochemische Untersuchungen*, 1) has been apparently confirmed by Ostwald's investigations (*Ann. Chem. Phys. Ergb.*, 8, 154, and 2, 429). The author points out, however, that Thomsen is inconsistent in regarding the solution in water of such substances as  $\text{Na}_2\text{O}$  and  $\text{SO}_3$  as purely physical phenomena, and yet introducing the attendant heat changes into the calculation of a chemical constant. Ostwald, who has studied the volume changes attending the mixture of an acid and a base, entirely neglects the influence of the water of solution; and the author shows that when this latter is taken into account the expression for the phenomenon is not simply  $(\text{Na}_2\text{OAq}, \text{SO}_3\text{Aq})$ , but is much more complex.

Every such reaction is in fact a double decomposition, and it is doubtful if Berthollet's problem was correctly stated, since the influence of the solvent water must always enter into it. In the author's opinion, however, although the calculations of "avidity" are entirely false, the agreement between Ostwald's and Thomsen's results is important as confirming his theory of the residual energy, basic or acid, of neutral salts (*Studien über das Molecular-volumen einiger Körper*). This theory has been strengthened by the experiments of Trey (this vol., p. 102), who has shown that haloïd salts in general accelerate the catalytic decomposition of methyl acetate by hydrochloric acid, their residual energy being acid, while sulphates in general retard it, their residual energy being basic. Solutions of acids, bases, and salts, are in reality chemical combinations in indefinite proportions.

Ch. B.

**Hagemann's Critical Remarks on the Avidity Formula.** By J. THOMSEN (*Ber.*, 20, 1155—1157).—According to the author Hagemann in his criticisms (preceding Abstract) confuses positive changes of volume and contractions, or negative changes.

**Electrolysis of Hydrochloric Acid; a Lecture Experiment.** By M. ROSENFELD (*Ber.*, 20, 1154—1155).—In this paper, an apparatus is described to illustrate the electrolytic decomposition of hydrochloric acid, and the formation of a detonating mixture of hydrogen and chlorine. It consists of two concentric cylinders, the outer one of which serves for a steam jacket, and in the inner one is placed a mixture in equal volumes of hydrochloric acid and water, which has previously been saturated, when hot, with sodium chloride. This solution is electrolysed by two carbon poles connected with a battery. By the use of this apparatus, an explosive mixture of the two gases is obtained very rapidly.

V. H. V.

**Lecture Experiment.** By C. SCHALL (*Ber.*, 20, 915—916).—The specific heat of zinc is nearly twice as great as that of tin, and this, taken in conjunction with the fact that both metals have nearly the same specific gravity, renders them suitable for demonstrating Dulong and Petit's law for lecture purposes. Rods of the two metals of similar section and equal weight are heated to 150—170°, and then placed on paraffin-wax; the paraffin melted by each can be weighed, and is proportional to the specific heat of the metal in question.

W. P. W.

**A Constant Gas Generator.** By C. SLEENBUCH (*J. pr. Chem.* [2], 35, 364—368).—The essential part of the apparatus consists of a kind of U-tube, the one limb of which is of a shape suitable to contain the marble, zinc, manganese dioxide, &c., the other prolonged and terminating in a bulb. At the base of the U-tube, another tube is blown, which is fitted by means of a cork into a Woulff's bottle, and reaches nearly to the bottom of this. In the latter tube, a small side tube is sealed to enable the air in the Woulff's flask to be driven out by the liquid. In this way the spent and heavy acid flows into the Woulff's bottle (and may from time to time be syphoned off by a tube leading from the other neck of the bottle), while the available acid in the pressure tube is always the lighter and fresher acid. By surrounding the limb of the apparatus containing the manganese dioxide, &c., with a coil of metal tubing through which steam is passed, the apparatus may be used as a chlorine generator.

L. T. T.

## Inorganic Chemistry.

**Amount of Oxygen in the Atmosphere.** By U. KREUSLER (*Ber.*, 20, 991—999).—The author has determined the amount of oxygen in the atmosphere for 45 consecutive days, and found only very slight variations, the extremes being 20·901 and 20·939 per cent. (compare *Landwirtschaft Jahrb.*, 14, 305). Tables are given showing the percentage of oxygen obtained each day, and also the meteorological conditions under which the experiments were made.

N. H. M.

**Boiling Point of Ozone: Solidification of Ethylene.** By K. OLSZEWSKI (*Monatsh. Chem.*, 8, 69—72).—Ozone was liquefied by passing a current of ozonised oxygen through a tube cooled by liquid oxygen boiling at atmospheric pressure. It liquefies with ease at  $-181\cdot4^{\circ}$  to a dark-blue liquid, whilst the oxygen passes away through the open end of the tube. The boiling point of the liquefied ozone, determined by the aid of liquid ethylene, with a carbon bisulphide thermometer, was found to be  $-109^{\circ}$ ; this corresponds with  $-106^{\circ}$  of the hydrogen thermometer. It is necessary to exercise great care in performing the above experiment on account of the readiness with which liquid ozone explodes with violence when it comes in contact with

ethylene gas. A small quantity of liquid ozone sealed up in a glass tube changed, at the ordinary temperature, to a bluish gas.

Former experiments to solidify ethylene were unsuccessful (Abstr., 1885, 1101), but the author has now succeeded in solidifying this gas to a white, crystalline, somewhat transparent mass, by allowing the liquid gas to boil under a pressure of 1 mm. at the boiling point of oxygen ( $-181.4^{\circ}$ ). The melting point of the solid ethylene is  $-169^{\circ}$ .

G. H. M.

**Reaction of Nitrous Acid with Sulphurous Acid.** By F. RASCHIG (*Ber.*, 20, 1158—1163).—In a former paper (this vol., p. 549) the author has shown that hydroxylamine reacts with sulphurous acid to form an amido-sulphonic acid. In this preliminary communication, speculations are put forward regarding the possible reactions between free nitrous and sulphurous acids, with especial reference to the chemical changes which occur in the leaden chambers of the sulphuric acid manufacture. These speculations are not here, however, supported by experimental evidence.

V. H. V.

**Oxidation of Ammonia in Presence of Platinum or Palladium.** By K. KRAUT (*Ber.*, 20, 1113—1114).—If in the well-known experiment illustrating the oxidation of ammonia by means of a glowing spiral or foil of platinum, a current of oxygen is passed into the solution of ammonia, a white cloud of ammonium nitrate is at first produced, and subsequently fumes of nitrogen peroxide appear, which increase until an inflammable or even explosive mixture of gas is formed.

V. H. V.

**Hydroxylated Solid Hydrogen Phosphide.** By B. FRANKE (*J. pr. Chem.* [2], 35, 341—349).—The so-called oxide of phosphorus is generally looked on as a mixture of phosphorous and phosphoric acids. Le Verrier (*Annalen*, 27, 167) obtained this substance in greater purity by exposing to the air phosphorus half covered with phosphorous chloride. The aqueous solution of the substance so obtained decomposed at  $80^{\circ}$  into free phosphoric acid and yellow flocks of a substance which he believed to be a hydrated oxide of phosphorus. The author has obtained the same substance by the action of water on  $P_4I_2$ . The iodide is prepared by mixing the required quantities of phosphorus and iodine in carbon bisulphide solution; this solution is then gradually added, with constant agitation, to water. No separation of phosphorus occurs, but the aqueous solution (of  $OH \cdot P_4H, HI$ ) becomes of a golden-yellow colour whilst the carbon bisulphide becomes colourless. The aqueous layer is separated and heated to  $80^{\circ}$ , when it becomes colourless, deposits yellow flocks, and contains now only hydriodic and a little hypophosphorous acids. These flocks have the composition  $P_4H \cdot OH$ . This substance decomposes, slowly under water, more rapidly in moist air, into hypophosphorous acid, phosphorus, and gaseous hydrogen phosphide. The analysis was made by heating strongly in a current of carbonic anhydride. The residue, consisting of amorphous phosphorus and phosphoric anhydride, was weighed, then oxidised with nitric acid, and re-weighed; the gaseous hydrogen phosphide evolved was measured.

This hydroxylated hydrogen phosphide dissolves in alcoholic potash with evolution of hydrogen from the compound to  $P_4H \cdot OK$ , but on adding water to the solution decomposition takes place according to the equation—

This substance forms part of the reddish-white coating which gradually covers phosphorus when kept under water.

The author finds that when hydrogen phosphide is acted on by dilute potash it is completely decomposed, probably according to the equations—

L. T. T.

**Hydrates of Potassium Hydroxide.** By C. GÖTTIG (*Ber.*, **20**, 1094—1096).—In this paper, two new definite compounds of potash with water are described: of these, one has the composition  $2KHO + 9H_2O$ , separating from concentrated alcoholic solutions of the alkali (sp. gr. 1.05—1.058) in pyramidal crystals, melting below  $40^\circ$ ; when kept over sulphuric acid, it loses 3 mols.  $H_2O$ . The second compound,  $2KHO + 5H_2O$ , is obtained by concentrating alcoholic solutions of potash until a boiling point of  $116^\circ$  is reached; on cooling, the liquid solidifies to a thick magma of interlaced needles. This compound melts below  $50^\circ$ , and when kept over sulphuric acid loses  $1\frac{1}{2}$  mols.  $H_2O$ , with formation of the hydrate  $KHO + H_2O$ .

Both the above compounds, when introduced in small quantities into water, exhibit at first a peculiar rotatory motion and then dissolve rapidly.

V. H. V.

**So-called Argentous Compounds.** By W. MUTHMANN (*Ber.*, **20**, 983—990).—A microscopic examination of the crystals obtained by dissolving silver molybdate, chromate, and tungstate in ammonia to saturation, heating at  $90^\circ$ , and passing hydrogen for some time (Rautenberg, *Annalen*, **114**, 119), shows that they consist of the unaltered salt crystallised with very finely divided metallic silver. Addition of ammonia dissolves the salt and leaves metallic silver undissolved; and if in the foregoing process ammonia is constantly added to replace that removed by the passage of hydrogen through the ammoniacal solution, only finely divided silver is obtained instead of the so-called argentous salts. Silver citrate when heated at  $108^\circ$  decomposes with the formation of metallic silver, and the aqueous solution is not coloured red; when the salt is heated at  $100^\circ$  in hydrogen, argentous citrate and citric acid are not formed as stated by Wöhler and v. Bibra (*Annalen*, **30**, 3), but decomposition-products of citric acid (comp. Trans., 1887, 416) and finely divided silver are obtained together with unaltered salt. The product, contrary to the behaviour of so-called argentous salts, dissolves in ammonia without decomposing into finely divided silver and the corresponding silver salt; the solution is clear, intensely red, and feebly fluorescent, and when largely diluted with water appears transparent and grass-green by transmitted, but opaque and violet by reflected light. The colour of the solution is not due to the presence of argentous salt, but of

finely divided silver; it is instantly destroyed by the addition of acids or salts such as potassium nitrate and sodium sulphate or acetate, and silver is precipitated; shaking with recently ignited animal charcoal removes it, and on dialysis of the solution a deposit of silver is found on the membrane of the dialyser. Addition of gum arabic to the red solution and subsequent precipitation with alcohol removes the colour, and the precipitate gives a red solution with water; moreover, when it is kept at  $-12^{\circ}$  for some hours and the ice formed subsequently melted, a liquid is obtained which is no longer red and transparent, but black and opaque, and deposits finely divided silver on standing. The author concludes, therefore, that argentous salts do not exist.

W. P. W.

### Double Phosphates and Arsenates of Strontium and Sodium.

By A. JOLY (*Compt. rend.*, **104**, 905—908).—The author has previously found (*Compt. rend.*, **103**, 1197) that the reaction between disodium phosphate (1 mol.) and strontium chloride (1 mol.) takes place in three phases. A gelatinous trimetallic phosphate is formed, which then becomes crystalline, and is afterwards transformed into a distrontium phosphate, the neutral solution becoming acid to litmus. If the vessel is free from any crystals formed in a previous operation, the second and third stages can be distinctly separated. The thermometer remains stationary for some minutes, during which the crystalline trimetallic phosphate is isolated. It consists of cubic crystals of strontium sodium phosphate,  $\text{NaSrPO}_4 + 9\text{H}_2\text{O}$ , almost insoluble in cold water and not decomposed by washing with water.

If the precipitate is allowed to remain in the liquid, and phenolphthalein is added and then aqueous soda, a white, gelatinous precipitate is formed which crystallises rapidly. When the indicator changes, one equivalent of alkali has been added, and the whole of the strontium is precipitated as strontium sodium phosphate, which is not affected by water.

When a solution of strontium chloride (1 mol.) is added to a solution of disodium arsenate (1 mol.), no precipitate is formed, and the solution remains alkaline, but after some time, if the sides of the vessel are rubbed, a crystalline precipitate gradually separates, and the liquid becomes acid to litmus but remains neutral to methyl-orange. If the liquid is not agitated, but crystallisation is allowed to take place very slowly, large, cubic crystals are formed and the reaction is complete in 24 hours. The crystals are strontium sodium arsenate,  $\text{NaSrAsO}_4 + 9\text{H}_2\text{O}$ ; the mother-liquor is acid and some of the arsenate remains in solution. If, however, one equivalent of soda is added to the solution, precipitation becomes complete and the precipitate does not alter in contact with water. It likewise undergoes no change even if left in the acid solution.

Similar double salts seemed to be formed with calcium, but in the case of barium the transformation of the precipitate is so rapid that the formation of a double salt cannot be observed.

C. H. B.

**Ammoniacal Compounds of Cadmium Chloride.** By G. ANDRÉ (*Compt. rend.*, **104**, 908—910).—When cadmium chloride is dissolved in well-cooled aqueous ammonia of 20 per cent., and a

current of ammonia gas is passed into the cooled solution, the compound  $\text{CdCl}_2, 5\text{NH}_3$  separates in small, anhydrous crystals. Another preparation gave crystals of the composition  $\text{CdCl}_2, 4\text{NH}_3 + \text{H}_2\text{O}$ . Both compounds readily decompose. Divers prepared the compound  $\text{ZnCl}_2, 5\text{NH}_3 + \text{H}_2\text{O}$  by a similar method, and some years ago the author obtained the anhydrous compound  $\text{ZnBr}_2, 5\text{NH}_3$ . When cupric chloride is treated in the same way, it yields the compound  $(\text{CuCl}_2, 5\text{NH}_3)_3 + 3\text{H}_2\text{O}$ .

As in Divers's process, the author dissolved the precipitated cadmium compound in ammonia at a gentle heat; when the liquid cooled it deposited large octahedra of the compound  $(\text{CdCl}_2, 3\text{NH}_3)_4 + \text{H}_2\text{O}$ , which alter rapidly immediately on removal from the mother-liquor. In presence of water, it is decomposed with formation of a bulky, white precipitate. Other experiments, in which heating was continued for a longer time and the conditions of cooling were somewhat different, gave the compound  $(\text{CdCl}_2, 4\text{NH}_3)_2 + \text{H}_2\text{O}$ . When the copper compound is dissolved in ammonia, it recrystallises without alteration on cooling.

The compound  $(\text{CdCl}_2, 2\text{NH}_3)_2 + \text{H}_2\text{O}$ , described by Crofts, is readily obtained by adding a saturated solution of cadmium chloride to well-cooled ammonia, and evaporating at a gentle heat. The author also confirms Hauer's statement that when cadmium oxide is boiled for a long time with ammonium chloride it yields the compound  $\text{CdCl}_2, 4\text{NH}_4\text{Cl}$ . Cupric oxide, under the same conditions, yields no double salt; zinc oxide likewise yields no double salt, but forms the compound  $(\text{ZnCl}_2, 2\text{NH}_3)_2 + \text{H}_2\text{O}$ . C. H. B.

### Ammoniacal Compounds of Cadmium Sulphate and Nitrate.

By G. ANDRÉ (*Compt. rend.*, 104, 987—990).—When a current of ammonia gas is passed into a solution of cadmium sulphate in ammonia, the compound  $\text{CdSO}_4, 4\text{NH}_3, 2\text{H}_2\text{O}$  separates as a crystalline precipitate composed of small needles. The same substance is obtained in somewhat larger crystals by dissolving the precipitate in the ammonia at a gentle heat, and allowing the solution to cool. The ratio of cadmium to ammonia is the same as that of copper to ammonia in the corresponding compound, but the cadmium is not completely precipitated. This compound is also obtained by pouring a layer of alcohol on a solution of cadmium sulphate in ammonia. When prepared in this way, it does not lose ammonia so readily as when prepared by the other methods.

Cadmium oxide dissolves somewhat readily in ammonium sulphate, but even after prolonged action the crystals which separate are variable mixtures of ammonium sulphate and cadmium ammonium sulphate. If, however, a solution of ammonium sulphate saturated in the cold is heated with cadmium oxide for several hours, the solution carefully concentrated, and the crystals of ammonium sulphate separated as they form, the compound  $\text{CdSO}_4, 3(\text{NH}_4)_2\text{SO}_4 + 10\text{H}_2\text{O}$  is obtained in crystals. Copper oxide and ammonium sulphate under the same conditions yield crystals of ammonium sulphate coloured blue by a small quantity of copper. Zinc oxide treated in the same

way yields crystals of the compound  $\text{ZnSO}_4(\text{NH}_4)_2\text{SO}_4 + 7\text{H}_2\text{O}$ , mixed with some ammonium sulphate. The salt obtained by mixing the two sulphates has the same composition.

If cadmium nitrate crystals are added to 20 per cent. ammonia, they at first dissolve rapidly, but the addition of a further quantity produces a bulky, crystalline precipitate which redissolves on gentle heating. When the solution cools, it deposits crystals of the composition  $\text{Cd}(\text{NO}_3)_2 \cdot 6\text{NH}_3 + 2\text{H}_2\text{O}$ ; these, when heated, melt with evolution of a little water, and then blacken with a slight explosion. The same substance is obtained in bulky, anhydrous crystals, when ammonia gas is passed into a solution of cadmium nitrate in ammonia. Both the anhydrous and the hydrated salts are decomposed by water with formation of an amorphous, white precipitate. Under similar conditions, copper nitrate yields an analogous compound. The author was unable to obtain the other ammoniacal copper nitrates described by Berzelius and by Kane.

The ammoniacal zinc chloride recently described by Thoms (this vol., p. 551) was prepared by the author three years ago (*Ann. Chim. Phys.* [6], 3, 84 and 98).  
C. H. B.

**Effect of Manganese and other Substances on the Properties of Steel.** By F. OSMOND (*Compt. rend.*, 104, 985—987).—Manganese retards the molecular change of the iron and recalcence during cooling from a high temperature, or in other words keeps the carbon in solution and the iron in the condition  $\beta$ , the effect being greater the greater the proportion of manganese. The same effect is produced by the rapid cooling of non-manganiferous steel, so that the presence of manganese exerts much the same influence as the process of tempering. Tungsten has the same property in a still more marked degree, but chromium seems to produce no similar effect. Silicon has no influence on the effect of the manganese, but sulphur seems to combine with part of the manganese, and thus diminishes its action. Phosphorus has no appreciable effect on the modification of the iron, nor on recalcence.

Every foreign substance in the steel produces its own peculiar effects, but it is to carbon alone that steel owes its characteristic differences from the other forms of iron.  
C. H. B.

**Alkaline Vanadates.** By A. DITTE (*Compt. rend.*, 104, 902—905, and 1061—1064).—When a solution of vanadic anhydride (1 mol.) in a solution of potassium oxide (1 mol.) is evaporated in a vacuum, it deposits slender needles of the salt  $2\text{K}_2\text{V}_2\text{O}_6 + 5\text{H}_2\text{O}$ , and the mother-liquor yields white, silky, nacreous needles of the hexahydrate  $\text{K}_2\text{V}_2\text{O}_6 + 6\text{H}_2\text{O}$ . If potassium oxide is in excess, the vanadate separates in brilliant, silky, elongated prisms, which only contain 4 mols.  $\text{H}_2\text{O}$ . A solution of vanadic anhydride in an equivalent quantity of potassium carbonate deposits the hydrate  $\text{K}_2\text{V}_2\text{O}_6 + 3\text{H}_2\text{O}$  in stellate groups of needles.

All these hydrates lose their water when heated, and melt to a pale-yellow liquid which solidifies to a white, nacreous mass of the anhydrous vanadate, which has a lamellar fracture. The anhydrous

vanadate is only slightly soluble in water, whilst the hydrates are readily soluble.

A solution of potassium carbonate saturated with an excess of vanadic anhydride at  $80^{\circ}$  forms a garnet-red liquid, which on cooling deposits the compound  $\text{K}_2\text{O}, 2\text{V}_2\text{O}_5 + 10\text{H}_2\text{O}$  in orange-red plates. At a higher temperature, the crystals contain  $8\text{H}_2\text{O}$ , and have a deeper colour. If the solution is acidified with acetic acid and concentrated at  $80^{\circ}$ , the salt containing  $10\text{H}_2\text{O}$  is deposited in brilliant, transparent, hexagonal plates, whilst if crystallisation takes place at a higher temperature, the crystals are orange, and contain  $3\text{H}_2\text{O}$ . If these crystals are boiled in the mother-liquor they alter as the liquid becomes more concentrated, and form small, deep-red, very brilliant crystals of the anhydrous divanadate  $\text{K}_2\text{O}, 2\text{V}_2\text{O}_5$ . When the mother-liquor from a previous crystallisation, containing a certain proportion of potassium acetate, is concentrated by boiling and allowed to cool, it deposits orange-red plates of the composition  $2\text{K}_2\text{O}, 3\text{V}_2\text{O}_5 + 6\text{H}_2\text{O}$ .

When an excess of vanadic anhydride is dissolved in potassium carbonate and mixed with a large quantity of acetic acid, a garnet-red solution is obtained, and if this is heated at  $70^{\circ}$  it deposits orange crystals of the compound  $\text{K}_2\text{O}, 3\text{V}_2\text{O}_5 + 5\text{H}_2\text{O}$ . If the mother-liquor is filtered off and allowed to cool, transparent, garnet-red crystals of the hydrate  $\text{K}_2\text{O}, 3\text{V}_2\text{O}_5 + 5\text{H}_2\text{O}$  separate. When heated, all these hydrated acid salts lose their water and melt to a brown liquid, which solidifies to an almost black, crystalline mass, only slightly soluble in water.

If a solution of vanadic anhydride (1 mol.) in water containing rather more than 2 mols. of potassium oxide is filtered and evaporated in a vacuum, it yields colourless, transparent crystals of the salt  $2\text{K}_2\text{O}, \text{V}_2\text{O}_5 + 4\text{H}_2\text{O}$ , which lose water when heated, then melt, and solidify on cooling to a crystalline mass of the anhydrous salt,  $2\text{K}_2\text{O}, \text{V}_2\text{O}_5$ .

A solution of 3 mols. potassium oxide and 1 mol. of vanadic anhydride, yields very deliquescent, colourless, transparent, channelled crystals of the vanadate  $3\text{K}_2\text{O}, \text{V}_2\text{O}_5$  with 9 or 12 mols.  $\text{H}_2\text{O}$ , according to the temperature at which crystallisation takes place. It readily forms supersaturated solutions.

A solution of vanadic anhydride containing a large excess of potash deposits no crystals, but if it is agitated with alcohol an oily layer separates, and when this is washed with alcohol it solidifies to a very hygroscopic crystalline mass with a radiating structure. When this is dried on porous plates in a vacuum, it forms brilliant white needles of the composition  $4\text{K}_2\text{O}, \text{V}_2\text{O}_5 + 20\text{H}_2\text{O}$ ; these lose their water when heated, and yield the white anhydrous salt which fuses with difficulty even at a red heat.

The compound  $\text{Na}_2\text{O}, \text{V}_2\text{O}_5$ , formed when vanadic anhydride (1 mol.) is dissolved in a solution of sodium oxide (1 mol.), crystallises with difficulty, but if a large quantity of the solution is slowly concentrated it deposits translucent nodules consisting of slender, radiating needles of the composition  $\text{Na}_2\text{O}, \text{V}_2\text{O}_5 + 4\text{H}_2\text{O}$ . If the syrupy solution which will not crystallise is treated with a mixture of alcohol and water, it deposits an oily layer which quickly solidifies and can be

recrystallised from dilute alcohol, when it forms brilliant white, silky needles of the hydrate  $\text{Na}_2\text{O}, \text{V}_2\text{O}_5, 5\text{H}_2\text{O}$ .

When vanadic anhydride is dissolved in a solution of an equivalent quantity of sodium carbonate, the liquid crystallises with difficulty, but when treated with alcohol it yields white needles of the composition  $\text{Na}_2\text{O}, \text{V}_2\text{O}_5 + 6\text{H}_2\text{O}$  or  $\text{Na}_2\text{O}, \text{V}_2\text{O}_5 + 8\text{H}_2\text{O}$ , according to the temperature.

If somewhat more than an equivalent quantity of vanadic anhydride is dissolved in a boiling solution of sodium carbonate, the liquid on cooling deposits a crystalline crust consisting of distinct red transparent crystals of the composition  $\text{Na}_2\text{O}, 2\text{V}_2\text{O}_5 + 5\text{H}_2\text{O}$ . If a solution of the normal vanadate is acidified with acetic acid and concentrated, it yields garnet-red, channelled needles of the composition  $\text{Na}_2\text{O}, 2\text{V}_2\text{O}_5 + 10\text{H}_2\text{O}$ .

The compound  $2\text{Na}_2\text{O}, 3\text{V}_2\text{O}_5 + 18\text{H}_2\text{O}$  is obtained in friable hexagonal tables, together with the preceding compound, by concentrating an acidified solution of the normal vanadate. It is also obtained in red, prismatic crystals with only  $16\text{H}_2\text{O}$ , by dissolving an excess of vanadic anhydride in sodium hydroxide solution, acidifying the cold liquid with acetic acid, and concentrating at about  $50^\circ$ .

A hot solution of soda saturated with excess of vanadic anhydride and concentrated by boiling, deposits brilliant, orange-red plates of the composition  $\text{Na}_2\text{O}, 3\text{V}_2\text{O}_5 + 3\text{H}_2\text{O}$ .

All the hydrated acid salts, when heated, lose water and become deep brown, melt at a higher temperature, and solidify on cooling to a crystalline mass of the very slightly soluble anhydrous salt.

When vanadic anhydride (1 mol.) is dissolved in a solution containing 2 mols. of sodium oxide, filtered, a small quantity of alkali added, and the solution concentrated in a vacuum, it yields colourless, transparent plates of the composition  $2\text{Na}_2\text{O}, \text{V}_2\text{O}_5 + 18\text{H}_2\text{O}$ . They melt to a colourless liquid which loses water, forming a white substance; this afterwards becomes pale yellow, and is finally converted into the white, very deliquescent, anhydrous salt. If the solution is evaporated to dryness, and the residue extracted with water and alcohol at about  $60^\circ$ , the liquid deposits brilliant needles of the composition  $2\text{Na}_2\text{O}, \text{V}_2\text{O}_5 + 8\text{H}_2\text{O}$  on cooling.

If vanadic anhydride is dissolved in a solution of three equivalents of sodium oxide and the liquid slowly concentrated, it deposits bulky colourless, transparent prisms of the disodium salt, and afterwards brilliant white, silky needles of the composition  $3\text{Na}_2\text{O}, \text{V}_2\text{O}_5 + 26\text{H}_2\text{O}$ . This salt is also often deposited in nodules which contain only  $24\text{H}_2\text{O}$ .

When vanadic anhydride is dissolved in a large excess of soda, the solution yields brilliant white needles of the salt  $4\text{Na}_2\text{O}, \text{V}_2\text{O}_5 + 30\text{H}_2\text{O}$ . If crystallisation takes place in a warm liquid, the crystals contain only  $26\text{H}_2\text{O}$ . When the crystals are heated they effloresce, melt in their water of crystallisation, and are finally converted into the very soluble anhydrous salt, which does not melt even at a bright red heat. In this respect, it resembles the corresponding potassium salt.

C. H. B.

**Crystallised Niobic Anhydride.** By A. KNOP (*Zeit. Kryst. Min.*, 12, 610—615).—The author has obtained niobic anhydride in crystals. Borax glass was fused in a platinum crucible, and saturated with niobic anhydride, of which material 30 grams were at his disposal. On cooling slowly, the excess of anhydride crystallised out. It was found that 9.42 per cent. of niobic anhydride was contained in the clear borax glass, and separated out in an amorphous condition when the mass was dissolved in hot water. The larger crystals are in the form of cubes, and appear to belong to the regular system. Their optical properties, however, do not point to the regular system, but show that the crystals must be regarded as rhombic combinations of the three pinacoids,  $OP$ ,  $\infty\bar{P}\infty$ , and  $\infty\bar{P}\infty$ . All the plane angles are exactly  $90^\circ$ . It is therefore doubtful whether niobic anhydride crystallises in the regular system with optical anomalies, or in the rhombic with a molecular system approaching that of the regular. Ebelmen (this Journal, 1848, 181), who prepared crystallised niobic anhydride from boric acid, was unable to measure the crystals he obtained on account of the small quantity of material at his disposal. He merely stated that they were prismatic. B. H. B.

**Ammoniacal Platinum Compounds.** By A. COSSA (*Gazzetta*, 17, 1—11).—After reference to the experiments of Reisel, Cleve, and others on ammoniacal platinum compounds, the results of experiments are given on the admixture of solutions of platinic chloride or sodium platinochloride with platosodiamine chloride. At ordinary temperatures, if the solutions are neutral, a yellow, amorphous compound, of the composition and properties of a platosodiamine platinochloride, is produced. This changes slowly at ordinary temperatures, more rapidly on boiling, into platinodiamine platinochloride (Cleve's salt), when the original substances are mixed in equimolecular proportions, or into the green salt of Magnus and platinodiamine chloride if in the original mixture the proportion of platosodiamine chloride predominates. The results of experiments with various mixtures are given in full. It is evident that the platosodiamine platinochloride has the same percentage composition as platinodiamine platinochloride; thus the yellow, amorphous substance may only be a so-called physical isomeride of the red, crystalline salt obtained directly at temperatures above  $60^\circ$ . In order to determine this point, the reaction between the yellow substance and potassium platinochloride is examined; for if the former is platosodiamine platinochloride it should give by double decomposition platosodiamine platinochloride (Magnus' salt) and potassium platinochloride, thus:  $Pt(NH_3)_4Cl_2, PtCl_4 + 2KCl, PtCl_2 = Pt(NH_3)_4Cl_2, PtCl_2 + 2KCl, PtCl_4$ . This was confirmed by experiment. V. H. V.

## Mineralogical Chemistry.

**Origin of Hydrogen Chloride, Sulphurous Anhydride, and Iodine in the Gases of Volcanoes.** By L. RICCIARDI (*Gazzetta*, 16, 38—42).—Gay-Lussac, Bunsen, and others, who have studied the gaseous emanations from craters and fumaroles, have concluded that at the commencement of the eruption, hydrogen chloride is evolved, which is succeeded immediately by sulphurous anhydride and other compounds. On the other hand, in the case of the eruption of Etna in the year 1883, the author found this order to be reversed, in that sulphurous anhydride was first evolved and subsequently hydrogen chloride; this point, however, is not insisted on.

As regards the origin of the hydrogen chloride, it probably arises from the decomposition of metallic chlorides, especially magnesium chloride, in the presence of steam at a high temperature. In confirmation of this view, it is shown that finely-powdered granite and lava, mixed with pure sodium chloride, evolves hydrogen chloride, the quantity of which is increased by blowing in a current of steam. On repeating the experiment, with the addition of a small quantity of potassium iodide, iodine is evolved, an element which has been found in the gaseous emanations from the crater of the island Vulcano in the Æolian group. Lastly, the formation of sulphurous anhydride is in all probability due to the interaction of calcium and magnesium sulphates, either singly or conjointly with the silica, whereby silicates are produced with separation of sulphuric oxide, which is decomposed into sulphurous oxide and oxygen. Thus (1)  $\text{SiO}_2 + \text{MgSO}_4 = \text{MgSiO}_3$  (enstatite) +  $\text{SO}_3$ ; (2)  $\text{SiO}_2 + \text{CaSO}_4 = \text{CaSiO}_3$  (wollastonite) +  $\text{SO}_3$ ; and (3)  $\text{SiO}_2 + \text{CaSO}_4 + \text{MgSO}_4 = \text{MgCaSiO}_4$  (monticellite) +  $2\text{SO}_3$ . It was found that an artificial mixture of granite with magnesium or calcium sulphates evolved sulphurous anhydride.

On the other hand, Bunsen attributes the formation of sulphurous anhydride to the oxidation of hydrogen sulphide, as also to the decomposition of sulphates of the alkalis and alkaline earths at high temperatures.

V. H. V.

**Stromeyerite from Mexico.** By G. A. KÖNIG (*Zeit. Kryst. Min.*, 12, 621).—An analysis of stromeyerite from Zacatecas in Mexico gave the following results:—

| S.    | Ag.   | Cu.   | Insol. | Total. |
|-------|-------|-------|--------|--------|
| 15·81 | 50·18 | 33·69 | 0·26   | 99·94  |

This corresponds with the formula  $(\text{AgCu})_2\text{S}$ . The mineral occurs in imperfect prismatic crystals in quartz. Its sp. gr. is 6·23.

B. H. B.

**Braunite from Jakobsberg in Wermland.** By L. J. IJELSTRÖM (*Zeit. Kryst. Min.*, 12, 659—660).—This mineral, discovered by the author some years ago, is found massive or in small crystals in

Archæan limestone. Analyses of the crystals gave the following mean results:—

| SiO <sub>2</sub> . | MnO.    | FeO. | MgO,CaO. | PbO. | O.   | Total. |
|--------------------|---------|------|----------|------|------|--------|
| 8·67               | (80·23) | 1·33 | 0·95     | 0·65 | 8·17 | 100·00 |

The silica gelatinises with hydrochloric acid.

B. H. B.

**Buratite from Laurium.** By E. JANNETTAZ (*Zeit. Kryst. Min.*, **12**, 645).—The mineral forms small bundles of pale-green needles. The needles exhibit oblique extinction. Analysis gave the following results:—

| CO <sub>2</sub> . | CuO.  | ZnO.  | H <sub>2</sub> O. | Residue. | Total. |
|-------------------|-------|-------|-------------------|----------|--------|
| 15·45             | 18·07 | 50·45 | 14·75             | 0·50     | 99·22  |

B. H. B.

**Analyses of Bohemian Minerals.** By B. ERBEN (*Zeit. Kryst. Min.*, **12**, 664—666).—The author gives analyses of the following minerals:—1. Carbonates from the felspar-basalt of Kolozruky between Laun and Brück; 2. Fibrous barytes from Mies; 3. Comptonite from Katzenburg, near Leitzmeritz (formula  $RAl_2Si_2O_8 + 2\frac{1}{3}H_2O$ ); 4. Aluminium and ferric sulphates from Weberschan: (a.) white microcrystalline aggregate soluble in water, sp. gr. 1·72; formula  $(Al,Fe)_2(SO_4)_3 + 15H_2O$ , that is, the composition of keramohalite less  $3H_2O$ ; (b.) compact yellow mass, becoming deep red on exposure to moist air, easily soluble in water; sp. gr. 2·038; formula  $(Fe,Al)_2(SO_4)_3 + 12H_2O$ , that is, the composition of Schrauf's ihleite.

B. H. B.

**Cyprusite.** By J. DEBY (*J. Roy. Mic. Soc.*, **4**, 186—191; *Zeit. Kryst. Min.*, **12**, 616—618).—This mineral was first described by Reinsch (Abstr., 1882, 578). It forms thick veins in a melaphyr or dolerite containing zeolites. The principal locality where it is found is near Kynussa on the right bank of the Balahussa stream. The mineral is usually friable, but sometimes quite hard. Its sp. gr. is 1·8. It is insoluble in water, but soluble in acids, leaving an insoluble residue of 16·90 per cent. An analysis of the soluble portion gave the following results:—

| Fe <sub>2</sub> O <sub>3</sub> . | Al <sub>2</sub> O <sub>3</sub> . | SO <sub>3</sub> . | H <sub>2</sub> O. | Total. |
|----------------------------------|----------------------------------|-------------------|-------------------|--------|
| 49·68                            | 3·89                             | 35·34             | 11·06             | 99·97; |

from which the author deduces the formula  $Al_2S_3O_{12}, 8Fe_2SO_8 + 18H_2O$ . The difference from the composition found by Reinsch is considerable. Under the microscope, the mineral is found to consist of hexagonal tablets, and an optical investigation showed that it belongs to the hexagonal system.

The author observed in several places the efflorescences mentioned by Reinsch. Their composition is as follows:—

| Insol. in H <sub>2</sub> O. | Cu.  | Al <sub>2</sub> O <sub>3</sub> . | SO <sub>3</sub> . | H <sub>2</sub> O. | Total. |
|-----------------------------|------|----------------------------------|-------------------|-------------------|--------|
| 4·88                        | 0·45 | 17·70                            | 35·19             | 39·00             | 97·22  |

Iron was found to be absent. The mineral was of a greenish-white

colour, and looked exactly like weathered ferrous sulphate. Its formula is  $2\text{Al}_2\text{O}_3, 5\text{SO}_3 + 25\text{H}_2\text{O}$ . B. H. B.

**Hæmatostibiite, a New Mineral from Örebro.** By L. J. IGELSTRÖM (*Zeit. Kryst. Min.*, 12, 650—651).—At the Sjögrufvan iron mine, Örebro, Sweden, in fissures in compact tephroite in granulite interstratified in Archæan limestone, there occur barytes, a mineral resembling chondroarsenite, and the new mineral. The latter appears black, but is blood-red and transparent in thin sheets. It is rhombic, and exhibits distinct dichroism. Analysis gave the following results:—

| $\text{Sb}_2\text{O}_5$ . | MnO. | FeO. | MgO + CaO. | Total. |
|---------------------------|------|------|------------|--------|
| 37·2                      | 51·7 | 9·5  | 1·6        | 100·0  |

In composition, the new mineral is very similar to manganostibiite (Abstr., 1886, 25). B. H. B.

**Composition of Columbite from Graveggia in Val Vigezzo.** By A. COSSA (*Gazzetta*, 17, 31—37).—Steuever has recently found columbite among the pegmatite minerals of Graveggia. It appears that columbite occurs in three typical forms, namely (i) black crystals of metallic lustre, sp. gr. = 5·67, appearing brownish-red, when pulverised; (ii) more lustrous crystals than the preceding, sp. gr. 5·78; and (iii) crystals covered with a paste of a light green colour. An analysis of a specimen of the first type gave the following results:—

| $\text{Nb}_2\text{O}_5$ and $\text{Ta}_2\text{O}_5$ . | FeO. | MnO. | $\text{SnO}_2$ . | CaO. | MgO.  | Total. |
|---|------|------|------------------|------|-------|--------|
| 78·52   | 9·84 | 8·98 | 0·23             | 1·17 | trace | 98·74  |

In the course of these analyses, it was observed that Marignac's method for the separation of niobic and tantalic acids, which is based on the difference in solubility of potassium fluotantalate and oxy-fluoniobate, although convenient for obtaining the acids in a state of purity, is not applicable to their quantitative separation. According to Marignac, potassium fluotantalate crystallises in the trimetric system, but the author shows by examination of the crystals by polarised light that they belong to the clinohedric form, a view confirmed by an examination of a large sample of the salt from the columbite of Connecticut. V. H. V.

**Pectolite from Auchensterry Quarry, Kilsyth.** By J. YOUNG (*Zeit. Kryst. Min.*, 12, 620).—The specimens described are the finest examples ever seen from Western Scotland, where pectolite is of somewhat rare occurrence. The mineral occurs in the form of fine greyish-white needles, with harmotome and a black mineral, probably tourmaline, in thin veins in the dolerite at Kilsyth, north-west of Glasgow. Analysis gave—

| $\text{SiO}_2$ . | $\text{Al}_2\text{O}_3$ . | $\text{Fe}_2\text{O}_3$ . | MgO. | CaO.  | $\text{Na}_2\text{O}$ . | $\text{H}_2\text{O}$ . |
|------------------|---------------------------|---------------------------|------|-------|-------------------------|------------------------|
| 52·74            | 0·67                      | 1·20                      | 1·52 | 31·86 | 9·60                    | 2·00                   |

**Manganese-zinc Serpentine from Franklin, New Jersey.**

By G. A. KÖNIG (*Zeit. Kryst. Min.*, **12**, 621—622).—The mineral examined was compact, dark brown in colour, translucent at the edges, and had a semi-conchoidal fracture; sp. gr. 2·635. The mean of two analyses gave the following results (I):—

|         | SiO <sub>2</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | MnO. | ZnO. | MgO.  | H <sub>2</sub> O. | Total. |
|---------|--------------------|----------------------------------|------|------|-------|-------------------|--------|
| I ....  | 42·20              | 2·80                             | 7·44 | 3·90 | 29·24 | 14·04             | 99·62  |
| II .... | 41·70              | —                                | 6·91 | 3·10 | 29·24 | 14·04             | 94·99  |

Analysis II gives the results obtained after subtracting 4·15 per cent. of franklinite. The author regards the mineral as a serpentine in which the magnesium is partially displaced by manganese and zinc.

B. H. B.

**Biotite.** By A. KNOP (*Zeit. Kryst. Min.*, **12**, 588—607).—The author gives the following analyses of biotite:—

|                                    | I.     | II.    | III.  | IV.    | V.     | VI.    |

I. Biotite from Böstenbach near Petersthal; II. Biotite from Freiersbach; III. Biotite from Easton, Pennsylvania; IV. Biotite from Oberbergen in the Kaiserstuhl; V. Biotite from the Klausen-alpe; VI. Barium-biotite from the koppite-limestone of Schelingen in the Kaiserstuhl. These analyses exhibit great constancy in the percentages of alumina and alkalis; whilst the percentages of ferrous oxide and magnesia vary in such a way that their sums remain approximately equal. The mean of the six analyses gives the following oxygen ratio:—

|    |                 |   |                               |   |     |
|----|-----------------|---|-------------------------------|---|-----|
|    | RO <sub>2</sub> | : | R <sub>2</sub> O <sub>3</sub> | : | RO  |
| as | 2·1             | : | 1                             | : | 1·4 |

This represents the formula R<sup>IV</sup><sub>4</sub>R<sup>VI</sup><sub>2</sub>Si<sub>3</sub>O<sub>13</sub>. This formula might also be written R<sub>3</sub>Si<sub>3</sub>O<sub>9</sub> + RAl<sub>2</sub>O<sub>4</sub>; in which case biotite may be regarded as a molecular combination of amphiboloid material with spinell.

B. H. B.

**Pseudo-biotite.** By A. KNOP (*Zeit. Kryst. Min.*, **12**, 607—609).—A mineral resembling biotite, occurring in the granular limestone of

Schelingen in the Kaiserstuhl Mountains, was found on analysis to have the following composition:—

| SiO <sub>2</sub> . | TiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | Mn <sub>2</sub> O <sub>3</sub> . | MgO.  | K <sub>2</sub> O. | H <sub>2</sub> O. | Total. |
|--------------------|--------------------|----------------------------------|----------------------------------|----------------------------------|-------|-------------------|-------------------|--------|
| 35·91              | 1·15               | 15·18                            | 10·85                            | 0·89                             | 22·80 | 2·90              | 10·77             | 100·45 |

Formula :  $R_4Al_2Si_4O_{15} + 2H_2O$ . This altered biotite is termed by the author *pseudo-biotite*. B. H. B.

**Analysis of a Pink Clay.** By A. DAMOUR (*Zeit. Kryst. Min.*, 12, 655).—The argillaceous mineral described by Baret is soluble in dilute hydrochloric acid to the extent of 2·95 per cent. The residue is still of a pink colour. Analysis gave the following results:—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | FeO. | MnO. | MgO. | K <sub>2</sub> O. | H <sub>2</sub> O. | Total. |
|--------------------|----------------------------------|------|------|------|-------------------|-------------------|--------|
| 53·11              | 21·22                            | 1·04 | 0·40 | 2·32 | 0·79              | 21·70             | 100·58 |

Formula :  $Al_4Si_9O_{21}, 12H_2O$ . Sp. gr. 2·70. B. H. B.

**Meteoric Iron at Fort Duncan, Texas.** By S. MEUNIER (*Compt. rend.*, 104, 872—873).—This meteorite, which was discovered in 1882, is surrounded by a dull black crust, formed during its passage through the air. The interior has the colour of tin, with a characteristic silky lustre, and a crystalline fracture which shows cleavage. It contains elongated inclusions of the colour of silver, and darker masses with the colour of tombac. The meteorite has the composition : Iron, 92·02; nickel (with traces of cobalt), 6·10; insoluble matter, 1·80 = 99·92; sp. gr. = 7·699. The insoluble matter consists of prismatic crystals of the variety of schreibersite known as rhabdite. The tombac-coloured inclusions are pyrrhotine,  $F_7S_8$ , which is associated with daubréelite. In its composition, sp. gr., and the nature of the inclusions, this meteorite is almost identical with that which fell at Branau, July 14th, 1847. C. H. B.

**Examination of Schützenhof-Quelle, Wiesbaden.** By H. FRESSENIUS (*J. pr. Chem.* [2], 35, 237—254).—Yield about 160 litres a minute; temperature, 21st March, 1879, 49·2°; sp. gr. at 10°, 1·004999. The analysis gave in 1000 parts by weight:—NaCl, 5·154046; KCl, 0·157510; LiCl, 0·025228;  $NH_4Cl$ , 0·012340;  $CaCl_2$ , 0·585858; NaBr, 0·002534; NaI, 0·000028;  $CaSO_4$ , 0·134366;  $SrSO_4$ , 0·020362;  $BaSO_4$ , 0·000010;  $CaCO_3$ , 0·139495;  $MgCO_3$ , 0·124487;  $FeCO_3$ , 0·002179;  $MnCO_3$ , 0·000671;  $Ca_3As_2O_8$ , 0·000060;  $Al_2P_2O_8$ , 0·000334; aluminium silicate, 0·000401;  $SiO_2$ , 0·050907; total, 6·410816; combined carbonic anhydride, 0·127669; carbonic anhydride free, 0·308144; nitrogen, trace; also traces of rubidium, caesium, nitric and boric acids, copper, hydrogen sulphide, and organic substances. Of the gases given off at the spring, 38·47 per cent. are absorbed by potash. The water contains no bacteria. The water was led from the spring by enamelled iron pipes, but the water acted on them and the packing of the joints, with evolution of hydrocarbons and hydrogen sulphide, but since these pipes have been replaced by earthenware ones, no change is perceptible in the water as delivered at the baths, &c. H. B.

**Analysis of Mineral Waters from Servia.** By S. M. LOSA-NITSCH (*Ber.*, 20, 1114—1115).—The table gives the analyses expressed in parts per 1000 of the springs of (I) Wrnjačka banja, (II) Bukowik, (III) Palanka, (IV) Alexinačka banja, (V) Ribarska banja, (VI) Wranjska banja, and (VII) Brestowačka banja :—

**Analysis of the Water of a Saline Lake near the Stolupin Mineral Springs.** By P. BULITSCH (*J. pr. Chem.* [2], 35, 360—363).—The author has analysed the water from a triple lake about 40 miles from Balakowo, Samara. 1000 parts contained in grams 25·855 Cl, 0·009 SiO<sub>2</sub>, 0·002 Fe<sub>2</sub>O<sub>3</sub>, 2·343 SO<sub>3</sub>, 1·755 CaO, 2·099 Mg, 4·722 KCl, 28·497 NaCl, 0·019 Br, and total solid residue 45·483. The water was colourless, had an odour of hydrogen sulphide, a bitter saline taste, and a sp. gr. 1·0348 at 18°.

The water was concentrated till it attained a sp. gr. of 1·21 at 18°, during which process calcium sulphate crystallised out. The mother-liquor had a yellowish colour, and slightly acid reaction. 1000 parts contained in grams 160·575 Cl, 0·025 SiO<sub>2</sub>, 1·399 SO<sub>3</sub>, 11·908 CaO, 11·200 Mg, 17·617 KCl, 174·244 NaCl, 0·793 Br, and a total residue of 262·606 grams.

## Organic Chemistry.

**The Relation between Petroleum and the Hydrocarbons of Coal-tar and Shale-tar.** By G. KRAEMER and W. BÜTTCHER (*Ber.*, 20, 595—609).—The results arrived at by the authors in an examina-

tion of German petroleum combined with those obtained by Markownikoff in the case of Baku oil (Abstr., 1884, 1276) are held to prove that the hydrocarbons of petroleum and those present in coal- and shale-tar differ, not in character, but in the relative proportions of the two classes of hydrocarbons: those unattacked and those attacked by concentrated sulphuric or nitric acids. To the first group belong the paraffins and naphthenes, and to the second benzene- and, according to the authors' views, naphthene-derivatives. W. P. W.

**New Class of Ferrocyanides and Ferricyanides.** By J. A. MULLER (*Compt. rend.*, 104, 994—996).—The formation of a violet precipitate on adding ferric chloride to certain solutions of ferri- or ferro-cyanides has been observed by Ortlieb and by Schützenberger, but the substance was not examined.

The author has obtained a considerable quantity of this violet substance, and has submitted it to investigation. The substance was treated with a warm solution of potassium carbonate insufficient for complete decomposition, filtered, the filtrate made alkaline with potash, boiled, again filtered, concentrated to saturation, and mixed with alcohol to precipitate potassium ferrocyanide. The last filtrate when carefully concentrated yields thin scales and rectangular tablets of the composition  $(K_3FeC_6N_5O)_2 + 7H_2O$ , which become anhydrous at  $110^\circ$ . 100 parts of water at  $18^\circ$  dissolve 148 parts of the salt. The solution is neutral to litmus and phenolphthalein, and gives the following reactions with solutions of metallic salts: cadmium chloride, a white precipitate soluble in hydrochloric acid; cobalt nitrate, a pale-pink precipitate, becoming blue when heated, but regaining its original colour on cooling, insoluble in hydrochloric acid; copper sulphate, an apple-green precipitate, insoluble in hydrochloric acid; ferrous ammonium sulphate, a white precipitate which immediately becomes blue on addition of nitric acid; manganese chloride, a bulky white precipitate, soluble in hydrochloric acid; ferric chloride, a violet coloration, and after one or two days a precipitate of the same colour, partially soluble in cold dilute hydrochloric acid; ammonium molybdate in nitric acid, a canary-yellow precipitate; auric chloride, a red-brown coloration; uranium nitrate, an orange-yellow precipitate, insoluble in acetic acid, but soluble in ammonium acetate solution.

When heated at  $300\text{--}400^\circ$ , out of contact with air, until evolution of gas ceases, the anhydrous salt loses 9.05 per cent., and yields 8.33 per cent. of carbonic oxide (calc. 8.47 per cent.), together with potassium cyanide and iron cyanides. The composition and properties of this compound involve the assumption of the existence of a trivalent radicle, *carbonyl-ferrocyanogen*,  $\begin{matrix} \text{CO} \\ \diagup \\ \text{Fe} \end{matrix} > \text{Cy}_3\equiv$ .

If a solution of the potassium salt is mixed with chlorine-water until it no longer gives a violet coloration with ferric chloride, a yellow solution is obtained which contains the carbonyl ferricyanide. It gives a violet-blue precipitate with ferrous sulphate, a white precipitate with mercurous nitrate, and with silver nitrate a maroon precipitate which rapidly becomes white. When this solution is

treated with sodium amalgam, it yields the ordinary ferrocyanide and the carbonyl ferrocyanide.

Friedel points out that the existence of this compound supports the formula for ferrocyanides which he proposed some years ago. According to this view, the ferrocyanides contain a ring of carbon-atoms. In Muller's compound, the group  $\text{NH}''$  is replaced by the element  $\text{O}'$  without any alteration of the nucleus.

C. H. B.

**Constitution of the Melamines.** By B. RATHKE (*Ber.*, 20, 1056—1059).—The author considers that Ponomareff's observation that silver cyanurate reacts with alkyl iodides with formation of normal alkyl cyanurates, besides isocyanurates, decides the question of the constitution of cyanuric acid and melamine in favour of Hofmann's view (*Abstr.*, 1886, 931). As the normal ethers readily change into isoethers, and the reverse reaction does not take place, the normal ethers must be the primary products of the decomposition.

The formula  $\text{NH} \langle \begin{array}{c} \text{C}(:\text{NR}) \cdot \text{NH} \\ \text{C}(:\text{NR}) \cdot \text{NH} \end{array} \rangle \text{C}:\text{NR}$  is suggested for triphenylmelamine as well as the nitrile formula  $\text{N} \langle \begin{array}{c} \text{C}(\text{NHR}) \cdot \text{N} \\ \text{C}(\text{NHR}) \cdot \text{N} \end{array} \rangle \text{C} \cdot \text{NHR}$ . The essential difference between these formulæ and that of the iso-compound  $\text{NR} \langle \begin{array}{c} \text{C}(\text{NH}) \cdot \text{NR} \\ \text{C}(\text{NH}) \cdot \text{NR} \end{array} \rangle \text{C}:\text{NH}$ , is that whilst in the former the alkyl is contained in the side-chain, in the latter it is attached to the ring.

N. H. M.

**Thiammeline.** By B. RATHKE (*Ber.*, 20, 1059—1065).—Thiammeline is readily obtained by direct combination of dicyandiamide with thiocyanic acid; the same compound has also been obtained by Klason by the action of potassium hydrosulphide on the substance  $(\text{CN})_3(\text{NH}_2)_2\text{Cl}$ , obtained from cyanogen chloride and ammonia. Thiammeline functions both as an acid and a base; the *oxalate*,  $(\text{C}_3\text{H}_5\text{N}_5\text{S})_2\text{C}_2\text{H}_2\text{O}_4$ , and *nitrate* crystallise in needles, the *sulphate* in leaflets; a *potassium* salt crystallising in needles, and a silver salt, a white precipitate, are described. A characteristic reaction of thiammeline is the production of a yellow, flocculent precipitate when a solution of its salt is boiled with copper sulphate and ammonia; when heated with concentrated hydrochloric acid, it is decomposed into cyanuric acid, ammonia, and hydrogen sulphide. Attempts to prepare an ethyl-derivative of thiammeline were unsuccessful, but with ethylene bromide an ethylenethiammeline hydrobromide,  $\text{C}_6\text{H}_7\text{N}_5\text{S} \cdot \text{HBr}$ , was obtained, crystallising in colourless pyramids; the free base was not isolated.

V. H. V.

**Cocceryl Alcohol and Coccerylic Acid.** By C. LIEBERMANN and O. BERGAMI (*Ber.*, 20, 959—966; comp. *Abstr.*, 1885, 1045).—The

formula  $C_{30}H_{62}O_2$ , previously ascribed to cocceryl alcohol, is confirmed by further investigation. The *acetyl*-derivative,  $C_{30}H_{60}(OAc)_2$ , is obtained by heating two parts of the alcohol with one part of acetic anhydride at  $170^\circ$  for two hours; it forms snow-white crystalline flocks, melts at  $48-50^\circ$ , and is readily soluble in ether, warm alcohol, and acetic acid, very sparingly soluble in acetone. The *benzoyl*-derivative,  $C_{30}H_{60}(OBz)_2$ , is prepared by heating one part of cocceryl alcohol with two parts of benzoic anhydride at  $210-220^\circ$  for three hours; it forms white flocks, melts at  $60-62^\circ$ , does not readily solidify when heated above its melting point, and is less soluble than the acetyl-derivative in the solvents just mentioned. When oxidised with chromic acid in acetic acid solution, cocceryl alcohol is converted into a new pentadecylic acid, the chief product, a second acid of high melting point and sparing solubility, and a neutral compound.

*Pentadecylic acid*,  $C_{15}H_{30}O_2$ , is crystalline, melts at  $59-60^\circ$ , and is very readily soluble in alcohol, ether, benzene, and acetic acid, less soluble in light petroleum. It begins to boil at  $257^\circ$  under 100 mm. pressure, but the temperature rises during the distillation. The yield amounts to 40 per cent. of the cocceryl alcohol employed. Its *calcium* and *barium* salts were analysed; the *methyl* salt,  $C_{15}H_{23}O_2Me$ , is crystalline and melts at  $66-68^\circ$ .

Coccerylic acid is only partially oxidised with chromic acid in acetic acid solution, about 40 per cent. remaining unchanged. The chief oxidation product is pentadecylic acid (m. p. =  $62^\circ$ ), and the yield amounts to 40 per cent. of the coccerylic acid employed.

W. P. W.

**Oxidation of Polyatomic Alcohols.** By E. FISCHER and J. TAFEL (*Ber.*, 20, 1088—1094).—By the oxidation of polyatomic alcohols, carboxylic acids only have as yet been obtained; the aldehydes and ketones which are formed, have not been isolated as intermediate products, owing to the inefficiency of methods used.

In this paper, the phenylhydrazine test is employed to indicate the formation of those aldehydes and ketones, and a class of substance obtained which it is proposed to call the osazones.

Thus on warming glycerol with nitric acid (sp.gr. = 1.18), for a short time a violent reaction ensues; after removal of the nitrous acid with carbamide, a liquid is obtained, which reduces Fehling's solution, and gives with phenylhydrazine hydrochloride a crystalline substance of the composition  $C_{15}H_{16}NO_4$ , a *phenylglycerosazone*, which melts at  $131^\circ$  and decomposes at  $170^\circ$  with evolution of gas; it is sparingly soluble in hot water, readily in alcohol and ether. To it the constitutional formula  $OH \cdot CH_2 \cdot C(N_2HPh) \cdot CH : N_2HPh$  is provisionally assigned, as more probable than the alternative formula

In order to decide whether the product of oxidation is an aldehyde or ketone, the nature of the substance obtained by treatment of dibromacetaldehyde with baryta is examined. After removal of the excess of baryta, the substance formed reduces Fehling's solution and gives with phenylhydrazine a crystalline precipitate of the composition  $C_{18}H_{22}N_4O_4$ , resembling phenylglucosazone in physical properties and

external appearance; it is probable that a glucose is formed in the reaction thus:  $2\text{C}_3\text{H}_4\text{Br}_2\text{O} + 2\text{Ba}(\text{OH})_2 = \text{C}_6\text{H}_{12}\text{O}_6 + 2\text{BaBr}_2$ .

In like manner erythrol, on oxidation with dilute nitric acid, yields a substance which reduces Fehling's solution and gives with phenylhydrazine a crystalline substance,  $\text{C}_{16}\text{H}_{18}\text{N}_4\text{O}_2$ , melting at  $166-167^\circ$ , sparingly soluble in hot water, more readily in ether and benzene; the reaction with dulcitol is precisely similar. On the other hand, isodulcitol, although classified with the above hexatomic alcohols, differs from them in yielding a crystalline precipitate with phenylhydrazine without previous oxidation with nitric acid. This substance,  $\text{C}_6\text{H}_{10}\text{O}_3(\text{N}_2\text{HPh})_2$ , crystallises in needles, melting at  $180^\circ$  with decomposition, soluble in alcohol and ether. Thus isodulcitol belongs rather to the aldehydic or ketonic alcohols, and its formula is probably  $\text{C}_6\text{H}_{12}\text{O}_5$ ; it combines with water in like manner to chloral and glyoxylic acid; it is possibly the methyl-derivative of arabinose.

V. H. V.

**A New Galactan. Properties of Galactose.** By E. O. v. LIPPMANN (*Ber.*, 20, 1001—1008).—The liquid obtained in the manufacture of sugar from the lime sludge after being freed from lime by means of carbonic anhydride and oxalic acid and evaporated down, yielded, when kept for two months, a thick, gelatinous precipitate. This was kneaded with water until the wash-water remained colourless, dissolved in boiling milk of lime, and the liquid evaporated whilst carbonic anhydride was passed in. It was then put into tall cylinders to settle, the clear liquid drawn off, evaporated, and when cold treated with excess of hydrochloric acid and precipitated with absolute alcohol. This operation was repeated and the gum purified by fractional precipitation with absolute alcohol; it was then kneaded under absolute alcohol and finally left in small pieces in alcohol. It then forms an almost white, brittle mass, very readily soluble in water (the impure substance is insoluble in cold water and alcohol). It has the formula  $\text{C}_6\text{H}_{10}\text{O}_5$ ; the aqueous solution is dextrorotatory:  $[\alpha]_D = +238^\circ$  (in a 10 per cent. solution at  $20^\circ$ ), it does not reduce Fehling's solution. When inverted with dilute sulphuric acid, it is completely converted into galactose; the name  *$\gamma$ -galactan* is therefore given to the compound.

The author's previous statement that galactose ferments when treated with yeast has been confirmed by Tollens, although according to Kiliani (*Ber.*, 13, 2305) no fermentation takes place. N. H. M.

**Preparation of Normal Propylamines and Isoamylamines.** By H. MALBOT (*Compt. rend.*, 104, 998—1000).—Normal propyl alcohol and fermentation amyl alcohol were converted into the corresponding chlorides, and after purification these were heated with an equivalent quantity of ammonia in sealed tubes at  $140-165^\circ$  for 12 to 24 hours (see this vol., p. 356). The proportion of primary amine diminishes as the molecular weight of the radicle increases; it is one-fifth for the propylamines, one-tenth for the isobutylamines, and very small indeed for the isoamylamines. The formation of tertiary amines is probably due to a reaction between the primary amines first formed and the still unaltered alkyl chloride. C. H. B.

**Homologues of Acetyl-acetone : Formation of Ketones of the Acetic Series.** By A. COMBES (*Compt. rend.*, 104, 920—921).—Acetyl-acetone dissolves sodium with evolution of hydrogen and formation of a solid compound,  $\text{CHNa}(\text{COMe})_2$ , which is soluble in ether and is decomposed by water into acetone and sodium acetate. If this sodium-derivative is heated with ethyl iodide in sealed tubes at 130—140°, it yields sodium iodide and *monethyl-acetyl-acetone*,  $\text{CHEt}(\text{COMe})_2$ , a colourless liquid which boils at 175°, and is only slightly soluble in water. It dissolves with development of heat in a solution of sodium hydrogen sulphite, but no crystallisation takes place until the solution is cooled to a low temperature.

This reaction constitutes a general method for the preparation of the homologues of acetyl-acetone. With amyl iodide, the sodium-derivative yields amyl-acetyl-acetone which boils at 225°.

The second atom of hydrogen in the group  $\text{CH}_2$  can also be displaced by sodium, and the disodium-derivatives react with alkyl iodides. It is thus possible to obtain diketones of the two types,

All the homologues of acetyl-acetone are decomposed into an acetate and a ketone when treated with an alkali. Ethyl-acetyl-acetone yields the methyl propyl ketone discovered by Friedel, and amyl-acetyl-acetone yields a liquid which boils at 170°, and is identical with the methyl hexyl ketone described by Béhal. The decomposition of diketones homologous with acetyl-acetone furnishes a new method for the preparation of ketones of the type  $\text{Me} \cdot \text{CO} \cdot \text{C}_n\text{H}_{2n+1}$ . All the stages in the operation give almost theoretical yields. C. H. B.

**Fatty Acids occurring in Resin Oil.** By J. LWOFF (*Ber.*, 20, 1017—1023). The mixed sodium salts obtained by extracting resin oil with aqueous soda were treated with a concentrated solution of sodium chloride to precipitate such sodium salts as are insoluble in presence of salt; the supernatant liquid was poured off, treated with hydrochloric acid, and distilled. The acids were separated by conversion into amides. Valeric, cœnanthylic, nonylic, and undecylic acids were isolated. The amides of the last two acids melt respectively at 77—78° and 80—81°, and both crystallise in lustrous plates soluble in hot water containing ammonia. N. H. M.

**Octyl Mono-, Di-, and Tri-chloracetates.** By G. GEHRING (*Compt. rend.*, 104, 1000—1001).—The octyl alcohol was obtained by the action of potassium hydroxide on castor-oil, and is therefore the secondary alcohol described by Bouis.

The ethereal salts were obtained by passing hydrogen chloride into a mixture of the alcohol and acid, or, in the case of the dichloracetate, of the alcohol and the potassium salt.

Octyl monochloracetate is a colourless, neutral, very mobile oil with an ethereal odour and a burning taste. It boils at 234°, produces a permanent stain on paper, burns with a green flame, and is insoluble

in water but dissolves in alcohol and ether in all proportions; sp. gr. at  $10^{\circ} = 0.9904$ .

The dichloracetate boils at  $244^{\circ}$ , and is a neutral, colourless, mobile liquid, lighter than water, and very similar in its properties to the monochloracetate, but its odour and taste are less marked. The trichloracetate boils at about  $260^{\circ}$ , and is a colourless oil with an ethereal odour. It is lighter than water, and closely resembles the two preceding compounds in its general properties. C. H. B.

**Metallic Propionates.** By A. RENARD (*Compt. rend.*, **104**, 913—916).—*Aluminium propionate* cannot be isolated from its solution, which is decomposed on heating with almost complete precipitation of the basic compound  $(C_3H_5O_2)_4OAl_2$ . *Ammonium propionate*, syrupy, noncrystallisable, soluble in water and alcohol. *Barium propionate* crystallises simultaneously from the same solution in two forms: (a) bulky, transparent prisms,  $(C_3H_5O_2)_2Ba + H_2O$ , which become anhydrous at  $110^{\circ}$ ; and (b) brilliant, transparent needles,  $(C_3H_5O_2)_2Ba + 6H_2O$ , which lose  $3H_2O$  in dry air and become anhydrous at  $110^{\circ}$ , melt above  $300^{\circ}$ , and then decompose; insoluble in alcohol; 100 parts of water dissolve 54.1 of dry salt at  $12^{\circ}$  and 7.6 at  $100^{\circ}$ . *Calcium propionate*,  $(C_3H_5O_2)_2Ca + H_2O$ , brilliant flattened needles, which become anhydrous at  $100^{\circ}$  and melt above  $300^{\circ}$ ; insoluble in alcohol; 100 parts of water dissolve 41.7 parts at  $12^{\circ}$  and 45.6 at  $100^{\circ}$ . *Cadmium propionate*, non-crystallisable syrup, soluble in all proportions in water and alcohol. *Chromic propionate*, obtained as the basic salt,  $(C_3H_5O_2)_4OCr_2$ , a hard, deep-violet, amorphous mass, by concentrating a solution of chromic hydroxide in propionic acid. *Cobalt propionate*,  $(C_3H_5O_2)_2Co + 3H_2O$ , forms wine-coloured crystalline crusts, which become anhydrous at  $100^{\circ}$ , melt at about  $250^{\circ}$  to an indigo liquid; very soluble in alcohol; 100 parts of water dissolve 35.5 parts at  $11^{\circ}$ ; aqueous solution deep wine-red, becomes blue on heating. *Copper propionate*,  $(C_3H_5O_2)_2Cu + H_2O$ , emerald-green prisms which become anhydrous at  $100^{\circ}$  and decompose at  $110^{\circ}$ . The neutral solution, heated for some time at  $100^{\circ}$ , deposits the pale-blue basic salt,  $(C_3H_5O_2)Cu, CuO + H_2O$ . *Ferrous propionate*, greenish crystals which very rapidly oxidise. *Ferric propionate* forms a hard, friable, reddish-brown solid; its aqueous solution decomposes when heated, with precipitation of ferric hydroxide. *Lithium propionate*,  $C_3H_5O_2Li + H_2O$ , forms deliquescent crystals, which become anhydrous in dry air; 100 parts of water dissolve 63.4 parts of dry salt at  $14^{\circ}$  and 88.8 parts at  $100^{\circ}$ ; 100 parts of alcohol of  $95^{\circ}$  dissolve 5.1 parts at  $14^{\circ}$  and 6.3 at its boiling point. *Magnesium propionate*,  $(C_3H_5O_2)_2Mg + H_2O$ , a white powder which becomes anhydrous at  $100^{\circ}$ , and is very soluble in water and alcohol. *Manganese propionate* forms a pale rose-coloured, syrupy mass which gradually crystallises; very soluble in water and alcohol. *Mercurous propionate*,  $(C_3H_5O_2)_2Hg_2$ , obtained by double decomposition, a white crystalline powder which melts at  $225^{\circ}$  and decomposes; 100 parts of cold water dissolve 1.4 parts of salt; boiling water decomposes the salt into mercury and mercuric propionate, but the decomposition is prevented by a few drops of propionic acid; the salt is also decomposed by

alcohol. *Mercuric propionate*,  $(C_3H_5O_2)_2Hg$ , forms needles which melt at  $110^\circ$  to a colourless liquid, and decompose at about  $180^\circ$  with loss of propionic acid and formation of mercurous propionate; 100 parts of water at  $15^\circ$  dissolve 19.2 parts; decomposed by water and by alcohol with separation of mercuric oxide. *Nickel propionate*,  $(C_3H_5O_2)_2Ni + 2H_2O$ , a pale-green syrup which slowly crystallises in dry air and becomes anhydrous at  $100^\circ$ . *Lead propionate*,  $(C_3H_5O_2)_2Pb$ , forms a thick syrup which very gradually changes to a soft, crystalline mass melting below  $100^\circ$ , and soluble in water and alcohol. If its solution is boiled with lead monoxide and filtered, the filtrate deposits small needles of the basic salt  $(C_3H_5O_2)_2Pb.PbO$ ; 100 parts of water dissolve 8.8 parts of this basic salt at  $20^\circ$  and 6.3 parts at  $85^\circ$ . *Potassium propionate*,  $C_3H_5O_2K + H_2O$ , crystallises in soft deliquescent plates which become anhydrous at  $120^\circ$  and melt above  $300^\circ$ ; 100 parts of water dissolve 178 parts of dry salt at  $16^\circ$  and 309 parts on boiling; 100 parts of alcohol of  $95^\circ$  dissolve 22.2 at  $13^\circ$  and 26.4 on boiling. *Potassium hydrogen propionate* forms deliquescent plates which do not lose propionic acid at  $100^\circ$ . *Sodium propionate*,  $C_3H_5O_2Na + H_2O$ , forms a soft, deliquescent, crystalline mass, which becomes anhydrous at  $100^\circ$ ; 100 parts of water dissolve 99.1 parts of dry salt at  $15^\circ$  and 187 parts on boiling; 100 parts of alcohol of  $95^\circ$  dissolve 4.4 parts at  $13^\circ$  and 8.4 on boiling; no acid propionate is formed. *Strontium propionate*,  $(C_3H_5O_2)_2Sr + 6H_2O$ , crystallises in prismatic needles, which lose 3 mols.  $H_2O$  in dry air and melt in their water of crystallisation and become anhydrous at  $100^\circ$ ; 100 parts of water dissolve 27 parts of dry salt at  $12^\circ$ ; it is insoluble in alcohol. *Zinc propionate*,  $(C_3H_5O_2)_2Zn + H_2O$ , crystallises in needles which become anhydrous in dry air; 100 parts of water dissolve 32 parts of dry salt at  $15^\circ$ ; 100 parts of alcohol dissolve 2.8 parts at  $15^\circ$  and 17.2 parts on boiling.

C. H. B.

**Chlorinated Derivatives of Crotonic Acid.** By J. WISLICENUS (*Ber.*, 20, 1008—1110).— $\alpha$ - $\beta$ -Dichlorobutyric acid,  $C_4H_6Cl_2O_2$ , is prepared by passing a strong current of chlorine through a solution of solid crotonic acid in carbon bisulphide. The solvent is evaporated, the residue freed by filtration from adhering oil, and crystallised several times from a small quantity of ether. It forms large, lustrous, colourless prisms which melt at  $62.5$ — $63^\circ$ .

$\alpha$ -Chlorisocrotonic acid,  $C_4H_5ClO_2$ , is formed when  $\alpha$ - $\beta$ -dichlorobutyric acid is treated with an excess of aqueous soda. When the reaction takes place in a hot solution,  $\alpha$ -chlorocrotonic acid is also formed; the two acids can be readily separated as potassium salts; the salt of the new acid being readily soluble in cold alcohol. It crystallises from water in needles melting at  $66.2$ — $66.5^\circ$ . The potassium salt crystallises from alcohol in needles of a slightly silky lustre.

$\alpha$ -Chlorocrotonic acid melts at  $99$ — $99.5^\circ$  (not  $97.5^\circ$ ).

When liquid isocrotonic acid is treated with chlorine, a liquid product is formed which contains, however, solid  $\alpha$ - $\beta$ -dichlorobutyric acid. When treated with excess of alkali,  $\alpha$ -chlorocrotonic acid (m. p.  $99$ — $99.5^\circ$ ) and  $\alpha$ -chlorisocrotonic acid are formed.

*α*-Chlorisopropylene,  $C_3H_5Cl$ , is obtained by heating an aqueous solution of the potassium salt of solid *α*-*β*-dichlorobutyric acid. It resembles its isomeride and boils at 33·2—33·5°. Propylaldehyde is formed in the reaction. Ordinary *α*-chloropropylene can be obtained in like manner from liquid *α*-*β*-dichlorobutyric acid. (Compare A. Michael and G. M. Browne (next Abstract.)).

N. H. M.

**Isomerism in the Crotonic Acid Series.** By A. MICHAEL and G. M. BROWNE (*J. pr. Chem.* [2], 35, 257—260).—The so-called *β*-bromocinnamic acid is not identical with the additive product of hydrobromic acid and phenylpropionic acid (Abstr., 1886, 702). The *β*-bromocrotonic acid prepared from *α*-*β*-dibromobutyric acid is similarly not identical with the additive product prepared from tetrolic acid. Pure tetrolic acid when treated with hydrobromic acid at 0° deposits crystals which may be crystallised from light petroleum. It differs from its two isomerides in its melting point, 94·5—95°, and its solubility and crystalline form; the silver salt is amorphous and the barium salt crystallises with 1 mol. of water.

H. B.

**Synthesis in the Paraffin Series by Means of Aluminium Chloride.** By A. COMBES (*Compt. rend.*, 104, 855—858).—If the compound  $C_{12}H_{14}O_6, Al_2Cl_6$  (this vol., p. 127) is added in small portions to well-cooled alcohol, an energetic reaction takes place with evolution of hydrogen chloride, and when the product is poured into water a reddish liquid separates, which is a mixture of ethyl acetate, ethyl acetoacetate, and a colourless liquid which has the composition  $C_8H_{12}O_4$ , and boils at 120—125°; vapour-density 5·90. This is ethyl acetoacetylacetate,  $CH_2Ac \cdot CO \cdot CH_2 \cdot COOEt$ , and the formation of ethyl acetoacetate and ethyl acetate is due to the readiness with which it splits up in presence of alcohol and acetic acid. A solid product is also obtained, which is insoluble in water, but dissolves in warm alcohol, benzene, and light petroleum, and crystallises from these solvents in red prisms melting at 129—130°. It has the composition  $Al_2(C_8H_{11}O_4)_6$ , and is formed by the union of 6 mols. of ethyl acetoacetylacetate with 2 atoms of aluminium. It is very stable, and is not attacked by sulphuric or nitric acid in the cold, but its alcoholic solution is decomposed by alkalis with precipitation of the aluminium and formation of a crystalline compound.

When butyric chloride is treated in the same way as acetic chloride (*loc. cit.*), it yields a similar compound which boils at 216° under a pressure of 14 mm. and rapidly becomes solid. After recrystallisation it has the composition  $nC_4H_8O$  and melts at 107°. It does not volatilise without decomposition, but when its alcoholic solution is treated with alkalis it yields salts of the composition  $C_{12}H_{18}O_4Na$ , and therefore its formula is  $C_{12}H_{18}O_3$ . This compound is the anhydride of a diketonic acid, butyro-butryl-butyric acid, the elimination of water from the molecule taking place in much the same way as in the formation of lactones.

C. H. B.

**Action of Bromine on Carbamide.** By A. SMOLKA (*Monatsh. Chem.*, 8, 64—68).—The following experiments were undertaken in the

endeavour to obtain a bromine substitution product by the direct action of bromine on carbamide. When bromine is added drop by drop to a concentrated alcoholic solution of carbamide, the product consists almost entirely of ammonium bromide. Bromine and carbamide heated together in equivalent proportions yielded cyanuric acid, ammonium bromide, and free nitrogen; this forms a very convenient method for the preparation of the first named substance.

When bromine and carbamide are heated together in a sealed tube ammonium bromide and cyamelide are formed. G. H. M.

**Antimony Tartrate.** By GUNTZ (*Compt. rend.*, 104, 850—852).—When an excess of antimony trioxide is boiled with an aqueous solution of tartaric acid, 1 mol. of the oxide is dissolved for every 5 mols. of acid present, no matter how long ebullition is continued, and this ratio is also independent of the concentration of the solution provided that it be not too dilute, in which case the solubility of antimony oxide in water affects the ratio. The free tartaric acid in the solution is determined by means of standard baryta with phenolphthalein as an indicator, and the antimony trioxide is determined by means of potassium permanganate. The solution is evaporated to a syrup, and on cooling deposits almost the whole of the antimony in the form of a crystalline acid tartrate, which is purified by washing with absolute alcohol. The original solution may also be evaporated to complete dryness and the excess of tartaric acid removed by treating the residue with alcohol, when the antimony tartrate is left in crystalline leaflets of the composition  $C_4H_4O_6, SbO \cdot OH$ .

Its heat of formation was determined by dissolving it in hydrofluoric acid, and also dissolving in the same acid a mixture of tartaric acid and antimony oxide in the same proportions.

It is evident that the substitution of antimony oxide for hydrogen develops practically the same amount of heat whether the substitution takes place in tartaric acid or potassium hydrogen tartrate. Antimony hydrogen tartrate is decomposed by water but dissolves in a solution of tartaric acid. The heat of dissolution of antimony trioxide,  $Sb_2O_3$ , in tartaric acid (5 mols.) is +11.2 Cal.

Berthelot obtained +7.1 Cal. as the heat of formation of the antimony tartrate by dissolving antimony trichloride in tartaric acid. The author has likewise observed that the heat of formation seems to vary with the method of preparation, and further experiments are being made. C. H. B.

**Constitution of Pyrotritartaric Acid.** By C. PAAL (*Ber.*, 20, 1074—1077).—According to Fittig, the constitution of pyrotritartaric acid is best represented by the formula  $\begin{matrix} <CO \cdot CH_2 \\ CH : CMe \end{matrix}>CH \cdot COOH$ , that is, as an unsaturated ketonic acid and a derivative of pentamethylene.

But the recent investigations of the author, showing that the acid takes up at first four atoms of bromine to form a tetrabromo-acid, which is reconverted by hydrogenation into the original acid, and that this acid by the further addition of four atoms of bromine gives an additive product, as also yields a pentabromo-derivative, indicate that pyrotritartaric acid is analogous to and probably a derivative of pyromucic acid. This view is confirmed by its synthesis from ethylacetylacetoacetate and its reactions with phenylhydrazine and hydroxylamine; pyrotritartaric acid is then probably a dimethylfurfuranecarboxylic acid,  $\begin{matrix} \text{O} \text{---} \text{CMe} \\ \text{CMe} \text{: CH} \end{matrix} \text{C} \cdot \text{COOH}$ .

V. H. V.

**Derivatives of Pyrotritartaric Acid.** By F. DIETRICH and C. PAAL (*Ber.*, 20, 1077—1080).—Hitherto the derivatives of pyrotritartaric acid, with the exception of the salts, have not been investigated, owing to its indifference towards some reagents, and its complete decomposition by others. By bromination in chloroform solution, a tetrabromopyrotritartaric acid,  $\text{C}_6\text{H}_3\text{Br}_4\text{O} \cdot \text{COOH}$ , is formed, which crystallises in well-formed prisms melting at  $161^\circ$ , soluble in alcohol and ether, insoluble in water and petroleum; its metallic and ethereal salts are unstable. When treated with bromine, it takes up four more atoms of bromine to yield *tetrabromopyrotritartaric acid tetrabromide*,  $\text{C}_6\text{H}_3\text{Br}_8\text{O} \cdot \text{COOH}$ , which crystallises in short prisms melting at  $168\text{--}170^\circ$ ; the salts of this acid are unstable, and it is completely decomposed by alkalis. On treating the tetrabromo-derivative with excess of bromine in sealed tubes, a pentabrominated acid,  $\text{C}_6\text{H}_2\text{Br}_5\text{O} \cdot \text{COOH}$ , is formed. This crystallises in elongated rhombohedra, and melts at  $197^\circ$ .

Wislicenus and Stadnicki found that when pyrotritartaric acid is treated with phosphoric chloride it yields an acid chloride, decomposed by water to re-form the acid; but if the reaction is conducted at a higher temperature, a dichloro-compound is formed; the latter is a colourless, heavy oil of disagreeable odour, converted by exposure to damp air into pyrotartaric acid and a resin.

During the distillation of carbopyrotritartaric acid, a dimethylfurfuran, identical with that obtained from acetylacetone, together with pyrotritartaric acid and *uvione*, are formed. This last substance,  $\text{C}_{14}\text{H}_{12}\text{O}_4$ , crystallises in tufts of needles, melting at  $247.5^\circ$ ; with bromine, it yields an octabromo-derivative,  $\text{C}_{14}\text{H}_2\text{Br}_8\text{O}_4$ , crystallising in pyramidal prisms, sparingly soluble in most menstrua; when heated, it carbonises with evolution of bromine and hydrobromic acid.

V. H. V.

**$\beta$ -Bromofurfuran.** By F. CANZONERI and V. OLIVERI (*Gazzetta*, 17, 42—44).—Two bromo-derivatives of furfuran are indicated by theory, namely, one in which the bromine displaces a hydrogen-atom in either of the CH groupings attached to the oxygen-atoms, and the second in which a hydrogen-atom is displaced in one of the CH groupings not attached to the oxygen. Both these substances have been obtained by the decomposition of the bromopyromucic acids. In order to prepare  $\beta$ -bromofurfuran, the corresponding bromopyromucic acid

is first purified from the dibromo-acid by means of its ethyl salt, which is saponified, and the acid obtained is then distilled with an equal weight of lime. *β-Bromofurfuran*, thus produced, is a colourless, transparent liquid, boiling at 103°, heavier than and insoluble in water.

V. H. V.

**Synthesis of Hemellithene.** By O. JACOBSEN and W. DEIKE (*Ber.*, 20, 903—904).—Metaxylenesulphonic acid [ $\text{Me} : \text{SO}_3\text{H} : \text{Me} = 1 : 2 : 3$ ] is obtained by sulphonating dibromometaxylene

with chlorosulphonic acid, converting the sulphochloride formed into the sodium salt of the acid by means of alcoholic soda, and removing the bromine with zinc-dust and ammonia. When a hot solution of the sodium salt is treated with bromine dissolved in hydrochloric acid, the corresponding bromometaxylene is obtained, and this is converted into hemellithene by the action of sodium and methyl iodide in ethereal solution.

Bromometaxylene boils at about 206°, and does not solidify at  $-10^\circ$ .

W. P. W.

**Reduction of Trinitro- $\psi$ -cumene.** By F. MAYER (*Ber.*, 20, 966—973).—The constitution of the acid,  $\text{C}_9\text{H}_{12}\text{N}_2\text{SO}_5$  (this vol., p. 36), obtained when trinitro- $\psi$ -cumene is reduced with hydrogen sulphide, cannot be ascertained from an examination of its salts, which are unsatisfactory compounds, nor is it possible to characterise it either as a carboxylic acid or a mercaptan. If, however, it is heated with concentrated sulphuric acid at 140—150°, a considerable quantity of the sulphate of Fittig's nitro- $\psi$ -cumidine (*Annalen*, 151, 157), is obtained, and inasmuch as on heating either with concentrated hydrochloric acid or with water at 180°, it yields the same sulphate and also sulphuric acid, it follows that the compound must be regarded either as a nitro- $\psi$ -cumidinesulphonic acid or as a nitro- $\psi$ -cumidine-sulphaminic acid,  $\text{NO}_2\cdot\text{C}_6\text{HMe}_3\cdot\text{NH}\cdot\text{SO}_3\text{H}$ . The synthetical formation of the compound by heating nitro- $\psi$ -cumidine sulphate with chlorosulphonic acid at 165° for four hours does not distinguish between the formulæ, and no evidence has been obtained to show which of the two is correct.

*Acetylnitro- $\psi$ -cumidinesulphonic acid*,  $\text{C}_9\text{H}_{11}\text{N}_2\text{SO}_5\text{Ac}$ , melts at about 230° with decomposition, and is readily soluble in water and alcohol, sparingly soluble in ether.

The constitution of nitro- $\psi$ -cumidine [ $\text{Me} : \text{NO}_2 : \text{Me} : \text{Me} : \text{NH}_2 = 1 : 2 : 3 : 4 : 6$ ] and of nitro- $\psi$ -cumidinesulphonic acid follows from the fact that both compounds, on reduction with tin and hydrochloric acid, yield meta- $\psi$ -cumylenediamine [ $\text{Me} : \text{NH}_2 : \text{Me} : \text{Me} : \text{NH}_2 = 1 : 2 : 3 : 4 : 6$ ], whilst the former, by elimination of the amido-group and subsequent reduction with stannous chloride, is converted into third  $\psi$ -cumidine which must have the formula [ $\text{Me} : \text{NH}_2 : \text{Me} : \text{Me} = 1 : 2 : 3 : 4$ ].

*Meta- $\psi$ -cumylenediamine* crystallises in long, hard needles, melts at 84°, and dissolves readily in benzene. Ferric chloride gives to its solution an intense dark-red colour. When treated with diazo-com-

pounds, chrysoïdines are obtained, whilst with nitrosodimethylaniline hydrochloride it yields a dye analogous to Witt's toluylene-red.

$\gamma$ -Cumidine boils at  $236^{\circ}$ , and does not solidify at  $-15^{\circ}$ . Its acetyl-derivative,  $C_9H_{12}NAc$ , melts at  $186^{\circ}$ . This cumidine is probably identical with that obtained by Nölting and Forel (Abstr., 1886, 58). The corresponding nitrotrimethylbenzene melts at  $30^{\circ}$ .

W. P. W.

**Action of Sulphuric Acid on Pentamethylbenzene.** By O. JACOBSEN (*Ber.* **20**, 896—902).—Pentamethylbenzene, obtained by the action of methyl chloride on mesitylene or pseudocumene in the presence of aluminium chloride, can readily be separated from the accompanying hexamethylbenzene by fractional crystallisation from alcohol; its purification from small quantities of durene and possibly of isodurene is, however, more difficult, and is best effected by sulphonating the impure hydrocarbon with chlorosulphonic acid. Pentamethylbenzene sulphone and sulphochloride are formed, and the latter is converted into the sodium sulphonate, separated from any durene-sulphonate by crystallisation, converted into the sulphonamide, and together with the sulphone saponified at  $170^{\circ}$  with concentrated hydrochloric acid. The sodium, potassium, barium, calcium, silver, and copper salts of pentamethylbenzenesulphonic acid are described; they are crystalline, anhydrous, and sparingly soluble in water; the chloride,  $C_6Me_5SO_2Cl$ , crystallises from ether in large, flat prisms, and melts at  $82^{\circ}$ ; the amide forms large, flat prisms, showing a vitreous lustre, melts at  $186^{\circ}$ , is sparingly soluble in cold alcohol, and when oxidised with potassium permanganate yields a sulphonamic acid melting at about  $265^{\circ}$ . The sulphone crystallises in very long, slender, colourless needles, melts at  $98.5^{\circ}$ , is readily soluble in alcohol, and on distillation yields pentamethylbenzene.

When sodium pentamethylbenzenesulphonate is shaken with concentrated sulphuric acid and light petroleum, hydrolysis occurs and the pure hydrocarbon is obtained on evaporation of the latter. The sulphonic acid cannot be prepared by the action of concentrated sulphuric acid, inasmuch as pentamethylbenzene when repeatedly shaken with 3 to 4 times its weight of the acid during 36 to 48 hours, and then treated with ice, yields prehnitenesulphonic acid and a solid hydrocarbon, which is found to be hexamethylbenzene and not an octamethylantracene (Abstr., 1886, 694). The action of sulphuric acid on durene (*loc. cit.*) may, therefore, be regarded as resulting in the formation of pseudocumene and pentamethylbenzene, the latter in the presence of the acid undergoing further change into prehnitine and hexamethylbenzene.

W. P. W.

**Resorcinol-derivatives.** By W. WILL and W. PUKALL (*Ber.*, **20**, 1119—1136).—Æsculetin has been recognised as a dihydroxy-derivative of coumarin, but the trihydroxybenzene, from which it is derived, has as yet not been isolated. The starting point of experiments made in this direction was the preparation of benzeneazo-resorcinol,  $C_6H_3(OH)_2 \cdot N_2Ph$  [ $OH : OH : N_2Ph = 1 : 3 : 4$ ], from resorcinol, by means of the diazo-reaction. This substance, previously

described by other investigators, yields with ethyl iodide in presence of potash a mono- and a di-ethoxy-derivative. The former,

crystallises in prisms resembling alizarin; it melts at  $87^\circ$ , is readily soluble in alcohol, insoluble in water; the latter crystallises in yellowish-red needles melting at  $70.5^\circ$ , soluble in alcohol and ether. On hydrogenation with tin and hydrochloric acid, the stannochlorides of aniline and amidodiethoxyresorcinol are produced. The hydrochloride of the latter exists in two modifications, namely, as glistening needles or a grey, crystalline powder, both of which melt at  $198^\circ$ , and are converted the one into the other according to the conditions of crystallisation. The free base,  $\text{C}_6\text{H}_3(\text{OEt})_2 \cdot \text{NH}_2$ , crystallises in broad needles melting at  $32^\circ$ ; its salts are very soluble and readily oxidised; the *dibromo*-derivative crystallises in needles melting at  $112^\circ$ ; the *acetyl*- and the *benzoyl*-derivatives melt at  $120.5^\circ$  and  $113.5^\circ$  respectively. When amidodiethoxyresorcinol is oxidised either by exposure to air or more readily by a ferric salt, a deep blue liquid is obtained, from which a violet-brown precipitate separates, and may be purified by sublimation. This compound,  $\text{C}_{18}\text{H}_{21}\text{NO}_5$ , is formed thus:  $2\text{C}_6\text{H}_3(\text{OEt})_2\text{NH}_2 + \text{O}_2 = \text{C}_{18}\text{H}_{21}\text{NO}_5 + \text{NH}_3 + \text{EtOH}$ ; it crystallises in steel-blue needles melting at  $170^\circ$ , and is soluble in alcohol, insoluble in ether. It is probably a derivative of quinone, of the formula  $\text{OEt} \cdot \text{C}_6\text{H}_2\text{O}_2 \cdot \text{NH} \cdot \text{C}_6\text{H}_3(\text{OEt})_2 [\text{O} : \text{NHC}_6\text{H}_3(\text{OEt})_2 : \text{OEt} : \text{O} = 1 : 2 : 3 : 4]$ .

Amidodiethoxyresorcinol, on oxidation with chromic acid, yields an *ethoxyquinone*,  $\text{C}_6\text{H}_3\text{O}_2 \cdot \text{OEt}$  [ $\text{O} : \text{OEt} : \text{O} = 1 : 3 : 4$ ], crystallising in yellow needles melting at  $117^\circ$ ; it dissolves in water, and its solution gives on addition of a trace of amidoethoxyresorcinol a blue coloration from formation of the above intermediate condensation-product. *Ethoxyquinol*,  $\text{C}_6\text{H}_3(\text{OH})_2 \cdot \text{OEt}$ , obtained by reduction of the quinone with sulphurous acid, crystallises in colourless prisms melting at  $112.5^\circ$ , and is soluble in water, alcohol, and ether. The triethoxy-derivative,  $\text{C}_6\text{H}_3(\text{OEt})_3$ , crystallises in glistening needles melting at  $34^\circ$ ; from the corresponding phenol, *æsculetin* is derived.

*Ethylamidoresorcinol*,  $\text{OH} \cdot \text{C}_6\text{H}_3(\text{OEt}) \cdot \text{NH}_2$  [ $\text{OH} : \text{OEt} : \text{NH}_2 = 1 : 3 : 4$ ], prepared in a manner similar to the above diethoxy-compound, forms colourless needles melting at  $148^\circ$ , soluble in water and alcohol. On oxidation with chromic acid, it seems to yield a quinone.

V. H. V.

**Resorcinol-derivatives.** By W. PUKALL (*Ber.*, **20**, 1136—1152).—*Diazodiethylresorcinol chloride*,  $\text{C}_6\text{H}_3(\text{OEt})_2 \cdot \text{N}_2\text{Cl}$ , obtained under particular conditions from amidodiethylresorcinol sulphate, is an unstable, crystalline substance, soluble in water with greenish-yellow coloration. By boiling water, as also by alkalis, it is readily converted into a diethylresorcinol, although the reaction is complicated by subsidiary changes, which lead probably to the formation of diresorcinol-derivatives. These substances were, therefore, separately examined.

*Tetrazyldiresorcinol*,  $\text{C}_{12}\text{H}_6(\text{OEt})_4$ , prepared from diresorcinol and ethyl iodide in presence of alkali, crystallises in large, colourless

leaflets melting at  $100^{\circ}$ , soluble in ether, insoluble in water, acids, and alkalis.

*Diethylresorcinolparazoresorcinol*,  $C_6H_3(OEt)_2 \cdot N_2 \cdot C_6H_3(OH)_2$ , prepared from diazodiethoxyresorcinol and resorcinol, forms glistening green crystals melting at  $193.5^{\circ}$ , insoluble in water and dilute acids, readily soluble in alcohol.

*Orthophenylazoethylresorcinol*,  $PhN_2 \cdot C_6H_3(OH) \cdot OEt$ , obtained together with the para-derivative, in small quantities by the ethylation of crude phenylazoresorcinol, crystallises in carmine-red needles, melts at  $150^{\circ}$ , is readily soluble in alcohol and ether, and in contradistinction to the para-derivative, is soluble in alkalis. By further ethylation, it is converted into the diethyl-derivative,  $PhN_2 \cdot C_6H_3(OEt)_2$ , which forms glistening tabular crystals melting at  $90^{\circ}$ , insoluble in water, acids, and alkalis. On reduction with tin and hydrochloric acid, it is converted into *orthamidodiethylresorcinol hydrochloride*,

which crystallises in colourless needles; the free base crystallises in leaflets melting at  $124^{\circ}$ , soluble in alcohol, insoluble in water. On oxidation, it yields a compound,  $C_{18}H_{20}N_2O_3$ , the constitution of which was not further investigated; it crystallises in brown-red needles melting at  $207^{\circ}$ . Attention is drawn to the formation of an ortho-, together with a para-, derivative in the diazo-reaction. Liebermann considers that the production of the ortho-derivative in this reaction is more common than has been hitherto suspected, but the quantities formed are insufficient for their separation.

*Diethylresorcinolorthazoresorcinol*,  $C_6H_3(OEt)_2 N_2 C_6H_3(OH)_2$ , prepared from diazodiethoxyresorcinol and an aqueous solution of resorcinol, is a reddish-yellow, crystalline precipitate, melting at  $182.5^{\circ}$ , soluble in alcohol and ether, insoluble in water.

Experiments made with a view of obtaining the corresponding phenol led to no satisfactory results.

V. H. V.

**Triphenylthiammeline and a Third Triphenylammeline.** By B. RATHKE (*Ber.*, 20, 1065—1074).—*Triphenylthiammeline*,

is obtained, together with other products, by heating triphenylthiodicyandiamine; it crystallises in leaflets melting at  $238^{\circ}$ , and is sparingly soluble in alcohol, moderately soluble in chloroform. It functions both as an acid and a base, forming with mineral acids crystalline salts, such as the hydrochloride and sulphate, and also dissolving in alkalis to form crystalline metallic derivatives, decomposed by carbonic anhydride. When heated with ethyl bromide and alcohol, triphenylthiammeline yields the hydrobromide of the corresponding mercaptide,  $C_3N_5HPh_3 \cdot SEt \cdot HBr$ . This crystallises in colourless, strongly refractive prisms, of neutral reaction, and is converted into triphenylammeline when boiled with alcohol. This substance, also obtainable from tetraphenylmelamine, crystallises in

colourless leaflets, often twinned, and melts at  $275^{\circ}$  (uncorr.); its *hydrochloride* crystallises in white needles, and the *platinochloride* is a yellow, crystalline precipitate. This substance seems to be isomeric with the two triphenylammelines described by Hofmann.

If the mercaptide above mentioned is heated with alcoholic ammonia, a *triphenylmelamine* is obtained, which crystallises in minute needles melting at  $185$ — $188^{\circ}$ , and is moderately soluble in alcohol. This substance is isomeric with the three known triphenylmelamines; its probable constitution is discussed. V. H. V.

**Primary and Secondary Xylylamines from Xylenols.** By P. MÜLLER (*Ber.*, 20, 1039—1042).—When ammonio-zinc bromide (1 part), ammonium bromide (3 parts), and  $\alpha$ -orthoxylenol [Me: Me: OH = 1: 2: 4] (1 part), are heated for 40 hours at  $300^{\circ}$ , xylidine boiling at  $215$ — $220^{\circ}$  (the acetyl-derivative melts at  $134^{\circ}$ ), and dixylylamine are obtained. The latter boils, with partial decomposition, at  $330$ — $345^{\circ}$ ; it solidifies to a glassy mass when cooled by means of a mixture of ether and carbonic anhydride.

$\alpha$ -Metaxylylidine was prepared from  $\alpha$ -metaxylenol in a manner similar to the ortho-compound. It is colourless, but soon becomes brown; it boils at  $210$ — $215^{\circ}$ . The acetyl-derivative melts at  $129.5^{\circ}$ . The di- $\alpha$ -metaxylylamine, obtained in the same reaction, is an oil which boils at  $305$ — $310^{\circ}$ . Like the diortho-derivative, it solidifies when treated with ether and calcium anhydride. N. H. M.

**Aromatic Hydroxylamines.** By A. MICHAEL and G. M. BROWNE (*J. pr. Chem.* [2], 35, 358—359).—When an alcoholic solution of picric chloride is treated with aqueous hydroxylamine, *dipicrylhydroxylamine*,  $[\text{C}_6\text{H}_2(\text{NO}_2)_3]_2\text{N}\cdot\text{OH}$ , is obtained. This forms yellow needles soluble in alcohol. If ethyl picrate is substituted for the chloride, *picrylhydroxylamine*,  $\text{C}_6\text{H}_2(\text{NO}_2)_3\text{NH}\cdot\text{OH}$ , is produced; this forms silky, yellow needles, is soluble in alcohol, ether, and glacial acetic acid, and melts at  $99$ — $100^{\circ}$ . L. T. T.

**Azo-compounds.** By J. V. JANOVSKY (*Monatsh. Chem.*, 8, 49—63; compare *Abstr.*, 1886, 794 and 1024).—The bromazobenzene melting at  $187^{\circ}$ , and formerly described (*loc. cit.*) as monobromazobenzene, is the *dibromide*. *Parabromazobenzene* (N: Br = 1: 4) melts at  $82^{\circ}$ , and crystallises in brilliant orange plates. It is easily soluble in hot and cold alcohol, ether, &c. When treated with nitric acid in glacial acetic acid solution, it yields two substances—(a) a *bromonitroazobenzene* (N: Br = 1: 4) melting at  $107$ — $108^{\circ}$  (uncorr.), and crystallising in yellow needles; when boiled with ammonium sulphide this gives *amidobromazobenzene* crystallising in brilliant plates; (b) a *para-dinitroazobenzene*, melting at  $190^{\circ}$  and crystallising in woolly needles; when boiled with ammonium sulphide, this yields an amido-compound possessing strong tinctorial powers. When parabromazobenzene is treated with fuming sulphuric acid, a *bromazobenzenesulphonic acid*,  $\text{C}_{12}\text{H}_8\text{BrN}_2\cdot\text{SO}_3\text{H} + 3\text{H}_2\text{O}$ , is formed; it crystallises in orange-brown needles with a golden lustre; it gives well-defined, crystalline *sodium*, *potassium*, and *zinc* salts. The sodium salt is very insoluble in water.

The acid appears to be identical with the parazonbenzeneparasulphonic acid previously described by the author (Abstr., 1884, 1146).

The metabromazobenzene previously described (*loc. cit.*), when treated with fuming sulphuric acid, yields *metabromazobenzene-sulphonic acid*,  $C_{12}H_8BrN_2 \cdot SO_3H + 1\frac{1}{2}H_2O$ , which gives very insoluble alkaline salts. The *potassium* salt is precipitated from a 1 per cent. solution of the chloride in the form of pearly needles; the *sodium* salt is also thrown down from a 1 per cent. solution of sodium chloride in yellow, nacreous needles.

When orthodibromazobenzene (*loc. cit.*) is treated with nitric acid in acetic acid solution, it yields a *trinitrodibromazobenzene*, melting at  $135^\circ$  and crystallising in red needles.

When orthonitroazobenzene, previously described (*loc. cit.*), is treated with bromine, it yields a *monobromonitroazobenzene*, melting at  $132^\circ$ .

Orthonitroazobenzene behaves towards reducing agents in a manner entirely different from paranitroazobenzene (*loc. cit.*). The substance with strong tinctorial powers previously described is now considered

by the author to be *hexa-azoxybenzene*,  $O \begin{cases} N-C_6H_4N : NC_6H_5 \\ | \\ N-C_6H_4N : NC_6H_5 \end{cases}$ , an in-

termediate reduction product. It is an orange-yellow powder consisting of microscopic scales, and melts at  $206^\circ$  without decomposition. The mononitrosulphonic acids of azobenzene have been previously described by the author (Abstr., 1882, 834, and 1883, 867).

Orthoamidoazobenzene, the preparation of which has been previously described (*loc. cit.*), melts at  $123^\circ$ , and forms yellow needles with a brilliant lustre. Its salts are distinguished from those of ordinary amidoazobenzene by their form.

Another substance formed by the nitration of azobenzene in glacial acetic acid seems to be a *nitroazoxybenzene*; it melts at  $122^\circ$ , and forms red, pearly tables, often twinned like muscovite. When treated with bromine, it yields a bromine-compound, melting at  $126^\circ$ .

G. H. M.

**Reaction of Diazoamido-compounds with Phenols.** By K. HEUMANN and L. OECONOMIDES (*Ber.*, 20, 904—909).—Further investigation has shown that the formation of a hydroxyazo-compound by the action of diazoamidobenzene on phenol (this vol., p. 480) is also brought about when other diazoamido-compounds are employed. Diazoamidobenzene, when added to fused resorcinol and carefully heated, yields aniline and benzeneazoresorcinol (Abstr., 1878, 219). Diazoamidoparatoluene yields paratoluidine and paratolueneazophenol (this Journ., 1876, i, 268) when heated with phenol on a water-bath, and when added to fused resorcinol it forms paratoluidine and *paratolueneazoresorcinol*,  $C_7H_7 \cdot N_2 \cdot C_6H_3(OH)_2$ . This crystallises in yellowish-red needles, melts at  $184^\circ$ , and is readily soluble in alcohol, ether, benzene, and chloroform, yielding orange-coloured solutions. From diazoamidoparachlorobenzene and phenol, when heated on a water-bath, parachloraniline is obtained together with *chlorobenzeneazophenol*,

$C_6H_4Cl \cdot N_2 \cdot C_6H_4 \cdot OH$ ; this crystallises from chloroform in reddish-yellow needles, and melts at  $151-152^\circ$ . The action of phenol on diazoamidometabenzoic acid takes place more slowly than is the case with the foregoing diazoamido-compounds, but proceeds similarly, inasmuch as metamidobenzoic acid and phenolazobenzoic acid are obtained.

Hydroxyazo-compounds are also formed by the action of phenols on mixed diazoamido-compounds, and the results of the experiments are given in quantitative form. When diazoamidobenzeneparatoluene is heated with phenol at  $100^\circ$ , approximately equal weights of aniline and paratoluidine are obtained together with a compound melting at  $122^\circ$ , and consisting of two hydroxyazo-compounds which have not yet been separated. Diazoamidobenzeneparatoluene and resorcinol heated on a water-bath yield aniline, paratoluidine, and a hydroxyazo-compound. On heating diazoamidoparachlorobenzenebenzene and phenol at  $90^\circ$ , parachloraniline and hydroxyazobenzene were obtained, whilst diazoamidoparachlorobenzeneeparatoluene and phenol heated first at  $80-90^\circ$  and afterwards at  $110^\circ$ , yield parachloraniline and paratolueneazophenol.

W. P. W.

**Cinnamyl Hydrazine.** By L. KNORR (*Ber.*, **20**, 1107—1108).—In order to examine whether the formation of pyrazoline-derivatives from phenylhydrazine and acids of the acrylic series is analogous to the formation of pyrazole-derivatives from unsaturated ketones, cinnamyl hydrazine was prepared and its products of decomposition investigated. The hydrazide,  $C_{13}H_{14}N_2O$ , prepared from cinnamic acid or its ethereal salt, crystallises in minute needles which melt at  $183^\circ$ . On dry distillation, an oil passes over which solidifies in the crystalline form; its composition is expressed by the formula  $C_{15}H_{12}N_2O$ ; it melts at  $251^\circ$ , is insoluble in water, sparingly soluble in alcohol and ether, readily in alkalis and acids. It is proposed to carry on further investigations on homologous compounds.

V. H. V.

**Phenazoxine—a New Chromogen.** By A. BERNTHSEN (*Ber.*, **20**, 942—944).—*Phenazoxine*,  $C_6H_4 < \begin{smallmatrix} NH \\ -O- \end{smallmatrix} > C_6H_4$ , is obtained when equimolecular proportions of catechol and orthamidophenol are heated at  $260-280^\circ$  for 40 hours, and after treating the residue with water and aqueous soda, can be extracted from it by ether. It crystallises in bright, colourless scales, melts at  $148^\circ$ , distils with slight decomposition, and is readily soluble in alcohol, ether, benzene, and chloroform, sparingly soluble in light petroleum. When treated with concentrated nitric acid, it yields a crystalline *nitro*-derivative, which on reduction with tin and hydrochloric acid, and subsequent oxidation with ferric chloride, is converted into a reddish-violet dye; the reaction corresponding with the formation of Lauth's violet (thionine) from thiodiphenylamine. Phenazoxine dissolves in concentrated sulphuric acid with a violet-red colour, and its alcoholic solution yields a dark bluish-green coloration with ferric chloride, and a deep blue with bromine-water.

W. P. W.

**Action of Dehydrating Agents on Benzylideneacetoxime.**  
By N. ZELINSKY (*Ber.*, 20, 922—924).—*Benzylideneacetoxime*,

is obtained when benzylideneacetone (1 mol.) dissolved in alcohol is added to a solution of hydroxylamine hydrochloride ( $1\frac{1}{2}$  mol.) and sodium hydroxide ( $1\frac{1}{2}$  mol.) in aqueous alcohol, and the whole heated for some hours on the water-bath. It is crystalline, melts at 115—116°, boils without decomposition at 220° under 100 mm. pressure, and with bromine yields an additive compound, melting at 144—145° with decomposition.

With acetic chloride, an acetyl-derivative,  $\text{CHPh} : \text{CH} \cdot \text{CMe} : \text{NOAc}$ , is obtained, melting at 90—91°. Sulphuric acid does not effect a condensation, but phosphoric anhydride, or still better, phosphorus oxychloride reacts with benzylideneacetoxime yielding an oil having basic properties.

W. P. W.

**Methyl- and Ethyl-orange, and the Derived Dimethyl- and Diethyl-thionines.** By A. BERNTHSEN and A. GOSKE (*Ber.*, 20, 924—934).—*Methyl-orange* (sodium methylamidoazobenzenesulphonate),  $\text{SO}_3\text{Na} \cdot \text{C}_6\text{H}_4 \cdot \text{N}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{NHMe}$ , is obtained by diazotising sulphanilic acid and gradually adding the product to an aqueous solution of pure methyl-aniline hydrochloride heated at 30°; reddish-violet needles separate in large quantity, and when filtered off are dissolved in aqueous soda. It crystallises in large, orange-red laminae, and is readily soluble in hot, but only sparingly soluble in cold water. The yield amounts to 30 per cent. of the theoretical quantity.

*Sodium diazomethylamidobenzenesulphonate*,  $\text{SO}_3\text{Na} \cdot \text{C}_6\text{H}_4 \cdot \text{N}_2 \cdot \text{NMePh}$ , is formed together with methyl-orange in the process just mentioned if dilute solutions are employed, and the product is kept nearly neutral throughout by the continued addition either of aqueous soda or of sodium acetate; the methyl-orange is decomposed by heating with concentrated ammonium sulphide at 100° the product obtained on addition of salt to the solution, the diazoamido-compound remaining unaffected. It crystallises in white or very pale-yellow scales, is readily soluble in hot water, insoluble in alcohol, and is not affected by boiling with dilute alkali. Although colourless, it shows all the properties of a diazoamido-compound: thus, dilute acids convert it into the corresponding amidoazo-acid; when heated with concentrated hydrochloric acid, it yields methylaniline and paraphenol-sulphonic acid, and when warmed with an acetic acid solution of resorcinol it yields the yellowish-brown coloration characteristic of diazoamido-compounds. The authors find, moreover, that paradiazo-amidotoluene, when heated with ammonium sulphide at 100°, is obtained on cooling in large, transparent, thin prisms of a pale-yellow colour, although diazoamidobenzene does not lose its yellow colour when similarly treated.

*Ethyl-orange* (sodium ethylamidoazobenzenesulphonate) is prepared by a method similar to that used to obtain the methyl-compound, with the exception that the mixed solutions are kept nearly neutral throughout with aqueous soda. It crystallises in orange-red laminae.

The *acid* crystallises in glistening, bluish-violet needles, melts at about  $244^{\circ}$  with decomposition, and is insoluble in cold water and hot alcohol.

*Methylparaphenylenediamine* [ $\text{NH}_2 : \text{NHMe} = 1 : 4$ ] is obtained together with sodium sulphanilate when methyl-orange is warmed with ammonium sulphide. It boils at  $257\text{--}259.5^{\circ}$ , does not solidify in a freezing mixture, and is readily soluble in water, alcohol, and ether. The *sulphate*,  $(\text{C}_7\text{H}_{10}\text{N}_2)_2\text{H}_2\text{SO}_4$ , crystallises in needles. The corresponding ethylparaphenylenediamine (this vol., p. 244) can be obtained similarly from ethyl-orange; its *sulphate*,  $\text{C}_8\text{H}_{12}\text{N}_2\text{H}_2\text{SO}_4$ , crystallises in long, colourless needles or thin prisms.

*Dimethylthionine*,  $\text{NMe} \left\langle \begin{array}{c} \text{C}_6\text{H}_3 \text{---} \text{S} \\ | \\ \text{N} \cdot \text{C}_6\text{H}_3(\text{NHMe}) \end{array} \right\rangle$ , is obtained by the action of ferric chloride and hydrogen sulphide on methylparaphenylenediamine in acid solution; at the same time, a red compound analogous to methylene-red is also formed. The base is sparingly soluble in ether and alcohol, and the alcoholic solution shows a red fluorescence. The *hydrochloride* dissolves in water with a beautiful blue colour, and shows a reddish-brown fluorescence; the *hydriodide* is a dark-blue powder, soluble in hot water and hot alcohol; it dyes silk an almost pure blue. When the base is boiled with much water, it is

converted into methylthionoline,  $\text{O} \left\langle \begin{array}{c} \text{C}_6\text{H}_3 \text{---} \text{S} \\ | \\ \text{N} \cdot \text{C}_6\text{H}_3(\text{NHMe}) \end{array} \right\rangle$ , and when further saponified with 70 per cent. sulphuric acid yields thionol (Abstr., 1886, 53).

*Diethylthionine* obtained in a similar manner from ethylparaphenylenediamine, very closely resembles dimethylthionine in the colour of solutions, and the positions of the absorption-bands of the two compounds are almost identical. The maximum absorption of the darker band lies between C and D and near  $\lambda' = 625$ , that of the lighter band near  $\lambda'' = 580$  to  $585$ .  
W. P. W.

**Action of Nitrous Acid on Orthoamidobenzamide.** By A. WEDDIGE and H. FINGER (*J. pr. Chem.* [2], 35, 262—264).—Equimolecular proportions of sodium nitrite and a salt of orthoamidobenzamide are mixed in aqueous solution, when a yellowish-brown crystalline substance separates. Its composition is represented by the formula  $\text{C}_7\text{H}_5\text{N}_3\text{O}$ , it melts at  $213^{\circ}$ , and is easily soluble in alkalis. The following derivatives are described: the sodium salt,  $\text{C}_7\text{H}_4\text{NaN}_3\text{O}$ ; the ammonium and silver salts; and the methyl salt,  $\text{C}_7\text{H}_4\text{MeN}_3\text{O}$ , which can also be obtained by the action of nitrous acid on orthoamidobenzomethylamide; the constitution of the substance  $\text{C}_7\text{H}_5\text{N}_3\text{O}$  is thus determined to be  $\text{C}_6\text{H}_4 \left\langle \begin{array}{c} \text{CO} \cdot \text{NH} \\ | \\ \text{N} : \text{N} \end{array} \right\rangle$ .  
H. B.

**Oximes of Paraxyloquinone.** By J. SULKOWSKI (*Ber.*, 20, 977—981).—*Paraxyloquinoneoxime*,  $\text{C}_6\text{H}_2\text{Me}_2\text{O} : \text{NOH}$  [ $\text{Me} : \text{O} : \text{Me} : \text{NOH} = 1 : 2 : 4 : 5$ ], is obtained, together with a small quantity of the dioxime, when 10 grams of paraxyloquinone dissolved in 300 cc. of

80 per cent. alcohol is boiled with 5 grams of hydroxylamine hydrochloride for two hours. It crystallises in small, yellowish needles, melts at  $168^{\circ}$ , and is insoluble in water, readily soluble in alcohol, ether, and benzene. On reduction with tin and hydrochloric acid, it yields *paramidoxylenol hydrochloride*, crystallising in small needles; the base forms silvery scales, and melts at  $242^{\circ}$  with decomposition.

*Paraxyloquinonedioxime* is formed, together with an equal proportion of the monoxime, when twice the above quantity of hydroxylamine hydrochloride is employed. It is crystalline, melts at about  $272^{\circ}$ , and is insoluble in water, very sparingly soluble in hot alcohol, benzene, and acetic acid. The *diacetyl*-derivative crystallises in small, yellow prisms, melts at  $170^{\circ}$ , and is readily soluble in hot alcohol and benzene, insoluble in dilute alkalis. When reduced with tin and hydrochloric acid, the dioxime yields *diamidoxylenol hydrochloride*; this crystallises in white, glistening scales, and the base forms scales melting at  $142^{\circ}$  with decomposition.

When paramidoxylenol is heated with chloranil in acetic acid solution, a beautiful bluish-violet dye is obtained, together with tetrachloroquinol. The dye is insoluble in water, but soluble in alcohol, ether, benzene, and acetone, alkalis dissolve it with a pure blue colour, and the bluish-green solution in sulphuric acid shows a general darkening of the red end of the spectrum; analyses point to the formula  $C_{24}H_{26}N_2O_3$ . W. P. W.

**Bromorthotoluic and Bromophthalic Acids.** By C. NOURRISSON (*Ber.*, 20, 1016—1017).—*Bromorthotolunitrile*,  $C_6H_3MeBrCN$  [1 : 5 : 2], is prepared from bromorthotoluidine by Sandmeyer's reaction; it crystallises from alcohol in long needles which melt at  $70^{\circ}$ ; it distils readily with steam. When 10 grams of the nitrile are boiled with a solution of 10 grams of caustic soda in 100 c.c. of alcohol for  $1\frac{1}{2}$  hours, a mixture of bromotoluic acid and its amide is obtained. The latter dissolves in 10 parts of boiling alcohol, and separates in lustrous plates melting at  $180^{\circ}$ : it sublimes in needles which melt at  $181$ — $182^{\circ}$ . When treated with concentrated alcoholic potash solution, or with diluted sulphuric acid, it is converted into bromorthotoluic acid,

melting at  $187^{\circ}$ . When bromorthotoluic acid is oxidised with potassium permanganate, it is converted into  $\beta$ -bromophthalic acid,  $[COOH_2 : Br = 1 : 2 : 5]$ ; this is very soluble in warm water, and melts at  $168^{\circ}$ ; the anhydride melts at  $106$ — $108^{\circ}$ , and boils at  $297$ — $301^{\circ}$ . 70 grams of bromorthotoluidine yielded 60 grams of nitrile, and then 56 grams of toluic acid and 53 grams of crude bromophthalic acid. N. H. M.

**Reduction of the Isomeric Bromocinnamic Acids.** By A. MICHAEL (*J. pr. Chem.* [2], 35, 357—358).—The author has succeeded in reducing the so-called  $\alpha$ - and  $\beta$ -bromocinnamic acids to cinnamic acids by treating their solutions in glacial acetic acid with zinc-dust. No evolution of hydrogen takes place until 2 or 3 drops of platinum chloride has been added to the mixture. The acids appear to show

slight differences of crystalline form, &c., but whether this is due to traces of impurities merely is now being investigated. L. T. T.

**Mono- and Di-hydroxytoluic Acids.** By S. WEINREICH (*Ber.*, 20, 981—983).—Hydroxytoluic acid can readily be obtained from paratoluidine by converting it into the nitrile by Sandmeyer's reaction, saponifying this with sulphuric acid, sulphonating the toluic acid with concentrated sulphuric acid at 150—160°, and fusing the potassium salt of the resulting sulphotoluic acid with four times its weight of potassium hydroxide.

*Dihydroxytoluic acid* is prepared by heating paratoluic acid with crystallised sulphuric acid and phosphorus pentoxide at 250°. The barium salt,  $\text{COOH}\cdot\text{C}_6\text{H}_2\text{Me}(\text{SO}_3)_2\text{Ba} + 5\text{H}_2\text{O}$ , of the disulphotoluic acid obtained was analysed. On fusing the potassium salt with potassium hydroxide, dihydroxytoluic acid is obtained; this sublimes in colourless needles, melts at 175—176°, and is readily soluble in water, alcohol, and ether, sparingly soluble in benzene, toluene, and light petroleum. W. P. W.

**Ethyl Phthalate Chloride and its Decomposition with Ethyl Sodiomalonate.** By N. ZELINSKY (*Ber.*, 20, 1010—1013).—*Ethyl phthalate chloride*,  $\text{COOEt}\cdot\text{C}_6\text{H}_4\cdot\text{COCl}$ , is obtained by the action of phosphorus trichloride on sodium ethyl phthalate in presence of benzene or toluene as diluent; the solutions should be kept as cool as possible. The compound could not be isolated. When the solution in benzene, after being poured off from the phosphorous acid formed in the reaction, is treated with ethyl sodiomalonate suspended in benzene, a reaction takes place with separation of sodium chloride. The product is filtered, distilled in a vacuum until free from hydrocarbon and unchanged ethyl malonate, and the residue gradually treated with alcoholic potash. A potassium salt is obtained which is washed with alcohol, dissolved in water, and treated with sulphuric acid; the acid thus liberated is recrystallised from ether. It has the formula  $\text{C}_{21}\text{H}_{16}\text{O}_{10}$ , and melts rather above 180° with evolution of carbonic anhydride. When the product of the reaction is treated with an excess of alcoholic potash, a potassium salt different from that first obtained is formed; it yields an *acid* of the formula

of which the acid  $\text{C}_{21}\text{H}_{16}\text{O}_{10}$  is the *monethyl salt*,  $\text{C}_{19}\text{H}_{11}\text{EtO}_{10}$ .

N. H. M.

**Action of Phenylhydrazine on Anhydrides of Bibasic Acids, and especially on Phthalic Anhydride.** By B. HÖTTE (*J. pr. Chem.* [2], 35, 265—298).—When phenylhydrazine and phthalic anhydride in molecular proportion are intimately mixed, phenylhydrazinephthalic acid,  $\text{COOH}\cdot\text{C}_6\text{H}_4\cdot\text{CO}\cdot\text{NH}\cdot\text{NHPh}$ , already described by Pellizzari (*Abstr.*, 1886, 1025), is formed. The author finds the melting point to be 165—166°. The name *anilidophthalaminic acid* is proposed as most appropriate for this substance. When heated at 160—170°, this compound loses water, and is converted into phthalylphenylhydrazine (*Abstr.*, 1886, 353). The author was quite unable

to obtain the isomeric compound melting at  $210^{\circ}$ , said by Pellizzari (*loc. cit.*) to be formed at the same time. The constitution of the above compound is  $\text{C}_6\text{H}_4 < \begin{smallmatrix} \text{CO} \\ \text{CO} \end{smallmatrix} > \text{N} \cdot \text{NHPH}$ .

$\alpha$ -Phthalylldiphenylhydrazine,  $\text{C}_6\text{H}_4 : (\text{CO})_2 : \text{N} \cdot \text{NPh}_2$ , is prepared by heating phthalic anhydride and diphenylhydrazine at  $150$ — $170^{\circ}$ ; it crystallises in greenish-yellow plates, is soluble in alcohol, and melts at  $154$ — $155^{\circ}$ .

$\alpha$ -Phthalylbenzoylphenylhydrazine,  $\text{C}_6\text{H}_4 : (\text{CO})_2 : \text{N} \cdot \text{NBzPh}$ , is obtained when  $\alpha$ -phthalylhydrazine and benzoic chloride in molecular proportion are heated together at  $160$ — $170^{\circ}$ . It forms small, monoclinic tables, soluble in benzene, alcohol, and ether, and melts at  $193^{\circ}$ . When heated in closed tubes with fuming hydrochloric acid, it yields phenylhydrazine, and phthalic and benzoic acids.  $\alpha$ -Phthalylnitrosophenylhydrazine,  $\text{C}_6\text{H}_4 : (\text{CO})_2 : \text{N} \cdot \text{NPh} \cdot \text{NO}$ , is formed by treating the hydrazide suspended in ether with nitrous anhydride. It crystallises in pale yellow, rhombic tables, sparingly soluble in ether, and melting at  $153$ — $154^{\circ}$ . During one preparation of this substance, the author obtained a substance crystallising in white scales, and decomposing with explosive violence slightly above  $80^{\circ}$ . The substance soon became brown, and decomposed to a thick liquid of irritating odour. The nitroso-compound can also be obtained by passing nitrous anhydride into glacial acetic acid in which the hydrazide is suspended, if care be taken to keep the mixture cool. If the current of anhydride is continued until the mixture becomes green,  $\alpha$ -phthalylnitrophenylhydrazine,  $\text{C}_6\text{H}_4 : (\text{CO})_2 : \text{N} \cdot \text{NPh} \cdot \text{NO}_2$ , is obtained. This forms yellow, rhombic tables, soluble in alcohol and ether, and melts with decomposition at  $147$ — $148^{\circ}$ . With aqueous potash, it is decomposed into phthalic acid, phenylhydrazine, and potassium nitrite. If nitrous anhydride be passed into a hot acetic solution of  $\alpha$ -phthalylphenylhydrazine,  $\alpha$ -phthalylldinitrophenylhydrazine is formed. This is soluble in glacial acetic acid, from which it is precipitated in yellow flocks on the addition of water. It melts with decomposition at  $182^{\circ}$ , and is also decomposed by boiling alcohol or water. The one nitro-group has undoubtedly displaced the imidic hydrogen, but the position of the second is doubtful. When  $\alpha$ -phthalylphenylhydrazine is heated with alcoholic ammonia in closed tubes at  $70$ — $80^{\circ}$  for about three hours, phthalylphenylhydrazidamide,  $\text{NH}_2 \cdot \text{CO} \cdot \text{C}_6\text{H}_4 \cdot \text{CO} \cdot \text{N}_2\text{H}_2\text{Ph}$ , is formed. It is soluble in alcohol, nearly insoluble in ether, and crystallises in white plates melting at  $146^{\circ}$ . When heated at  $160$ — $170^{\circ}$ , or when boiled with dilute alcohol, ammonia is evolved and  $\beta$ -phthalylphenylhydrazine (see below) is formed; the latter is also produced when the heating of the closed tubes is extended much beyond three hours.

When phthalic anhydride is mixed with excess of phenylhydrazine, reaction occurs as above, but if the mixture is heated at  $150^{\circ}$  for three or four hours, phthalylldiphenyldihydrazine (*dianilidophthalylldiamide*),  $\text{C}_6\text{H}_4(\text{CO} \cdot \text{NH} \cdot \text{NHPH})_2$ , is formed; this crystallises in white tables melting at  $191^{\circ}$ . When heated with dilute hydrochloric acid, it is decomposed into  $\alpha$ -phthalylphenylhydrazine and phenylhydrazine. If, however, the diamide is heated alone at  $160$ — $170^{\circ}$ , phenylhydrazine is eliminated and  $\beta$ -phthalylphenylhydr-

*azine*,  $C_6H_4<\begin{smallmatrix} CO\cdot NH- \\ CO\cdot NPh \end{smallmatrix}>$ , is formed. This is also produced if the original mixture is heated at  $160-170^\circ$ . It crystallises in colourless prisms soluble in boiling alcohol, chloroform, and ether, and in alkalis, and melts at  $210^\circ$ . This compound has already been obtained by Pellizzari (*loc. cit.*), but its formation is undoubtedly due to the intermediate formation of the diamide, and not to the direct action of phthalic anhydride and phenylhydrazine in molecular proportion, as stated by Pellizzari. Its ammonium salt yields with silver nitrate a white voluminous precipitate,  $C_6H_4<\begin{smallmatrix} CO\cdot NAg \\ CO\cdot NPh \end{smallmatrix}>$ , soluble in ammonia, and unaltered by light. The *ethyl salt* crystallises in white needles soluble in alcohol and ether, and melts at  $105-106^\circ$ . When  $\beta$ -phthalylphenylhydrazine is heated with excess of benzoic chloride at  $200^\circ$ ,  $\beta$ -phthalylbenzoylphenylhydrazine,  $C_6H_4<\begin{smallmatrix} CO\cdot NBz \\ CO\cdot NPh \end{smallmatrix}>$ , is formed. It is crystalline, and melts at  $122^\circ$ , and has a faint odour of ethyl benzoate.

When benzoylphenylhydrazine and phthalic anhydride are heated together at  $180^\circ$ , *phthalylphenylbenzohydrazinic acid*,

is formed. It crystallises in white prisms melting at  $172^\circ$ , and soluble in alcohol. If the acid is heated alone, or the original mixture is heated at  $220^\circ$  for about a day, benzoic acid is eliminated, and  $\beta$ -phthalylphenylhydrazine formed.

When phenylhydrazine is heated with succinic anhydride,  $\alpha$ -succinylphenylhydrazine,  $C_2H_4 : (CO)_2 : N\cdot NHPh$ , is obtained whether the hydrazine is in excess or not. It crystallises in white plates melting at  $155^\circ$ , and with nitrous acid yields a *nitroso-derivative* forming yellow, feathery crystals melting at  $83-84^\circ$ . No corresponding  $\beta$ -compound could be obtained.

Maleic anhydride yields with phenylhydrazine *malëylphenylhydrazine*,  $C_2H_2 : (CO)_2 : N\cdot NHPh$ . It crystallises in needles which darken at  $180^\circ$ , and melt at  $258-259^\circ$ . If excess of the hydrazine is used, a dark brown, resinous mass is formed, from which no crystalline substance could be isolated.

L. T. T.

**Ethyl Triphenylcarbinylmalonate and  $\beta$ -Triphenylpropionic Acid.** By G. G. HENDERSON (*Ber.*, 20, 1014—1015).—*Ethyl triphenylcarbinylmalonate*,  $CPh_3\cdot CH(COOEt)_2$ , is prepared by adding ethyl sodiomalonate to an ethereal solution of triphenylcarbinyl bromide. It crystallises from boiling absolute alcohol in slender needles melting at  $133.5^\circ$ .

$\beta$ -Triphenylpropionic acid,  $CPh_3\cdot CH_2\cdot COOH$ , is obtained by saponifying the above ethyl salt with alcoholic potash. It melts at  $177^\circ$ , is almost insoluble in water, soluble in alcohol, and very readily soluble in ether. The *sodium salt* (with 1 mol.  $H_2O$ ) is readily soluble; the *barium salt* (with 1 mol.  $H_2O$ ) crystallises in needles sparingly soluble in hot water; the *silver salt* is insoluble in water.

N. H. M.

**Action of Ethyl Sodacetoacetate and Ethyl Sodiomalonate on the Ethyl Salts of Unsaturated Acids.** By A. MICHAEL (*J. pr. Chem.* [2], 35, 349—357).—When ethyl sodiomalonate is added to an alcoholic solution of ethyl cinnamate, it dissolves, and if the solution is allowed to remain for some time, or is heated for a short time at 100°, and then mixed with water, an oil is obtained. This oil boils with partial decomposition at 305—310°, but under 15 mm. pressure distils without change at 213—215°. It has the constitution

When saponified with strong potash or baryta, the ether yields *phenylglutaric acid*,  $\text{COOH}\cdot\text{CH}_2\cdot\text{CHPh}\cdot\text{CH}_2\cdot\text{COOH}$ , which crystallises in prisms easily soluble in alcohol and ethyl acetate, sparingly in benzene, insoluble in water; it melts at 137·5—138·5°. The *silver salt* is stable towards light.

When ethyl sodacetoacetate is substituted for ethyl sodiomalonate in the above reaction, a similar additive product seems to be formed, but the author has not yet isolated it, as it decomposes on boiling, even in a vacuum. The aqueous layer, however, contains a compound,  $\text{C}_{15}\text{H}_{16}\text{O}_4$ , which is probably formed by the elimination of sodium methylate from the additive compound first formed. It crystallises in needles soluble in alcohol, and melts at 139·5—140·5°. It shows the properties of a monobasic acid, and yields a *silver salt* crystallising in needles.

Ethyl citraconate and ethyl sodacetoacetate yield an additive compound,  $\text{C}_{15}\text{H}_{24}\text{O}_7$ , which forms a colourless oil, boiling at 173—174° under 26 mm. pressure. The aqueous layer also contains an acid, which, however, has not yet been isolated. These results show that in the action of ethyl sodiomalonate on ethyl  $\alpha$ -bromacrylate lately described by the author (this vol., p. 468), the action need not necessarily be due to the direct elimination of sodium and bromine, but that an additive product may first be formed, and sodium bromide be afterwards eliminated. This reaction is therefore not a proof that Perkin's trimethylene-derivatives are open-chain derivatives.

The author finds that ethyl disodomalonate does not act on ethyl succinate in the cold, but that at high temperatures it seems to split up into ethyl sodiomalonate and sodium ethylate, and then ethyl succinosuccinate is formed.

L. T. T.

**Formation of Indigo-blue from Orthonitrophenolpropionic Acid by Means of Potassium Cyanide.** By A. MICHAEL (*J. pr. Chem.* [2], 35, 254—256).—A solution of sodium orthonitrophenylpropionate, when heated with pure potassium cyanide and a little glucose, gives rise to the formation of indigo-blue, even in the presence of a large excess of hydrocyanic acid. With potassium cyanide alone, nothing but intermediate products seem to be formed. The action is to be regarded as one of simultaneous oxidation and reduction.

H. B.

**Derivatives of Benzidine.** By P. BRUNNER and O. N. WITT (*Ber.*, 20, 1023—1030).—*Tetramidodiphenyl*,  $\text{C}_{12}\text{H}_6(\text{NH}_2)_4$ , is obtained by warming orthodinitrobenzidine with stannous chloride and hydro-

chloric acid. The product is warmed with tin, diluted, and treated with hydrogen sulphide. It is then filtered and quickly evaporated in a current of hydrogen sulphide; the *hydrochloride* separates in white needles (with 2 mols.  $\text{H}_2\text{O}$ ). This is very readily soluble in water, and is precipitated on adding hydrochloric acid. The free base crystallises in plates of a silvery lustre, resembling benzidine; it becomes black when filtered, and therefore could not be analysed. The *sulphate*,  $\text{C}_{12}\text{H}_6(\text{NH}_2)_4 \cdot \text{H}_2\text{SO}_4$ , crystallises in slender, white needles, very sparingly soluble in water, alcohol, and ether. When the acetate is treated with phenanthraquinone hydrogen sulphite (2 mols.) a *condensation product* is obtained. It is sparingly soluble, and sublimes in yellow needles. Sulphuric acid dissolves it with a fine violet colour, which, when the solution is diluted, changes to red, orange, and yellow. When the acetate is treated with a solution of benzil in glacial acetic

acid, the compound 
$$\begin{array}{c} \text{CPh}\cdot\text{N} \\ \parallel \quad | \\ \text{CPh}\cdot\text{N} \end{array} \text{C}_{12}\text{H}_6 \begin{array}{c} \text{N}\cdot\text{CPh} \\ | \quad \parallel \\ \text{N}\cdot\text{CPh} \end{array}$$
 is formed. It is a whitish-

yellow substance, insoluble in alcohol, but readily soluble in phenol, from which it crystallises on adding glacial acetic acid. It does not melt at  $270^\circ$ . When the solution in sulphuric acid is carefully diluted, the *sulphate* crystallises in lemon-yellow needles.

The properties of tetramidodiphenyl and its power of condensing with orthodiketones, show that the four amido-groups form two pairs in the ortho-position; this, together with the fact that amido-groups in the original benzidine used have the para-position, points to the constitution  $\text{C}_6\text{H}_3(\text{NH}_2)_2 \cdot \text{C}_6\text{H}_3(\text{NH}_2)_2$  [ $\text{NH}_2 : \text{NH}_2 : \text{C}_6\text{H}_3(\text{NH}_2)_2 = 4 : 3 : 1$ ] for tetramidodiphenyl. In Strackosch's dinitrobenzidine (*Ber.*, 5, 236), the nitro-groups have the meta-position. When it is diazotised and the product boiled with alcohol, *dinitrodiphenyl*,  $\text{C}_6\text{H}_4(\text{NO}_2) \cdot \text{C}_6\text{H}_4(\text{NO}_2)$  [ $\text{NO}_2 = 3$ ], is obtained almost quantitatively. The latter crystallises from alcohol and glacial acetic acid in small yellow needles. It is dichroic, and melts at  $197\text{--}198^\circ$ .

*Symmetrical metadiamidodiphenyl*,  $\text{C}_6\text{H}_4(\text{NH}_2) \cdot \text{C}_6\text{H}_4(\text{NH}_2)$  is prepared by reducing the nitro-compound with tin and hydrochloric acid. It is obtained as an oil, which solidifies after some days, and is sparingly soluble in water, readily in ether. The *diacetate* forms long needles, insoluble in water, sparingly soluble in alcohol, toluene, and cumene, more readily in phenol and glacial acetic acid. It melts at  $257\text{--}258^\circ$ . The *sulphate* crystallises in long needles, insoluble in cold water, sparingly soluble in alcohol. When the base is diazotised, and the product treated with sodium naphthionate, an isomeride of Congo-red is obtained; this forms a reddish-yellow solution in water. Unmordanted cotton-wool is dyed by it an orange colour; the colour is not so deep, and is less readily obtained than in the case of Congo-red.

N. H. M.

**Derivatives of Diphenylethane.** By K. HEUMANN and J. WIERNIK (*Ber.*, 20, 909—915).—The authors find that diamidodibenzyl (*Annalen*, 137, 260), tetramethyldiamidodiphenylethane (*Abstr.*, 1879, 714), and the dihydroxydiphenylethane obtained when the former is diazotised, are not leuco-compounds, since they do not

give dyes but only pale-brown, green, or colourless products when treated with various oxidising agents.

The *methiodide* of tetramethyldiamidodiphenylethane,

is formed when diamidodibenzyl is heated with methyl iodide and a small quantity of potassium hydroxide at 150—180° for some hours; it cannot, however, be converted into the base by heating it with hydrochloric acid at 150°, whilst when heated to incipient fusion it yields a new base crystallising in small crusts. In the preparation of tetramethyldiamidodiphenylethane by Schoop's method (*loc. cit.*), an oily base is also formed, and can be separated from it by cooling.

W. P. W.

**Tetramethyldiamidobenzophenone.** By J. H. ZIEGLER (*Ber.*, 20, 1111—1113).—Contrary to the observations of Münchmeyer, tetramethyldiamidobenzophenone readily yields a condensation-product with phenylhydrazine hydrochloride; the hydrazone obtained crystallises in groups of needles, melting at 174—175°, soluble in ether, light petroleum, and benzene. With concentrated sulphuric acid, it forms a red salt, dissolving in sulphuric acid with red coloration; on addition of water the red changes to yellow, with evolution of hydrochloric acid. The hydroxide gives Liebermann's reaction, and with oxidising agents yields a light-green, and subsequently a brown coloration.

V. H. V.

**Synthesis of Juglone.** By A. BERNTHSEN and A. SEMPER (*Ber.*, 20, 934—941).— $\alpha$ -Hydroxyphthalic acid [ $\text{OH} : \text{COOH} : \text{COOH} = 1 : 2 : 3$ ] is obtained when finely powdered juglone is gradually added to an alkaline solution of hydrogen peroxide, and the product, after treatment with sulphuric acid, is extracted with ether. This result confirms the author's view that juglone has the constitution [ $\text{OH} : \text{O} : \text{O} = 1' : 1 : 4$ ] (*Abstr.*, 1885, 548; 1886, 363), which is further supported by the synthetical formation of the compound from 1 : 4' dihydroxynaphthalene on oxidation. When dihydroxynaphthalene (*Proc.*, 1887, 43), made into a thin paste with water, is treated with an excess of chromic mixture and allowed to remain for 24 hours, a *hydroxynaphthaquinone* separates, and after purification is found to be identical with juglone. The acetyl-derivative and the oxime of the synthetical compound are likewise identical with the corresponding juglone-derivatives.

The *diacetyl*-derivative of 1 : 4' dihydroxynaphthalene is crystalline, melts at 159—160°, and is converted into acetyljuglone on oxidation with chromic mixture.

W. P. W.

**1 : 3 Naphthylenediamine.** By C. URBAN (*Ber.*, 20, 973—974).—The dinitronaphthalene (m. p. = 144°) obtained on diazotising Liebermann and Hammerschlag's dinitronaphthylamine (this Journal, 1876, ii, 80), yields 1 : 3 naphthylenediamine when reduced with tin and hydrochloric acid, inasmuch as the product reacts as a metadamine with nitrous acid, and with diazo-compounds yields a chry-

soidine. The *hydrochloride*,  $C_{10}H_6(NH_2)_2 \cdot 2HCl$ , is readily soluble in water, soluble in alcohol, and sparingly soluble in ether; the *acetyl-derivative* crystallises in colourless, transparent prisms, melts at  $154-156^\circ$ , and is readily soluble in benzene. W. P. W.

**$\beta$ -Naphthyl-derivatives.** By E. BAMBERGER and O. BOECKMANN (*Ber.*, 20, 1115—1119).— $\beta$ -*Naphtholthiamide*,  $C_{10}H_7 \cdot CS \cdot NH_2$ , obtained by digesting  $\beta$ -naphthonitrile with ammonium sulphide, crystallises in long, pale-yellow needles, melting at  $149^\circ$ , and soluble in alcohol and ether, as also in hot water, but with decomposition into the nitrile and hydrogen sulphide. The thiamide, on hydrogenation with zinc and hydrochloric acid, yields  $\beta$ -*naphthylmethylamine hydrochloride*,  $C_{10}H_7 \cdot CH_2 \cdot NH_2 \cdot HCl$ , which crystallises in flat prisms, melting at  $260-270^\circ$ ; the *platinochloride* and *picrate* forms sparingly soluble needles. The free base crystallises in glistening thick prisms; it absorbs carbonic anhydride from the air with great avidity, and is sparingly soluble in cold, more readily in hot water and alcohol. By nitrous acid, the amine is converted into the corresponding *naphthyl carbinol*,  $C_{10}H_7 \cdot CH_2 \cdot OH$ , crystallising in silky needles, melting at  $80-80.5^\circ$ ; when oxidised with chromic mixture, it yields the *aldehyde*,  $C_{10}H_7 \cdot CHO$ , which crystallises in a similar form, and melts at  $60.5-61^\circ$ . This aldehyde has previously been obtained from  $\beta$ -naphthoic acid, as also from naphthyl chloride; it reduces ammoniacal solutions of silver, gives a red coloration with rosaniline sulphite, and a leuco-base with zinc chloride and dimethylaniline.

V. H. V.

**Nitrosoanthrone.** By A. GIMBEL (*Ber.*, 20, 974—977).—When nitrosoanthrone (*Abstr.*, 1881, 99) is treated with various reducing agents, a small yield of a base is obtained, which readily oxidises in the air, with the loss of its basic properties and of a portion of its nitrogen. On heating equimolecular proportions of nitrosoanthrone and bromine dissolved in carbon bisulphide at  $75^\circ$ , dibromanthracene (m. p.  $221^\circ$ ) is formed together with nitrous acid and nitric oxide, but no hydrogen bromide; whilst when bromine alone acts on the compound, a mixture of bromine additive-compounds of brominated anthracene is obtained. These are white, amorphous powders, melt at about  $260^\circ$  with evolution of bromine, and are converted into high brominated anthracenes by the action of alcoholic potash. When nitrosoanthrone is heated with concentrated hydrobromic acid at  $260^\circ$ , the above dibromanthracene is formed; concentrated hydrochloric acid at  $180^\circ$  converts it into a mixture of mono- and dichloranthracene, and with carbonyl chloride in benzene solution at  $160^\circ$  it yields dichloranthracene.

W. P. W.

**Action of Hydrogen on Nitro-derivatives of Terebenthene.** By C. TANRET (*Compt. rend.*, 104, 917—919).—When the hydrazo-camphenes, the nitro-derivatives of essence of terebenthene,  $C_{10}H_{17} \cdot NO_2$ , are subjected to the action of nascent hydrogen (from iron and dilute sulphuric acid), until they give no violet coloration with ferric chloride, they yield bases with peculiar properties.

2 y 2

These bases have the same composition,  $C_{20}H_{34}N_2O_2$ , and the same reactions, but like their generators differ in their physical properties. They are anhydrous, dissolve very readily in alcohol, ether, and chloroform, volatilise somewhat below their melting point, and emit a camphoraceous odour when sublimed.

The  $\alpha$ -compound forms flattened, lanceolate crystals which melt at  $190^\circ$ , and boil at about  $300^\circ$ , with gradual decomposition; soluble in 12 parts of water at  $13^\circ$ , but more soluble in boiling water; rotatory power  $[\alpha]_D = +50^\circ$ .

Two compounds,  $\beta$  and  $\beta'$ , are obtained from  $\beta$ -hydrazocamphene, which is thus resolved into two constituents. They can be separated by taking advantage of their different solubilities in water. The  $\beta$ -compound crystallises in rhomboidal tables which melt at  $67^\circ$ , and boil at about  $290^\circ$ ; soluble in 10 parts of water at  $13^\circ$ , less soluble in hot water; rotatory power  $[\alpha]_D = +27^\circ$ . The  $\beta'$ -compound forms slender needles which melt at  $128^\circ$ ; soluble in 40 parts of water at  $13^\circ$ , and in 30 parts at  $100^\circ$ ; rotatory power  $[\alpha]_D = +8^\circ$ .

These compounds are neutral to litmus. When heated for a long time in sealed tubes with potash or hydrochloric acid, they yield no ammonia, and therefore are not amines. With acids they form well-defined, crystallisable salts, which, however, are somewhat unstable. Their solutions give precipitates with tannin, iodine solution, and potassium mercuric iodide. From these reactions, it is evident that they are closely related to the neutral alkaloids, such as caffeine and narcotine.

$\alpha$ -Dihydrocamphene sulphate,  $\alpha\text{-}C_{20}H_{34}N_2O_2 \cdot H_2SO_4$ , exists only in acid solutions, and is completely decomposed by water. The hydrochloride,  $\alpha\text{-}C_{20}H_{34}N_2O_2 \cdot 2HCl$ , obtained by evaporating a solution of the base in the concentrated acid, is somewhat more stable in presence of water, but effloresces in the air and loses hydrogen chloride. The nitrate,  $\alpha\text{-}C_{20}H_{34}N_2O_2 \cdot 2HNO_3$ , crystallises from water without decomposition, and is more stable than the chloride, in presence of air. All these salts are very soluble in chloroform, but in presence of a suitable quantity of water they give up their acid to the water, like the salts of caffeine.

The platinochloride,  $(C_{20}H_{34}N_2O_2)_2 \cdot 6HCl \cdot PtCl_4$ , is obtained by mixing concentrated solutions of the chloride and platinic chloride. The mercurio-chloride,  $C_{20}H_{34}N_2O_2 \cdot HgCl_2$ , is prepared by adding mercuric chloride to a solution of dihydrocamphene. If a large excess of soda is poured into the solution of the mercurio-chloride, a crystalline powder of the composition  $C_{20}H_{34}N_2O_2 \cdot HgO$  is precipitated. This base dissolves in 70 parts of water at  $13^\circ$ , and in 30 parts at  $100^\circ$ , crystallises in slender, white needles, is not volatile, becomes coloured at  $225^\circ$ , and melts to a brown liquid at  $260^\circ$ ; rotatory power  $[\alpha]_D = +47^\circ$ ; soluble in ether and chloroform. It has an alkaline reaction, and with some acids it forms salts, but others, such as sulphuric acid, decompose it immediately. When neutralised with hydrochloric acid, it yields a salt of the same composition as dihydrocamphene mercuriochloride. It follows that dihydrocamphene mercuriochloride is really the hydrochloride of a mercurial base, *hydrargyrine*.

C. H. B.

**Terpinol.** By G. BOUCHARDAT and R. VOIRY (*Compt. rend.*, 104, 996—998).—The terpinol described by previous observers has been a mixture of substances obtained by several different reactions.

Terpin was boiled with very dilute sulphuric acid, the product distilled with water, and then fractionated, when it separated into two parts, one boiling at 170—176°, under ordinary pressure, and the other at 130—135°, under a pressure of 40 mm. When the second fraction is distilled, it yields a viscous liquid, with an odour of hyacinths, which remains liquid indefinitely, but if brought in contact with a crystal of caoutchene monohydrate, is slowly converted into a crystalline mass of the composition  $C_{10}H_{18}O$ , identical or isomorphous with caoutchene monohydrate. The crystals melt at 30—32°, and readily remain in superfusion, the sp. gr. of the liquid being 0.952. It boils at 218°, without alteration under ordinary pressure, and is inactive like terpene and caoutchene monohydrates. When treated with hydrogen chloride, it is completely converted into a dihydrochloride,  $C_{10}H_{18}Cl_2$ , and water.

The formation of this compound shows that terpinol contains an inactive monohydrate of terpinene, for which the authors propose the name terpinol or terpol.

The first fraction has the composition  $(C_{10}H_{16})_2 \cdot H_2O$ , and remains liquid even at  $-50^\circ$ ; sp. gr. at  $0^\circ = 0.900$ , and is intermediate between that of the preceding hydrate and that of the hydrocarbon; vapour-density, 4.66. When fractionated with a Le Bel tube, with six bulbs, the fractions all have the same sp. gr. 0.905—0.902. The authors consider that this fraction may be regarded as containing a compound of the terpinenic hydrocarbon,  $C_{10}H_{16}$ , with the hydrate already described, this compound decomposing on volatilisation into the hydrocarbon and the monohydrate, a supposition which will explain the abnormal vapour-density. The production of such a compound mixed with an excess of either the hydrocarbon or the monohydrate, would explain the contradictory results of previous observers.

With hydrogen chloride, this fraction behaves like the monohydrate, and yields a readily crystallisable dihydrochloride.

C. H. B.

**Manufacture of Santonin.** By A. BUSCH (*J. pr. Chem.* [2], 35, 322—341).—The author has been investigating some of the difficulties met with in the process of the extraction (on the manufacturing scale) of santonin from wormwood (*Artemisia maritima*). He gives an historical account of the growth of this industry.

The large percentage of resin obtained during the separation of santonin from its lime compound is due mainly to too high a temperature being employed, and to too little lime being originally added. At high temperatures, hydrochloric acid causes much of the base to resinify. The quantity of lime added to the original extract should be about 20 per cent., as otherwise much organic impurity is obtained in the solution. Part of the loss of santonin is also due to its absorption by the animal charcoal with which it is treated during the process of purification.

The santonin resin is not a homogeneous substance, but a mixture

of products of decomposition. Metallic salts, and especially lead salts (lead acetate), do not precipitate santonin from its alcoholic solutions, but do precipitate the santonin resins, and may be therefore used as a means of separating these.

L. T. T.

**Conversion of Pyrroline into Pyridine-derivatives.** By G. CIAMICIAN (*Gazzetta*, 17, 11—17).—Ciamician and Dennstedt have shown that potassium pyrroline is converted by chloroform or bromoform into monochloro-, or bromo-pyridine (*Abstr.*, 1882, 867). It would appear probable, *à priori*, that by the method of synthesis parachloropyridine would be produced, whereas the experiments of Lieben, and Staitinger, and those of Weidel show that the meta-derivative is produced. In order to explain this, it is suggested that the formation of chloro- or bromo-pyridines may be represented thus:  $C_4H_4NH + CHCl_3 = C_4H_3ClNCH + 2HCl$ ; consequently the halogen, no longer united to that carbon-atom which makes up the pyridine nucleus, replaces a hydrogen-atom in the meta-position. Such an explanation affords no account, however, of the similar formation of chloropyridine by means of carbon tetrachloride. In order to throw further light on this question, the reaction of benzal chloride,  $C_6H_5CHCl_2$ , with potassium pyrroline is studied with a view of obtaining the metaphenylpyridine, isolated by Skrap. It is shown by analysis, as also by the physical properties of the platinochloride, and of the picrate, that this phenylpyridine is identical with Skrap's compound. In view of these experiments, it is remarked that the formula for pyrroline proposed by R. Schiff can no longer be preferred to that of Baeyer, the latter of which illustrates more completely the relationship of pyridine, indole, thiophen, and furfuran.

V. H. V.

**Pyrazole-derivatives.** By L. KNORR (*Ber.*, 20, 1096—1106).—In order to examine the nature of the isomerism of the diphenylmethylpyrazoles obtained by treating phenylhydrazine with ethylic benzoylacetoacetate and benzalacetoacetate respectively, various methylphenyl-derivatives of pyrazole and pyrazoline were examined.

*Phenylhydrazinobenzalacetone*,  $C_{16}H_{16}N_2$ , obtained from phenylhydrazine and benzalacetone, crystallises in yellow needles melting at  $156^\circ$ , and is insoluble in water, soluble in hot alcohol and acetic acid. When distilled, it is converted into a mixture of 1 : 5 : 3 diphenylmethylpyrazole and 1 : 5 : 3 diphenylmethylpyrazoline; the latter is separated by its solubility in ether; it crystallises in large prisms.

*Phenyldimethylpyrazolecarboxylic acid*,  $\begin{matrix} \text{NPh} \cdot \text{CMe} \\ \text{N} = \text{CMe} \end{matrix} \text{C} \cdot \text{COOH}$ , is obtained as an ethyl salt from phenylhydrazine and ethyl ethylideneacetoacetate or ethyl acetylacetoacetate; it crystallises in needles melting at  $197^\circ$ ; it is almost insoluble in water and dilute acids, sparingly soluble in ether and petroleum; its silver, copper, and lead salts are amorphous precipitates; the ethyl salt forms colourless crystals melting at  $68^\circ$ , and boiling at  $286^\circ$  under a pressure of 260 mm. The acid, when heated above its melting point, gives off carbonic anhydride, and is converted into phenyldimethylpyrazole,

[Ph : Me<sub>2</sub> = 1 : 3 : 5], an oil boiling at 273°, of feeble basic character, insoluble in water and alkalis, soluble in alcohol, ether, and acids. When heated with methyl iodide, it yields a *methiodide*, C<sub>11</sub>H<sub>12</sub>N<sub>2</sub>, MeI, melting at 190°, soluble in alcohol and chloroform.

On treating phenyldimethylpyrazole with sodium amalgam, it is converted into the corresponding pyrazoline, C<sub>11</sub>H<sub>14</sub>N<sub>2</sub>, a liquid boiling at 290°; this may also be obtained from phenylhydrazine and ethylideneacetone.

V. H. V.

**Syntheses of Quinoline-derivatives by means of Ethyl Acetoacetate.** *γ*-Hydroxyquinaldine. By M. CONRAD and L. LIMPACH (*Ber.*, 20, 944—959).—When aniline and ethyl acetoacetate in molecular proportion are allowed to remain in the cold, or heated at 100° for some hours, ethyl anilacetoacetate is obtained. This compound, which the authors consider to be ethyl *β*-phenylamido-*α*-crotonate, NPh·CMe : CH·COOEt, decomposes when rapidly heated at 240° for a few minutes, and yields a distillate amounting to 40 per cent., consisting chiefly of ethyl alcohol, acetone and carbanilide, and a viscid residue from which water extracts *γ*-hydroxyquinaldine; the yield of this compound amounts to 26 per cent. At the same time, ethyl phenyllutidonemonocarboxylate is also obtained, and the relative proportions of the two compounds depend on the temperature and duration of the heating.

*γ*-Hydroxyquinaldine, [OH : Me = 2' : 4'], crystallises from water with 2 mols. H<sub>2</sub>O in glistening prismatic crystals; these become anhydrous at 114°, and have a solubility of 1 in 10 parts of boiling, and 1 in 100 parts of cold water, the solution being feebly alkaline. The anhydrous compound melts at 230—231°, distils above 360° with much decomposition, and is readily soluble in alcohol, very sparingly soluble in ether, benzene, and light petroleum. It has an intensely bitter taste, is not volatile with steam, and its aqueous solution yields an intense reddish-yellow coloration with ferric chloride. The *mercurochloride* forms slender needles; the *chromate* is sparingly soluble, and melts at 106—108°; the *picrate* crystallises in slender, bright-yellow needles, and melts at 200°; the *hydrochloride*, C<sub>10</sub>H<sub>9</sub>NO, HCl, is crystalline, and the *platinochloride*,

forms bright yellow, matted needles, melts at 215°, and is sparingly soluble in cold water. On oxidation with potassium permanganate acetylanthranilic acid is obtained.

*γ*-Hydroxyquinaldine, when treated with bromine-water in the cold, yields a yellow additive-compound, which after a time is converted into a white *dibromo-derivative*, C<sub>10</sub>H<sub>7</sub>Br<sub>2</sub>NO; an excess of bromine-water converts it into a white *tribromohydroxyquinaldine*, C<sub>10</sub>H<sub>6</sub>Br<sub>3</sub>NO, melting at 275°.

*Nitro-γ*-hydroxyquinaldine, C<sub>10</sub>H<sub>8</sub>(NO<sub>2</sub>)NO, is obtained when hydroxyquinaldine is heated with nitric acid (sp. gr. 1.4); it crystallises in slender needles, melts above 270°, and is very sparingly soluble in benzene or alcohol. On reduction with tin and hydro-

chloric acid, it yields *amido- $\gamma$ -hydroxyquinaldine*; this forms white, prismatic crystals, decomposes at  $225^{\circ}$  without melting, and is very sparingly soluble in ether, readily soluble in alcohol and hot water, the aqueous solution showing a bluish fluorescence. The *hydrochloride*,  $C_{10}H_8NO \cdot NH_2 \cdot HCl + H_2O$ , forms white crystalline tufts.

*$\gamma$ -Chloroquinaldine*,  $C_{10}H_8NCl$ , is obtained in almost the theoretical quantity by heating anhydrous  $\gamma$ -hydroxyquinaldine with phosphorus pentachloride at  $130$ — $140^{\circ}$ . It melts at  $42$ — $43^{\circ}$ , boils when carefully dried, at  $270^{\circ}$  without decomposition, and is sparingly soluble in water, readily soluble in alcohol, ether, benzene, chloroform, and carbon bisulphide. The *picrate* crystallises in tufts of long needles, and melts at  $178^{\circ}$ ; the *platinochloride*,  $(C_{10}H_8NCl)_2 \cdot H_2PtCl_6$ , is a yellow, crystalline precipitate. Chloroquinaldine when heated with water at  $220^{\circ}$  is converted into  $\gamma$ -hydroxyquinaldine, and when dissolved in acetic acid saturated with hydrogen iodide, and heated at  $250$ — $270^{\circ}$  for eight hours, is reduced to quinaldine. On treatment with bromine-water in the cold, chloroquinaldine appears to form an orange-coloured additive-compound with 4 atoms of bromine, but when this is heated with alcohol, ethyl bromide is evolved, and the *hydrobromide* of chloroquinaldine,  $C_{10}H_8NCl \cdot HBr$ , is obtained in white, acicular crystals.

*Phenylamidoquinaldine*,  $[Me : NHPh = 2' : 4']$ , is obtained by heating equimolecular proportions of chloroquinaldine and aniline at  $190^{\circ}$ . It crystallises in prisms, melts at  $150$ — $151^{\circ}$ , and dissolves sparingly in ether, but readily in alcohol and hot benzene.

*Methoxyquinaldine*,  $[Me : OMe = 2' : 4']$ , is formed when chloroquinaldine (1 mol.) and methyl alcohol are heated with sodium methoxide (1 mol.) at  $130$ — $140^{\circ}$  for two hours. It crystallises in long, slender needles, melts at  $82^{\circ}$ , distils at  $294$ — $298^{\circ}$  without decomposition, and is sparingly soluble in hot water, readily soluble in alcohol and ether. It has a peppermint-like taste, an alkaline reaction, and is only slightly volatile with steam. The *mercurochloride* melts at  $232^{\circ}$ .

*Methyl- $\gamma$ -quinaldone*,  $[Me : Me : O = 1' : 2' : 4']$ , can be obtained either by heating methoxyquinaldine in a sealed tube at  $315^{\circ}$ , or by heating  $\gamma$ -hydroxyquinaldine with methyl iodide at  $120^{\circ}$  for two to three hours. It forms white acicular crystals, fuses at  $156^{\circ}$ , melts at  $160^{\circ}$ , and is readily soluble in water, alcohol, and boiling benzene, sparingly soluble in ether. It has a pure bitter taste. The *mercurochloride* crystallises in slender, matted needles, and melts at  $187^{\circ}$ ; the *platinochloride*,  $(C_{11}H_{11}NO)_2 \cdot H_2PtCl_6$ , is crystalline and melts at  $240^{\circ}$  with decomposition.

When  $\gamma$ -chloroquinaldine in a moist or impure state is heated to the distilling point, a vigorous reaction occurs and the whole is suddenly converted into a bluish-violet mass; this is insoluble in ether, but dissolves in alcohol and water, with an intense bluish-violet coloration. The compound is the hydrochloride of a colour-base,  $C_{30}H_{22}N_3Cl \cdot 2HCl$ ; the base itself is insoluble in water, readily soluble in alcohol and ether, melts at about  $220^{\circ}$ , and yields intensely blue salts with acids.

W. P. W.

**Methylnaphthaquinolines and  $\beta$ -Naphthacridine.** By J. H. REED (*J. pr. Chem.* [2], 35, 298—322).—C. Beyer has shown (Abstr., 1886, 629) that dimethylquinoline is formed when aniline acts on a mixture of acetone and paraldehyde, and cincholepidine when the paraldehyde is replaced by methylal. The author carried out similar syntheses in the naphthalene series.

*Dimethyl- $\beta$ -naphthaquinoline*,  $C_{10}H_6 \begin{smallmatrix} \text{CMe : CH} \\ \text{—N : CMe—} \end{smallmatrix}$ , is formed when a cooled mixture of one part of paraldehyde and two of acetone is saturated with hydrogen chloride,  $\beta$ -naphthylamine hydrochloride (obtained by mixing  $\beta$ -naphthylamine with strong hydrochloric acid) then added, and the whole heated on the water-bath. The base crystallises in broad needles, soluble in alcohol, acetone, ether, glacial acetic acid, carbon bisulphide, and chloroform. It is only very sparingly soluble in boiling water and very slightly volatile in steam. It melts at 126—127°, and distils with partial decomposition above 300°. The *picrate* crystallises in small yellow needles, sparingly soluble in alcohol, ether, and acetone, and melting at 215°. The *dichromate*,  $(C_{15}H_{13}N)_2 \cdot H_2Cr_2O_7$ , crystallises in orange needles, sparingly soluble in pure water, easily so in water slightly acidified with sulphuric acid; it melts with decomposition at 115°. The *platinochloride*,  $(C_{15}H_{13}N)_2 \cdot H_2PtCl_6 + 2\frac{1}{2}H_2O$ , yields small needles. The *hydrogen sulphate*,  $C_{15}H_{13}N \cdot H_2SO_4$ , crystallises in small needles; the *nitrate* in thick needles melting at 181°; the *methiodide*,  $C_{15}H_{13}N \cdot MeI$ , in brownish needles. When nitrous anhydride acts on the base, either in the presence or absence of water, the nitrate is alone formed, no nitro- or nitroso-derivative being produced. When bromine acts on excess of the base in ethereal solution, the compound  $(C_{15}H_{13}NBr_2)_2 \cdot HBr$  is formed as an orange, crystalline powder, melting at 207°. When boiled with 90 per cent. alcohol and animal charcoal, this substance is converted into the *bromide* of the base,  $C_{15}H_{13}N \cdot HBr + 2H_2O$ , crystallising in white needles. *Dimethyl- $\beta$ -naphthaquinolinesulphonic acid*,  $C_{15}H_{12}N \cdot SO_3H + 1\frac{1}{2}H_2O$ , is obtained by dissolving the base in 5 parts of cold fuming sulphuric acid, and pouring the product into water. It crystallises in small, colourless needles which melt without decomposition, and yield crystalline *potassium* and *copper* salts. If the solution in fuming acid be heated for an hour at 150—160°, it yields the *disulphonic acid*,  $C_{15}H_{11}N(SO_3H)_2 + 4\frac{1}{2}H_2O$ , which crystallises in needles, very soluble in alcohol, ether, and water: when heated, it decomposes without previous fusion. The *copper salt* crystallises with  $5H_2O$ , the *barium salt* with  $7H_2O$ . When fused with potash, the disulphonic acid yields *dimethyl- $\beta$ -hydroxynaphthaquinolinesulphonic acid*,  $OH \cdot C_{15}H_{11}N \cdot SO_3H + 1\frac{1}{2}H_2O$ . This crystallises in yellow needles, and when heated decomposes without previous fusion. The dihydroxy-base could not be obtained. When oxidised with potassium permanganate, the base yields  *$\beta$ -dimethylphenylpyridinedicarboxylic acid*,  $C_{13}H_{11}N(COOH)_2$ . The free acid is a syrup, and gives a white *silver salt*.

*Dimethyl- $\alpha$ -naphthaquinoline* is formed when  $\alpha$ - is substituted for  $\beta$ -naphthylamine in the above reaction. It crystallises in thick colourless needles, which are easily soluble in light petroleum,

sparingly so in alcohol, and melt at 43—44°. The *picrate* crystallises from alcohol in long, yellow needles melting at 223°. The *platino-chloride* forms an unstable, yellow, crystalline precipitate. Bromine and methyl iodide form crystalline derivatives.

When a mixture of methylal and acetone is saturated with hydrogen chloride,  $\beta$ -naphthylamine hydrochloride added, and the whole heated on the water-bath, *methyl- $\beta$ -naphthaquinoline* is formed together with small quantities of  *$\beta$ -naphthacridine*, and a base,  $C_{24}H_{20}N_2$ .  $\beta$ -Naphthacridine crystallises in straw-coloured needles melting at 216°. Its *picrate*, *hydrochloride*, *sulphate*, and *nitrate* are sparingly soluble in alcohol. This  $\beta$ -naphthacridine is also produced when no acetone is employed, and is probably due to the formation, during the reaction, of formaldehyde from the methylal. The base  $C_{24}H_{20}N_2$  crystallises in short prisms, melting at 202—203°. The author considers that it is most likely *methyl- $\beta$ -amidonaphthylhydroquinoline*. The *picrate* and the *methiodide* are both crystalline. Methyl- $\beta$ -naphthaquinoline crystallises in needles, melts at 112°, and forms a crystalline *picrate*.

The author believes that the naphthacridine is formed according to the equations :—

L. T. T.

**Skatole from Strychnine.** By C. STOEHR (*Ber.*, 20, 1108—1111).—In a former paper (this vol., p. 604), the author showed that the product of distillation of strychnine with lime gave the pinewood reaction. At the end of the distillation, a most marked faecal odour is observed; and this is traced to the presence of skatole, as evidenced by analysis of the *picrate*, as also by the production of a yellow coloration when concentrated nitric acid is added to the aqueous solution, and the separation of a yellow, flocculent precipitate on addition of sodium nitrite. This result confirms the view that of the nitrogen-atoms in strychnine, the one forms part of a skatole or indole nucleus, the other of a hydride of a pyridine-derivative, probably methylpyridine.

V. H. V.

**Ecgonine.** By W. GINTL and L. STORCH (*Monatsh. Chem.*, 8, 78—81).—A notice as to the directions in which the authors are working.

**Bile Acids.** By P. LATSCHINOFF (*Ber.*, 20, 1043—1053).—An examination of the products of oxidation of ox-gall yielded the following results:—Anhydrous cholic acid (if it is capable of existing) has the formula  $C_{25}H_{42}O_5$ ; the hydrated cholic acid has the formula  $C_{25}H_{42}O_5 + \frac{1}{4}H_2O$  when dried at 175°.

Anhydrous choleic acid has the formula  $C_{25}H_{42}O_4$ ; the hydrated acid dried at 175° has the formula  $C_{25}H_{42}O_4 + \frac{1}{4}H_2O$ . It contains two alcoholic hydroxyl-groups, and loses 4 atoms of hydrogen on conversion into dehydrocholeic acid,  $C_{25}H_{38}O_4$ .

Mylius's desoxycholic acid (Abstr., 1886, 480) is identical with hydrated choleic acid.

Cholic and choleic anhydrides are obtained by heating the acids at  $165^{\circ}$ .

The proportion of choleic to cholic acid in ox-gall is about 1 to 3.3 (comp. *Ber.*, 18, 3043). N. H. M.

**Crystalline Form of Choleic Acid.** By P. LATSCHINOFF (*Ber.*, 20, 1053—1056).—Anhydrous choleic acid crystallises in the rhombic system (hemihedric),  $a : b : c = 1 : 0.5057 : 1.85979$ ,  $a$  being the macro-axis,  $b$  the brachy-axis, and  $c$  the principal axis. The faces observed are  $0P$ ,  $P_{\infty}$ ,  $2P_{\infty}$ ,  $P$ , and  $\infty P_{\infty}$ .

Choleic acid (with  $1\frac{1}{2}$  mol.  $H_2O$ ) crystallises in the quadratic system,  $a : c = 1 : 2.48282$  ( $c$  being the length of the principal axis). The crystals are a combination of three quadratic pyramids.

N. H. M.

**Action of Oxidising Agents on Albumin from Eggs.** By C. WURSTER (*Ber.*, 20, 1030—1033).—Fresh unfiltered albumin was treated with 1 per cent. sodium chloride solution and 1 per cent. lactic acid and shaken for 10 minutes; it was then mixed with hydrogen peroxide, placed in a eudiometer over mercury, and heated at  $37$ — $40^{\circ}$  in an incubator. Coagulation generally took place without evolution of gas; oxygen was in all cases absorbed, although in small quantity. When the product, to which the name egg-casein is ascribed, is digested in the eudiometer with pepsin and hydrochloric acid at  $37^{\circ}$ , no change in the volume of the oxygen could be observed.

*Egg-casein* is readily soluble in dilute ammonia, and is precipitated on adding an acid. When treated with ammonia in presence of hydrogen peroxide, it is converted into a sparingly soluble, transparent, gelatinous substance. The latter dissolves slowly in aqueous soda. It has the property of completely precipitating aniline dyes from their solutions. When dried, it becomes horny and insoluble.

N. H. M.

**Behaviour of Sodium Nitrite towards Albumin from Egg and the Colouring Matter of Blood.** By C. WURSTER (*Ber.*, 20, 1033—1039).—Albumin is not affected by  $\frac{1}{2}$  and 1 per cent. sodium nitrite solution at  $37^{\circ}$ . When the solution is made acid with lactic acid, it acquires a yellow colour, and coagulation takes place. When exposed to air in an incubator the colour darkens; when filtered and dried the precipitate becomes first orange-red, then fox-red.

The author showed previously that fresh blood does not decompose hydrogen peroxide in presence of lactic or acetic acids. The colouring matter of the blood is changed to a brownish-black substance, which is slowly decolorised by hydrogen peroxide, showing the various shades from dark-brown to white. No red colour is produced.

It is suggested that the colour of blonde and dark-brown hair may be due to the action of hydrogen peroxide on the colouring matter of the blood, whilst that of red and black hair is produced by the action of nitrous acid on the albumin and on the colouring matter of the blood respectively. The sudden becoming grey of

hair is accounted for by hydrogen peroxide being forced up into the hair, where it would give rise to an evolution of oxygen.

Observations made by the author on the formation of pigment in the skin under the influence of the sun are described.

N. H. M.

## Physiological Chemistry.

**Period required for Digestion in the Pig.** By ELLENBERGER and HOFMEISTER (*Bied. Centr.*, 1887, 158—160).—The emptying of the stomach commences in 18 to 24 hours after feeding, and is completed in 36 hours, but a portion of the less digestible food generally remains in the large intestine, and may remain there for eight days; hence it is here that sparingly soluble poisons will be found. A portion of the meal remains in the stomach until the next meal is given, provided the period of time between the two meal times is not too lengthy, and then, if the meal is ample, all the residue of the former meal will be removed from the stomach, but if otherwise, a portion will remain. The first portions of the meal enter the small intestine within three hours, and in three hours more the cæcum is filled. The food remains but a short time in the smaller, whilst it remains a long time in the larger intestine. The reaction of the contents of the intestines is as follows:—Contents of the stomach, acid; only at the commencement of digestion and in the neighbourhood of the cardiac is it alkaline. The first portion of the small intestine (two-thirds or five-sixths) has an acid reaction, the remainder is alkaline; the contents of the duodenum are acid, the ileum (*Hüft darm*) alkaline, and the jejunum variable.

**Behaviour of the Three Isomeric Nitrobenzaldehydes in the Animal Body.** By N. SIEBER and A. SMIRNOW (*Monatsh. Chem.*, 8, 88—93).—The experiments were made on dogs. 2 to 3 grams of each of the isomeric nitrobenzaldehydes were administered daily to dogs; this was continued for eight days, and then it was stopped for eight days, being given again at the end of that time. This treatment was continued for two months.

The results showed that all three nitrobenzaldehydes were oxidised in the organism to the corresponding nitrobenzoic acids, but were excreted in different forms. Paranitrobenzaldehyde is excreted as paranitrohippuric acid carbamide, metanitrobenzaldehyde as metanitrohippuric acid, and orthonitrobenzaldehyde as orthonitrobenzoic acid.

G. H. M.

**Therapeutic Action of Methylal.** By A. MAIRET and COMBE-MALE (*Compt. rend.*, 104, 1022—1024).—The authors have administered methylal in a large number of cases of mental derangement of various kinds. The results were highly satisfactory except in the case

of alcoholic frenzy, and the commencement of simple insanity with nocturnal agitation. The dose required is 5 to 8 grams, and the effect is purely hypnotic. The action on the brain is transient, and there is no after-depression, and no interference with nutrition or any other functions.

The system somewhat rapidly becomes accustomed to the drug, which then ceases to produce any useful hypnotic effect, and in order to obtain the best results its administration must be discontinued for two or three days.

## Chemistry of Vegetable Physiology and Agriculture.

---

**Decomposition of Carbonic Anhydride by Chlorophyll.** By PRINGSHEIM (*Bied. Centr.*, 1887, 168).—The author combats Regnard and Timiriazeff's conclusions drawn from their experiments on chlorophyll (*Abstr.*, 1886, 254 and 266), but considers that it is not the chlorophyll colouring matter which decomposes carbonic anhydride, but a compound which by reduction of the anhydride is converted into chlorophyll. If the author is correct, then the absorption-bands of chlorophyll between B and C stand in no relation to the decomposition of carbonic anhydride, seeing that the compound which according to Timiriazeff decomposes carbonic anhydride does not show or produce these bands.

E. W. P.

**Physiological Rôle of Vine Leaves.** By H. MUELLER (*Ann. Agronom.*, 13, 140).—A large number of leaf-bearing shoots should be sacrificed during the ripening of the fruit. These leaves require a large quantity of sugar for their development and for the support of their respiration. In removing the old leaves during the ripening of the fruit, too great a loss of assimilating tissues need not be feared, because the old leaves have only feeble assimilating power, and are moreover in the shadow of the upper leaves. The quantity of water contained in the leaves exercises a considerable influence on the amount of sugar they form. If two shoots are cut off and placed in darkness until all the starch has disappeared, then one of these simply placed in water, and the other injected with water under pressure, the latter will form starch much more abundantly than the former. The transformation of starch into sugar is similarly affected.

The vessels of climbing plants constitute important reserves of water, and in cultivating the vine as it is done in France these are lost. The vine cultivated in France also appears very inactive in habit, since the leaves do not commence the work of assimilation until June, whereas the American vines commence much earlier. Perhaps it is on this account they resist the phylloxera better.

J. M. H. M.

**Is Nitric Acid Formed in the Organism of Higher Plants?**

By U. KREUSLER (*Ber.*, 20, 999—1001).—Potatoes were grown in saw-dust treated with a solution containing suitable nourishment free from nitrogen. The plant was then tested for nitrates with negative results. Hence it is concluded that the high percentage of nitrates found in the potato plant at certain times is not the product of any process connected with vegetation.

N. H. M.

**Intermolecular Respiration.** By S. JENTYS (*Ann. Agronom.*, 13,

138).—Experiments on wheat, radish, and *Philadelphus coronarius* show that it is much easier to obtain intramolecular respiration in plants from amylaceous seeds than in those from oleaginous seeds; it takes place when the pressure of oxygen falls to 38 mm. When there is no oxygen, the first disengage much more carbonic anhydride than the second. Germinating seeds are much more sensitive to the diminution in the pressure of oxygen than older plants. With the buds of the *Philadelphus*, a very strong diminution in the oxygen pressure does not produce intramolecular respiration. The author admits with Detmer that it is the non-nitrogenous products of the decomposition of albuminoids which give rise to both sorts of respiration.

J. M. H. M.

**True Nature of Starch Cellulose.** By GRIESSMAYER (*Bied.*

*Centr.*, 1887, 190—192).—The investigation was undertaken to ascertain the true nature of the coating said to surround the true grains of starch (granulose). Meyer considers this coating not to consist of a compound present in the unaltered granule, but to be the result of change of the starch; this substance is obtainable by the action of acid, pepsin, &c., and is convertible into dextrin, and finally into saccharine compounds. This amyloextrin is with difficulty separated, unless it crystallises in spherocrystals; these crystals then react on polarised light in the same manner as starch grains, only that the dark cross is not orthogonal, but diagonal. The coatings can be obtained by the following method: 1000 grams of potato starch is allowed to remain for 100 days in 6 litres of 12 per cent. hydrochloric acid, the coatings are then separated and filtered off, and washed with water: when dried they weigh about 300 grams, and when boiled in water they dissolve almost entirely; there, however, remains a small portion of cellulose tissue, fat, &c.; from the solution, cold causes the dissolved compound to separate, forming spherocrystals of amyloextrin.

E. W. P.

**Sugars of the Soja Bean.** By T. MORAWSKI and J. STINGL

(*Monatsh. Chem.*, 8, 82—84; compare Abstract, 1886, 829).—The sugars, which occur in the soja bean to the extent of 12 per cent., were examined by precipitation with barium hydroxide and decomposition of the precipitate with carbonic anhydride. In this way, a light-coloured syrup was obtained, which was dissolved in 90 per cent. alcohol, and the solution fractionally precipitated with ether. Well-defined crystals of sucrose were obtained from the two last fractions with ether; this sugar was identified by polarisation before and after inversion. The uncrystallisable fractions contained sugars

which could not be identified with certainty; the rotatory power was higher than that of sucrose, and the sugars were more difficult to invert. The amount of sugar found, both by Fehling's solution and by polarisation, after inversion, was too small for the amount of sugar originally present.

G. H. M.

**Fat of the Soja Bean.** By T. MORAWSKI and J. STINGL (*Monatsh. Chem.*, 8, 85—87; compare Abstract, 1883, 1024).—The authors conclude from the results of the "saponification value," the "iodine value," and the determination of the amount of free fatty acid, that the soja bean oil lies between marrow-seed oil and sesame oil. It most resembles the former. The sp. gr. of the fat is 0.9270 at 15°.

G. H. M.

**Russian Black Earth.** By E. BRÜCKNER (*Bied. Centr.*, 1887, 148—149).—In many districts in West-South Russia soil is found containing a large percentage of humus (2 to 19 per cent.). Dokutschajef finds, as a rule, that this deposit consists of two layers; the upper, 0.5 m. thick, being homogeneous, fine-grained, and of a clayey consistency, and permeated by a thick network of grass roots; the lower layer of a similar character, but pierced with cavities and passages. No satisfactory explanation has as yet been given of the formation of this soil.

E. W. P.

**Value of the Phosphoric Acid in Thomas Slag.** By M. MÄRCKER (*Bied. Centr.*, 1887, 148—156).—Ground Thomas slag was compared with superphosphate and precipitated phosphates as manure for barley, oats, potatoes, and sugar-beet. The superphosphate yielded the highest results, and no difference in the composition of the crop as occasioned by the varieties of phosphate could be detected. On moorland soils, slag was found to surpass the other forms of phosphate, or at least to equal them.

## Analytical Chemistry.

---

**New Gas Burette.** By B. FRANKE (*J. pr. Chem.* [2], 35, 259—262).—The burette holds exactly 100 c.c., and is closed at one end by a small stopcock, at the other end by a wide bore stopcock leading into a wide tube holding some 50 c.c.; this serves to introduce the absorption reagent, and is closed by a stopper bearing a small stopcock. The sample of gas having been enclosed in the burette, the other half is completely filled with the absorption reagent, and the two well brought into contact by opening the wide bore stopcock and shaking; the reagent is then drained back into the reservoir, and ultimately poured out; the reservoir filled with water, and the whole being introduced into a cylinder of water, the large stopcock is opened, the pressure adjusted, and the volume read off. The apparatus is very simple and allows of very rapid estimations.

H. B.

**Burette Jet.** By W. LEYBOLD (*Zeit. anal. Chem.*, **26**, 230).—This jet, which requires no pinchcock, is closed at its upper end. A hole is blown in the side near that end, and the rough glass is filed away. The jet is thrust into the rubber tube so far that the hole is covered. The liquid is then delivered by squeezing up the rubber where it covers the hole.

M. J. S.

**Use of "Solid Bromine" for Decomposing Sulphuretted Minerals and Metallurgical Products.** By A. BRAND (*Zeit. anal. Chem.*, **26**, 222—226).—The article introduced into commerce by Franke as "*Bromum solidificatum*" consists of siliceous earth fritted together by means of a trace of alkali in the form of rods, and saturated with bromine. The rods of 7 mm. diameter contain about 1 gram; those of 15 mm. about 3 grams per centimetre. They afford a convenient and economical means of employing a definite quantity of bromine for any operation, especially as a substitute for chlorine in the attack of mineral sulphides, &c. The boat containing the substance is thrust into a tube connected with the bulbs for absorbing the volatile bromides; a sufficient number of the bromine rods are then inserted, and the tube is closed by a plug of plaster of Paris and a cork. The bromine is then driven over the heated substance by warming the rods. Sulphur, antimony, arsenic, and mercury are completely volatilised; copper, lead, nickel, cobalt, and silver remain in the boat; iron and zinc are incompletely driven over. A gram of substance can be completely decomposed in half an hour.

M. J. S.

**Iodometric Studies.** By G. TOPF (*Zeit. anal. Chem.*, **26**, 137—217).—The addition of ammonium carbonate to solution of thiosulphate, recommended by Mohr as a means of preserving its strength, has no such effect, and moreover leads to serious errors in titrating iodine in a solution which is not acidified. Although ammonium carbonate has little effect on iodide of starch, yet with iodine it forms both iodate and hypiodite, the latter of which immediately oxidises some of the thiosulphate to sulphate instead of to tetrathionate. The consequence is that less thiosulphate is required for decoloration, and although the addition of hydrochloric acid, after the disappearance of all the iodine, sets free that which had been converted into iodate, the results are still deficient by the amount consumed in forming sulphate. A series of titrations was made with thiosulphate solutions to which ammonium carbonates of various composition were added in the proportion of 2 and 5 grams per litre respectively. The deficiency in the quantity of iodine indicated was observed in every case, except in that in which, after the addition of the carbonate (2 grams per litre), carbonic anhydride was passed through the solution to produce ammonium hydrogen carbonate. The deficiency ranged from 3 to 20 per cent.; it increased with increase in the quantity of ammonium salt added, but diminished as that was more highly carbonated.

If an alkaline carbonate is present in a liquid, a little more iodine must be added to produce the blue colour with starch than would be the case in the absence of the alkali. On adding hydrochloric acid, all the missing iodine is recovered. The normal carbonates of the fixed

alkalis have a greater effect than that of normal ammonium carbonate, whilst the hydrogen carbonates of all the alkalis are practically without influence. Nevertheless even these, and other substances of very feeble alkalinity added to an iodine solution before titrating with thiosulphate, have an effect similar to that of ammonium carbonate on the thiosulphate solution, and to an extent far exceeding their retarding action on the formation of iodide of starch. With the hydroxides of sodium, barium, and calcium, the tendency is chiefly to the formation of iodate; nevertheless, as much as 34 per cent. of the iodine present has been observed to be consumed in the formation of sulphate. Dilution, or reduction of the proportion of alkali added, diminishes the total quantity of iodine absorbed, but increases the oxidation relatively to the formation of iodate. With the normal carbonates of sodium, potassium, and lithium, oxidation takes place to about the same extent as with the hydroxides, but there is less iodate formed. The hydrogen carbonates have a lower, but by no means insignificant action. It is entirely one of oxidation, no iodate being formed. With ammonia and normal ammonium carbonate, the tendency is chiefly to the formation of sulphate; the proportion of iodate rises with increased proportion of carbonic acid. The effect of ammonium hydrogen carbonate is far greater than that of the corresponding sodium and potassium salts.

Mixtures of alkaline carbonates with excess of barium, calcium, or zinc chloride, although neutral to phenolphthaleïn, still cause considerable oxidation to sulphate. Little or no iodate is formed. Zinc and magnesium hydroxides and magnesium carbonate cause both oxidation and formation of iodate. Aluminium hydroxide, on the contrary, has no action. An excess of alum added to ammonia produces a mixture which is entirely without influence on the titration of iodine.

M. J. S.

**Reaction of Thiosulphates.** By F. A. FLÜCKIGER (*Chem. Centr.*, 1887, 362; compare this vol., p. 297).—The reduction of thiosulphates to sulphides by sodium, or by a mixture of zinc and iron filings in presence of soda, or by simple ignition, had been already published by the author in his "Pharmaceutical Chemistry."

M. J. S.

**Zinc Determination.** By M. BRAGARD (*Chem. Centr.*, 1887, 365).—Of the methods of precipitation as zinc sulphide, that with an alkaline sulphide, when Fresenius' precautions are attended to, gives the sharpest results, but the precipitate is troublesome to filter. Finkener's modification, in which the zinc is precipitated by hydrogen sulphide from a liquid very feebly acidified with sulphuric acid and largely diluted, yields a pulverulent precipitate which is easily washed. Precipitation from a formic or acetic acid solution gives good results, and is suitable for the separation of zinc from iron and nickel.

In the volumetric determination by sodium sulphide, ferric hydroxide may be used as an indicator. If test-papers are used those of lead and thallium exceed all others in sensitiveness. In determining volumetrically by potassium ferrocyanide with uranic nitrate as indi-

cator, a piece of filter-paper must be laid over the uranium paper so that only the clear liquid comes in contact with the latter.

M. J. S.

**Detection and Estimation of Aluminium in Wine and Grapes.** By L. L'HOTE (*Compt. rend.*, **104**, 853—855).—250 c.c. of wine is evaporated to a syrup in a platinum dish, and mixed with pure sulphuric acid. The carbonised mass thus obtained burns readily to a white ash in a muffle. The ash is treated with 15 c.c. of nitric acid, mixed with 100 c.c. of a solution of ammonium molybdate in nitric acid (50 grams molybdic acid per litre), heated to boiling, the phosphomolybdic acid filtered off, and the iron and aluminium precipitated in the filtrate by ammonia and ammonium sulphide. The precipitate is roasted in presence of air, reduced in a current of hydrogen, and then heated in a current of hydrogen chloride, when the iron volatilises. The residue is treated with hydrofluoric and sulphuric acids to remove silica, strongly heated and weighed. It may be proved to be aluminium by heating it on charcoal with cobalt nitrate. A blank experiment is made with the same reagents and the aluminium found is deducted in each experiment.

Wines from seven localities were found to contain 0.012—0.036 gram of alumina per litre.

479 grams of red grapes gave 0.013 gram of alumina, whilst the stalks from which they had been stripped (6.482 grams) contained 0.003 gram.

C. H. B.

**Detection and Estimation of Vanadium in Minerals.** By L. L'HOTE (*Compt. rend.*, **104**, 990—992).—The substance (4 parts) is intimately mixed with carbon (1 part) and heated at 250° in a current of chlorine in a tube connected with a condensing apparatus consisting of several bulbs containing distilled water. If the substance contains arsenic, it should first be roasted in presence of air. The presence of vanadium is indicated by the formation of a red coloration, due to vanadic acid in the first bulb. If the quantity is too small to be recognised in this way, the contents of the bulbs are dissolved in dilute hydrochloric acid, evaporated to dryness, and moistened with *colourless* ammonium sulphide, when the characteristic colour of vanadium sulphide becomes visible.

Small quantities of vanadic acid can be estimated by Margueritte's method for the estimation of small quantities of iron. A standard solution of vanadium is prepared by dissolving vanadic anhydride in sulphuric acid; 1 c.c. of this solution = 0.00028 gram of vanadium. The solutions can be reduced with zinc and titrated with very dilute permanganate solution, care being taken to use distilled water which has no action on the permanganate.

If the proportion of vanadium in the mineral is considerable, the contents of the first bulb will be greenish-blue, and when evaporated with ammonia and heated to redness vanadic anhydride is left, and can be weighed.

By this method, the author has detected vanadium in two specimens of bauxite, two specimens of pitchblende, a hydrated ferric oxide, and basic Bessemer slag.

C. H. B.

**Estimation of Vanadic Acid.** By A. DITTE (*Compt. rend.*, 104, 982—987).—When ammonium vanadate is precipitated in presence of ammonium chloride and washed with a solution of this salt as in Berzelius' method, it is necessary to remove the ammonium chloride adhering to the precipitate, since it would partially reduce the latter on heating. If strong alcohol is used for this purpose, the ammonium chloride is precipitated in the filter, and is only dissolved with difficulty, whilst if dilute alcohol is employed, small quantities of the vanadate are dissolved. The following method avoids these difficulties.

When the vanadic acid is present in the form of a pure alkaline salt, the solution, if not already neutral or alkaline, is mixed with ammonia and heated until colourless. The solution is cooled to 30—40°, mixed with powdered ammonium chloride until nearly saturated, then with four or five volumes of alcohol, and allowed to remain. If the solution is saturated with the ammonium chloride at a temperature not exceeding 40°, the alcohol precipitates only a small quantity of the salt, and this readily dissolves during washing. Care should be taken to avoid rubbing the sides of the vessel. The precipitate is collected and washed with alcohol.

If the solution contains salts which are only slightly soluble in alcohol, it is mixed with a slight excess of solid ammonium chloride, then with 4 or 5 vols. of a saturated solution of this salt, and allowed to remain for several hours. The clear liquid is decanted off through a filter, and the precipitate mixed with a fresh quantity of ammonium chloride solution, care being taken that a small quantity of the undissolved solid is always present. After remaining for some hours, the liquid is again decanted off, and this treatment is repeated two or three times according to circumstances. The filter is then washed with hot water to dissolve the adhering precipitate, and the solution is allowed to run into the beaker containing the bulk of the precipitate, which is partially dissolved, and the liquid now contains ammonium vanadate partly in solution, partly precipitated, but free from other salts. It is treated in the manner described above.

The washed ammonium vanadate is dried and heated in a platinum capsule until the filter burns, and is then kept in fusion until the precipitate is completely oxidised. In order to prevent the formation of  $V_2O_4$ ,  $V_2O_5$ , the partially roasted precipitate is moistened with nitric acid, dried, and then fused.

When the vanadic acid is not present in combination with an alkali, the other metallic oxides must be removed by suitable methods, and the vanadic acid converted into an alkaline salt. C. H. B.

**Determination of Nitrates in Well Waters.** By L. SPIEGEL (*Chem. Centr.*, 1887, 363—364).—Wagner's chromic oxide method (this Journal, 1871, 753) did not give satisfactory results. The most accurate is the Schulze-Tiemann method (this Journal, 1873, 529, and 1874, 91), but it is necessary that the end of the gas delivery tube should be plunged deep in the soda solution, that boiled ferrous chloride and hydrochloric acid should be used, and that the last traces of nitric oxide should be driven over into the measuring tube by

carbonic anhydride. Of the methods depending on reduction to ammonia, that of Harcourt and Siewert with König's modifications is the most suitable. Heating over the free flame, however, inevitably causes potash to be carried over.

Good results can be obtained by the Marx-Trommsdorf indigo process, if the nitrate solution used in standardising is of approximately the same strength as that to be tested. Nitrites have, for the same quantity of available oxygen, the same oxidising power as nitrates. Both of these methods are vitiated by organic matter.

A colorimetric process based on the blue coloration with diphenylamine in strong sulphuric acid gives a fairly accurate determination very readily. At least 9 volumes of sulphuric acid must be used for 1 volume of water. Organic matter is without influence, but ferric salts produce a blue colour by themselves and must be removed.

M. J. S.

**Detection of Cane-sugar, Glucose, and Dextrin in Wines.** By TONY-GARCIN (*Compt. rend.*, 104, 1002—1003).—The wine is decolorised by means of animal charcoal, and its rotatory power and reducing power are determined.

When the reducing power is equivalent to 2 grams or less, and the rotatory power is more than  $+13'$ , the wine contains some foreign dextrogyrate substance. If the wine contains more than 2 grams of reducing matter per litre, 1.5 gram is deducted, and the remainder is multiplied by 6 and distinguished by the sign  $+$ . This is added algebraically to the observed rotatory power expressed in minutes, and if the sum is greater than  $+13'$ , the wine probably contains foreign dextrogyrate substances, and this conclusion is certain if the excess above  $+13'$  is equal to  $10'$ .

The nature of the foreign matter is determined by chemical methods; cane-sugar by inversion, dextrin by saccharification; glucose, in the absence of cane-sugar and dextrin, by the relation between the reducing action and rotatory power of the wine.

When polarimeters other than Laurent's are used, it may be taken that the rotatory power of wines free from foreign dextrogyrate matter is never more than  $+13'$ .

C. H. B.

**New Test for Coniferin.** By H. MOLISCH (*Chem. Centr.*, 1887, 366).—An alcoholic 20 per cent. solution of thymol is diluted with water as long as it remains clear; an excess of solid potassium chlorate is added and after some hours the mixture is filtered. Coniferin, treated with a drop of this solution and two drops of strong sulphuric acid, acquires a fine blue colour when evaporated in direct sunlight. A wood section, or wood-pulp paper moistened with this solution, and a drop of hydrochloric acid rapidly becomes blue even in the dark. Since coniferin is only present in lignified cell-walls, thymol may probably be of use in the microscopic detection of wood-fibre.

M. J. S.

## General and Physical Chemistry.

---

**Absorption-bands of Chlorophyll.** By F. STENGER (*Ann. Agronom.*, 13, 175—176).—Reinke has maintained that the dark bands in the absorption spectrum of chlorophyll do not correspond with the maximum absorption of light, but that some of them are mere effects of contrast, subjective impressions due to the eye itself. The present memoir is directed against this conclusion. J. M. H. M.

**Electromotive Force produced by Light in Selenium and the Consequent After-action.** By S. KALISCHER (*Ann. Phys. Chem.* [2], 31, 101—108).—About the same time that Bell discovered that an intermittent exposure to light generated a current in selenium which affected the telephone, the author met with a selenium cell which under the action of light produced a current which could be detected by a galvanometer. As it appeared that those who have paid special attention to the preparation of selenium cells have seldom met with cells which were so sensitive to light, an attempt was made in the first place to discover the proper mode of making such cells.

The cell consisted of two parallel wires wound round a stem, with selenium melted between them. In order to ensure the sensitiveness of the cell to light, it was heated to 190—195°, kept at this temperature for half an hour, and then allowed to cool for an hour. If at first not successful, a repetition of the process produced the desired result.

When such a cell is inserted in a galvanometer circuit and exposed to the action of light, there is a permanent deflection. It is found that the cells which are sensitive have a large specific resistance. To produce a current in general, a very intense source of light is necessary. The sensitiveness, and with it the specific resistance, were found in many cases to diminish with the time. The author believes that these facts are very well explained by the hypothesis advanced by Siemens that there is a metallic modification of selenium.

Again, if a cell is placed in an arm of a Wheatstone's bridge and the balance obtained in the usual manner, on allowing light to fall for an instant on the cell, there is a deflection, but the mirror does not return to its position of rest at once, and gradually creeps up to a fixed position. This is not due to the effect of heat, for it occurs even when the cell is shielded by an alum cell, or by a current of water circulating round it.

It is proposed to call this phenomenon after-action (*Nachwirkung*), from the analogy it presents to other well-known physical facts. The analogy is traced out by showing that the after-action is dependent on the duration and the intensity of the illumination of the cell. It is also shown to be independent of the direction of the current.

C. S.

**Density of Liquid Methane and of Liquefied Oxygen and Nitrogen.** By K. OLSZEWSKI (*Ann. Phys. Chem.* [2], 31, 58—74).—In some previous experiments, the author had determined the densities of liquefied gases at varying temperatures and pressures. It was impossible to compare the results with each other, because of the large coefficient of expansion of a liquefied gas and the very considerable alteration of volume by pressure. A determination of the densities at a common pressure, namely, the pressure of the atmosphere, and at the corresponding temperature of the boiling points, was attempted.

The chief part of the apparatus was a glass tube, into which the gas was condensed. This tube was very carefully annealed by heating it in anhydrous magnesia and allowing it to cool very gradually, a process which fitted it to withstand great changes of temperature and severe pressure.

Ethylene was made to circulate through a copper spiral, surrounded by a freezing mixture of carbonic anhydride and ether, contained in a vessel which was exhausted. Thus a large quantity of ethylene was rendered liquid, and passed into a vessel surrounding the condensing tube. When this vessel was exhausted so that the pressure sank to a few millimetres of mercury, the temperature of the ethylene fell so much that the gas in the tube was liquefied. The temperature of the boiling point had first to be measured. For this purpose about 12 to 15 c.c. of liquid gas was produced as already described under pressure, and after a time the pressure was gradually diminished to atmospheric pressure. The liquid was then gently boiled, and after a short time evaporation went on at the surface alone until the whole was vaporised. As this took about 5 to 15 minutes, there was ample time to take the temperature of the boiling point. This was determined by means of a hydrogen thermometer; a comparison instituted to compare the indications of thermometers filled with other gases showed that for the temperatures recorded the readings did not differ by more than about 1°.

To determine the density of the liquefied gas, it was condensed into the glass tube which had been calibrated, so that its volume was easily read off from a millimetre scale. The pressure being lowered to atmospheric pressure, the liquefied gas vaporised, and the amount of vapour produced was found from the volume of water displaced in an aspirator. Thus with the known readings of the barometer and thermometer the weight of the liquefied gas was determined, and from it the density.

The mean results of the experiments are given in the table:—

| Substance.     | Pressure. | Temp.   | Density. |
|----------------|-----------|---------|----------|
| Methane .....  | 736·6 mm. | −164·0° | 0·415    |
| Oxygen .....   | 742·1 „   | −181·4  | 1·124    |
| Nitrogen ..... | 742·1 „   | −194·4  | 0·885    |

**Vapour-density Apparatus.** By T. T. P. B. WARREN (*Chem. News*, 55, 228).—A modification of Victor Meyer's tube.

**Determination of Vapour-densities.** By C. SCHALL (*Ber.*, 20, 1435—1441).—A Jolly's air thermometer modified for vapour-density determination is described with sketch; results obtained by means of the apparatus are given. The author recommends the method for substances with high boiling points; it has the advantage over the methods of Habermann and La Coste, in not requiring such large amounts of substance or capacious apparatus for heating.

N. H. M.

**Expansion and Compressibility of Water: Displacement of the Point of Maximum Density by Pressure.** By E. H. AMAGAT (*Compt. rend.*, 104, 1159—1161).—The apparatus was so arranged that the water was always brought to the same volume at the particular temperatures, the pressure required being measured. If the same pressure is necessary at two different temperatures, it is evident that the point of maximum density lies between them. The effect of the alteration in the volume of the piezometer is eliminated, since it must be the same in both cases. The pressures employed exceeded 3200 atmos., and the temperature varied from 0—50°.

Under a pressure of 200 atmos., the point of maximum density is very near 0°, and seems to lie between 0° and 0.5°. At 700 atmos., it is below 0°.

If the phenomena at each temperature are represented by a curve with the pressures for abscissæ and the volumes for ordinates, the series of curves represent the volumes occupied by the same mass of water at different temperatures and pressures. These curves intersect at points which correspond with changes in the sign of the dilatation of the water, and as the pressure increases they arrange themselves successively in the order of the temperatures. At 200 atmos. they are normal, and are closer together the lower the temperature. As the pressure increases, the coefficient of expansion increases, at first rapidly, and afterwards more slowly, contrary to the phenomenon observed with all other liquids. At about 3000 atmos., the coefficient of expansion ceases to increase, and probably at still higher pressures it diminishes, like that of all other liquids. For equal pressures, the effect is less marked the higher the temperature.

Between two given pressures, the compressibility diminishes as the temperature rises, as previously observed by Grassi, a behaviour contrary to that of all other liquids. This result is a natural consequence of the disappearance of the point of maximum density. For the same reason, diminution in the coefficient of compressibility disappears as the pressure increases, and it also disappears with elevation of temperature, as Pagliani and Vicentini have observed. The temperature at which the inversion takes place is lower the higher the pressure.

A sufficiently high pressure brings water into the category of ordinary liquids; at about 3000 atmos., the last traces of perturbation of the ordinary laws, resulting from the existence of a point of maximum density, disappears.

No other liquid hitherto examined by the author has shown any signs of a point of maximum density under any pressure.

C. H. B.

**Compressibility of Aqueous Solutions of Chlorides.** By M. SCHUMANN (*Ann. Phys. Chem.* [2], 31, 14—58).—Four very sensitive piezometers were used. The compressibility,  $\mu$ , was determined from the formula—

$$\mu = \frac{\Delta v}{v} \frac{760}{p} + K,$$

where  $v$  is the volume of the solution, and  $\Delta v$  the change of volume produced by pressure  $p$ .  $p$  was measured by a mercury manometer,  $v$  by weighing the piezometer filled with distilled water,  $\Delta v$  by calibrating the capillary tube attached to the instrument.  $K$ , as Regnault and Grassi pointed out, is a constant which must be determined for each particular instrument by subtracting the apparent compressibility of water as observed in it from the value of the true compressibility given by Regnault.

Experiments were made with four or five solutions of different strengths of ammonium, barium, potassium, strontium, calcium, and sodium chlorides at two different temperatures, so that the temperature coefficient of compressibility could be found for the purpose of reducing all the results to one common temperature for the sake of comparison.

The general results of the paper are :—The compressibility of water is considerably altered by the addition of the chlorides, and in a different degree for each chloride. The compressibility of a solution diminishes as the strength increases. As regards the effect of temperature, all weak solutions have a greater compressibility at  $0^\circ$  than at higher temperatures, as in the case of water; in the case of ammonium and calcium chlorides, and seemingly of potassium chloride, this is true for all degrees of concentration. For sodium and strontium chlorides, after a certain strength of solution is reached, the influence of temperature is independent of the strength of the solution.

The results of the experiments are recorded in numerous tables, and the values obtained for the compressibility of the several solutions appear to agree well with the other determinations that have been made, especially with those of Röntgen and Schneider (*Ann. Phys. Chem.* [2], 29, 165).

The conclusion of the paper is occupied in tracing the connection between the compressibility of the solutions and the equivalent weights of the salts dissolved. The relation between the pressure required to produce the same change of volume as is caused by the solution of the salt, and the amount of salt dissolved, is investigated.

C. S.

**Rate and Vapour-tension of Dissociation.** By W. MÜLLER-ERZBACH (*Ann. Phys. Chem.* [2], 31, 75—78).—The present paper is a reply to some objections which have been made by Lescœur against the author's method of determining the vapour-tension of dissociation. Lescœur (this vol., p. 100) states that the rate of dissociation is a

function of the state of the body as well as of the tension, and on this ground considers Müller-Erzbach's formula to be erroneous.

On the other hand, it is pointed out that in the case of hydrated solutions, the author's method gives results in accordance with those which have been obtained by others from the barometric method. In the case of salts containing water of crystallisation, he finds that within wide limits the tension is independent of the weight of the substance employed and the dimensions of the tubes containing it. During the melting of sodium hydrogen phosphate, the vapour-tension remained constant. Finally he asserts that in many cases the barometric method is very unsatisfactory, because, especially after heating, the values of the tension are often too great, whereas his own method gave constant results for considerable periods of time.

C. S.

**Effect of Pressure on the Decomposition of Dissolved Chlorides.** By G. FOUSSEREAU (*Compt. rend.*, **104**, 1161—1163).—The method previously employed to determine the degree of alteration of chlorides in aqueous solution (*Abstr.*, 1886, 844, 975), has been used to investigate the effect of pressure on the rate and extent of the change. A variation of about 1 atmo. produces no sensible effect. A pressure of 175 atmos. causes a reduction of about 1 per cent. in the resistance of a dilute solution of ferric chloride, which indicates that the decomposition is increased by pressure. After removal of the pressure, the resistance of the liquid gradually resumes its normal value. The effect of pressure on very dilute solutions cannot be very great, since the dissociation is almost complete under ordinary pressure. With a stronger solution of ferric chloride, a pressure of 175 atmos. produces a diminution in the resistance amounting to nearly 5 per cent., and hence it is evident that with stronger solutions the effect of pressure is much greater. When the pressure is removed, the resistance gradually returns to the normal value.

A solution of aluminium chloride shows similar phenomena in a lower degree.

C. H. B.

**Velocity of Chemical Reactions.** By F. URECH (*Ber.*, **20**, 1634—1636).—This paper is an explanation of a criticism of Reicher on the author's statement that in any reaction between two substances, A and B, the velocity of the reaction is affected in different degrees by the presence in excess of A, or of its equivalent of B. On the other hand, the investigations of Reicher on saponification have shown that the presence on the one hand of excess of alkali, and on the other of excess of ethereal salt, does not affect the value of the specific velocity.

It is here shown that in the differential equation  $\frac{-dt}{dC} = \frac{1}{K_1 C \cdot C_1^2}$  C cannot be taken as either greater or less than  $C_1$  without alteration of the value for K, inasmuch as C is altered to the first, and  $C_1$  to the second power. The excess of one or other of the ingredients beyond that of the equivalent proportion must be considered as accelerating the change, and such an excess can in no wise be regarded as so much chemically inert matter.

V. H. V.

**Demonstration of Avogadro's Hypothesis.** By C. SCHALL (*Ber.*, 20, 1433—1435).—A balance provided with a combined scale is employed, to which large light vessels of as nearly equal capacity as possible are suspended. By means of the scale, which is described, the deviation produced in the index needle can be converted into a number expressing the density. N. H. M.

**Practical Thermo-regulator.** By L. RUGHEIMER (*Ber.*, 20, 1280—1284).—A modification of an air-mercury regulator, which presents no specially novel point of construction. The results of thermometer readings show a variation of  $\pm 0.5^\circ$ . V. H. V.

## Inorganic Chemistry.

**Perbromic Acid.** By R. W. E. MACIVOR (*Chem. News*, 55, 203).—Bromine is without action on hydrated perchloric acid, anhydrous perchloric acid, and perbromate of silver, even when the substances are heated together in closed tubes. R. R.

**Diamidogen or Hydrazine.** By T. CURTIUS (*Ber.*, 20, 1632—1634).—See p. 715.

**Nitrous Acid.** By E. DRECHSEL (*Ber.*, 20, 1456—1457).—When Fehling's solution is added to a solution of sodium nitrite, no reduction takes place; on treating the boiling solution with dilute sulphuric acid and then adding caustic soda until alkaline, a reduction takes place with formation of a yellow or red precipitate of cuprous oxide. The reduction is also produced by passing nitrous anhydride through Fehling's solution, but much more slowly than in the above reaction. It is suggested that in the reaction with sodium nitrite and sulphuric acid the reduction is due to the formation of hydroxylamine and nitric acid. N. H. M.

**Hydrates of Sodium Arsenate.** By H. LESCEUR (*Compt. rend.*, 104, 1171—1174).—The percentage of water in commercial sodium arsenate varies from 43.65 to 57.45, and the published statements as to the proportion of water normally present in the crystals are very conflicting.

Measurements of the vapour-pressure of crystallised disodium hydrogen arsenate indicate the existence of two definite hydrates only,  $\text{Na}_2\text{HAsO}_4 + 12\text{H}_2\text{O}$  and  $\text{Na}_2\text{HAsO}_4 + 7\text{H}_2\text{O}$ . The first is not very well defined, and its vapour-pressure is practically identical with that of a saturated solution of the salt. It effloresces in dry air at  $20^\circ$ , and forms the second hydrate. The heptahydrate is stable in dry air, but in a moist atmosphere it gradually absorbs water until it approximates in composition to the higher hydrate. If crystallisation

takes place above  $23^{\circ}$ , the heptahydrate only is formed, but if this is left in the mother-liquor, or is exposed to moist air, it is more or less completely converted into the duodecahydrate.

In preparing the arsenate, a product of constant composition can only be obtained by drying the finely-powdered crystals in air at the ordinary temperature. C. H. B.

**Particular Case of the Formation of Sodium Hydrogen Carbonate.** By P. DE MONDÉSIR (*Compt. rend.*, 104, 1102).—Normal sodium carbonate containing 1 mol.  $\text{H}_2\text{O}$  absorbs carbonic anhydride very slowly if at all at the ordinary temperature. If, however, it is mixed with a small proportion of the hydrogen carbonate the reaction commences immediately, and proceeds with a velocity which depends on the proportion of acid carbonate present and the perfection of admixture of the two salts. C. H. B.

**Solubility of Lithium Carbonate.** By C. N. DRAPER (*Chem. News*, 55, 169).—The author finds that the solubility of lithium carbonate at  $15^{\circ}$  is 1.4787 per cent., or nearly half as much again as that usually given; and at  $100^{\circ}$  it is 0.7162 per cent.

R. R.

**Argentous Compounds.** By E. DRECHSEL (*Ber.*, 20, 1455).—When an ammoniacal silver solution is kept for some time in contact with peptone, it gradually acquires a deep port wine colour like that of so-called argentous oxide; when a current of ozonised air is passed through the solution, it becomes colourless without precipitation. This reaction is most readily explained on the assumption that the red solution contains argentous oxide. On the other hand, it is conceivable that silver peroxide was formed from the silver, and that this reacted with the ammonia present with formation of silver oxide and evolution of nitrogen. N. H. M.

**The Lowest Compounds of Silver.** By O. v. D. PFORDTEN (*Ber.*, 20, 1458—1474; compare *Abstr.*, 1885, 955).—20 c.c. of a 12.5 per cent. solution of sodium tartrate, and a solution of 2 grams of silver nitrate, are mixed with  $1\frac{1}{2}$  litres of water; 2 c.c. of a 4 per cent. solution of sodium hydroxide is then added, the whole being stirred violently. After five hours, the supernatant liquid is poured off from the fine, black precipitate. The solution is treated in like manner three times with the same result. The united products of several experiments are washed by decantation with a dilute solution of sodium sulphate; water alone cannot be used. The purified black compound is probably argentous tartrate.

When a solution of 10 grams of silver nitrate in 20 c.c. of water, in presence of sufficient ammonia to give a clear solution, is gradually treated with 4 c.c. of a concentrated solution of phosphorous acid, a black precipitate is formed. The solution is filtered, and again treated in the same way with phosphorous acid. The black compound is washed with water until the filtrate comes through turbid, and then with ammonia.

*Argentous oxide*,  $\text{Ag}_2\text{O}$ , is prepared by treating either of the above black salts with alkali, and washing with water containing alkali. It forms a deep black, amorphous substance; it must be kept under dilute alkali. It cannot be dried without decomposition; water decomposes it. When treated with a mixture of potassium permanganate and sulphuric acid, it dissolves as an argentic salt. By means of this reaction, the formula of the compound was established; the wet substance was added to a mixture of titrated permanganate solution and dilute sulphuric acid, and the permanganate titrated back with a solution of ferrous ammonium sulphate; the silver was determined in the same solution, and the relative amounts of silver and of oxygen used up determined.

Argentous oxide is insoluble in ammonia and in acetic acid; it is converted by hydrochloric acid into a mixture of silver and silver chloride. Phosphorous and sulphurous acids do not dissolve it. Hydrogen peroxide has no action on it in the cold; when warmed, metallic silver is formed. Alcohol reduces it slowly. Mercury has no action on it. It is somewhat soluble in water; the solution is greenish, reacts neutral, and is not precipitated by soda solution or by hydrochloric acid. Sulphuric acid decomposes it with formation of silver and evolution of oxygen; the same result is produced but more slowly by hydrocyanic acid, by sodium chloride, and other indifferent solutions.

*Argentous sulphide*,  $\text{Ag}_2\text{S}$ , is prepared from the black argentous salts by the action of sodium hydrogen sulphide; it is a black, amorphous compound; when dried it is grey. Water decomposes it after a short time. It is insoluble in ammonia, dissolves sparingly in warm dilute nitric acid, decomposes with separation of sulphur when treated with strong nitric and sulphuric acids. It dissolves in hydrochloric acid, and is precipitated unchanged by water; it is also soluble in potassium cyanide solution (dilute sulphuric acid gives a black precipitate). Potassium permanganate and sulphuric acid dissolve it with separation of silver. When dried, or when kept under pure water, it changes into a mixture of silver (2 mols.) and silver sulphide (1 mol.). (Compare also Trans., 1887, 416.)

N. H. M.

**Specific Gravity of Lime-water.** By J. A. WANKLYN (*Chem. News*, 55, 217).—The author's determination of the specific gravity (1002.35) of lime-water containing 1.344 grams of calcium oxide per litre, shows that when 1.344 grams of lime was dissolved in 1001 c.c. of water, the substances contracted to 1 litre.

R. R.

**Action of Ammonia on Bleaching Powder; Constitution of Bleaching Powder.** By G. LUNGE and R. SCHOCH (*Ber.*, 20, 1474—1482).—When bleaching powder is treated with aqueous ammonia, 34.76 to 36.06 per cent. of lime is dissolved. When ammonia mixed with alcohol (Dreyfus, Abstr., 1885, 19) is used, the amount dissolved is rather less. The gas given off was examined, and found to consist of nitrogen, together with a small quantity (less than 3 per cent.) of oxygen and carbonic anhydride. These and further experiments,

showing the actual amount of nitrogen evolved in relation to the amount of bleaching powder employed, confirm the correctness of the equation suggested by Kolb (*Ann. Chim. Phys.* [4], 12, 269).

The results of seven experiments, in which chloride of lime was heated at its melting point, gave 5.24 to 6.08 per cent. of oxygen, 0.58 to 1.12 per cent. chlorine as hypochlorous acid, and 3.69 to 6.18 per cent. of free chlorine. The equation given by Dreyfus (*loc. cit.*), which requires 10.53 per cent. of chlorine and 7.1 per cent. of oxygen, is therefore incorrect.

N. H. M.

**Barium Phosphates; their Application in Acidimetry.** By A. VILLIERS (*Compt. rend.*, 104, 1103—1106).—Phosphoric acid is bibasic when phenolphthaleïn is used as an indicator, and can be titrated with a solution of potassium or barium hydroxides. Other free acids, such as hydrochloric, sulphuric, acetic, can be titrated in presence of phosphoric acid by means of potassium hydroxide, but not with baryta.

Joly has already shown that when barium chloride is added to disodium phosphate the solution becomes acid, but the author gives a somewhat different explanation of the phenomenon.

If the acid solution produced by mixing solutions of disodium phosphate and barium chloride is mixed with phenolphthaleïn, and then with baryta solution, the addition of the first few drops of the alkali causes a somewhat rapid appearance of the red colour, but after five or six minutes this disappears, and a somewhat considerable quantity of baryta is necessary for the production of a persistent coloration. The volume of baryta solution required to produce the second end reaction varies with the proportions of barium chloride and disodium phosphate.

In presence of a large excess of disodium phosphate, the precipitate after washing and drying at 120—130° is constant in composition; it is barium sodium phosphate,  $\text{BaNaPO}_4$ . Its formation takes place in two stages, the first of which is represented by the equation  $\text{Na}_2\text{HPO}_4 + \text{BaCl}_2 = \text{BaHPO}_4 + 2\text{NaCl}$ . The acidity of the liquid at this stage is due to the formation of a small quantity of tribarium phosphate, and the consequent liberation of free acid. In the second stage, the barium hydroxide acts on the barium hydrogen phosphate in presence of sodium chloride, with formation of barium chloride, water, and barium sodium phosphate.

Barium sodium phosphate has previously been obtained in hydrated crystals by Schulten by the action of sodium phosphate on sodium silicate and barium hydroxide (*Abstr.*, 1883, 711). It can also be prepared in an amorphous and less pure condition by the action of barium hydroxide on a solution of disodium phosphate, and in small quantity by adding barium chloride to a solution of trisodium phosphate, but it can only be obtained in a state of purity by the method described above.

Tribarium phosphate is obtained only by pouring sodium phosphate into a solution containing a large excess of baryta.

Barium hydrogen phosphate which has been precipitated for some time, and has become crystalline, is not readily converted into the

double phosphate, a proof of the alteration which the precipitate undergoes in course of time.

From these facts, it is evident that free acids cannot be accurately titrated by means of baryta in presence of disodium phosphate, and this is true also of the titration of phosphoric acid in presence of alkaline salts. Accurate estimations can, however, be made in either case by means of potassium hydroxide solution. C. H. B.

**Thallium in Platinum.** By H. N. WARREN (*Chem. News*, 55, 241).—The author detected thallium in platinum wire and foil spectroscopically. Ten grams of the wire was dissolved in aqua-regia, evaporated to dryness, redissolved, slightly acidified with nitric acid, and hydriodic acid added to precipitate the thallium as thallic iodide; the precipitate was washed with alcohol, dried, and weighed. From 0.02 to 0.1 per cent. thallium was found, the wire containing larger amounts than the foil. Traces of thallium were obtained from several samples of platinum ore, and alloys of platinum with thallium were found to be useless for wire when 0.5 of the latter metal was present, whilst 2 per cent. caused the metal to become fusible at a red heat.

R. R.

**Preparation of Anhydrous Metallic Chlorides.** By H. N. WARREN (*Chem. News*, 55, 192).—The metallic oxide, such as aluminium oxide, is heated to redness in a large tubulated earthenware retort into which the vapour of petroleum previously saturated with hydrochloric acid gas, or with chlorine, is distilled. Fumes of the chloride are at once evolved, and may be condensed in a receiver. R. R.

**Action of Nitrogen on certain Metals.** By H. N. WARREN (*Chem. News*, 55, 155).—Bars of iron, copper, nickel, cobalt, &c., maintained at a bright red heat for some hours in an atmosphere of dry ammonia, and then allowed to cool in the same, were found to exhibit crystalline surfaces and fractures together with great brittleness. These effects were found to be proportionate to the quantity of nitrogen contained in the metal, and this increased up to a certain point with the duration of the heating. Thus a bar of iron heated in ammonia for two hours yielded 0.004 per cent. of nitrogen; a similar one after four hours' heating contained 0.01 per cent.; and others after 10 or 12 hours' heating gave 0.5 per cent. These last were so brittle that they broke on falling from a height of 6 feet. Some of the copper bars that were brought into the air before they were quite cold, spontaneously split with some violence in a transverse direction. When anhydrous ferrous chloride was substituted for the iron bar, a silvery, spongy mass of iron nitride was obtained containing 4 per cent. of nitrogen. An amorphous, green powder of copper nitride was formed by gently heating cupric oxide in ammonia gas; this decomposed with violence at a dull red heat into copper and nitrogen gas. When mercuric oxide is similarly treated, the like reaction occurs, but at a temperature of 205° the compound formed explodes with fearful violence. R. R.

**Action of Ferric Sulphate on Iron.** By A. E. MENKE (*Amer. Chem. J.*, 9, 90—93).—The action increases approximately with the amount of ferric sulphate, whether at a boiling temperature or in sealed tubes at 110°. The addition of the theoretical amount of sodium or potassium carbonate necessary for the precipitation of the iron salt reduces the action to about one-third, but calcium carbonate has no effect, or not so much; the action is less on steel than on boiler plate.  
H. B.

**Titanium Carbide in Pig-iron.** By P. W. SHIMER (*Chem. News*, 55, 156—158).—From the residue left on dissolving 250 grams of pig-iron in dilute hydrochloric acid, the author separated about 1 gram of a material consisting largely of minute, cubical, metallic crystals. Analysis showed that 88 per cent. of this material was composed of titanium and carbon very nearly in atomic proportions; the crystals are therefore regarded as a titanium carbide,  $TiC$ . The five or six pig-irons examined all contained these crystals, and a sample of No. 1 Barrow foundry iron yielded 0.203 per cent. of titanium.

In separating the titaniferous material from the graphite, &c., in the residue, a very slightly inclined plane, 12 feet long and 5 inches wide, made of window glass, was made use of. The material was placed at the upper end, and water allowed to drip upon it slowly, by which the lighter particles were carried forward faster than the heavier crystals.  
R. R.

**Formation of Complex Inorganic Acids.** By E. DRECHSEL (*Ber.*, 20, 1452—1455).—Silicotungstic acid can be readily prepared as follows:—Pure sodium tungstate is dissolved in a little boiling water, almost neutralised with nitric acid, and filtered. The crystals are washed with cold water, dissolved in water, and boiled with gelatinous silica until the solution no longer gives a precipitate with hydrochloric acid. It is filtered, evaporated, treated when cold with a large excess of sulphuric acid previously diluted with an equal volume of water, and allowed to cool. Ether is then gradually added, when the liquid becomes turbid and separates into three layers—the lowest oily and containing most of the silicotungstic acid; the middle layer an aqueous solution of hydrogen sodium sulphate and sulphuric acid; the upper layer ether. The lowest layer is separated, freed from ether by evaporating on a water-bath (avoiding too high a temperature), and allowed to cool. The acid separates in splendid crystals.

When a concentrated aqueous solution of phosphotungstic acid is treated with an equal volume of ether, oily drops form at the surface of contact of the water and ether, and then sink, forming a third layer; the latter has the sp. gr. = 1.525. Crystallised phosphotungstic acid dissolved in the smallest amount of ether gives an oil, sp. gr. = 2.083.

Phosphotungstic acid is prepared by dissolving 500 grams of pure sodium tungstate and 250 grams of crystallised sodium phosphate in 500 c.c. of water and evaporating until a skin is formed on the surface. 700 to 800 c.c. of hydrochloric acid (sp. gr. = 1.14) is added to the boiling solution, which is again evaporated and allowed to cool. The

whole is gradually treated with pure ether, being well shaken all the time, until a layer is formed above the acid solution. It is then left until the lower layer is clear, separated and treated with an equal volume of water; the ether is then evaporated; if the solution becomes bluish, chlorine water is added. It is evaporated to dryness, dissolved in hot water; on cooling the acid separates in splendid crystals.

Phosphomolybdic acid is prepared in a similar manner.

N. H. M.

**Equivalent and Atomic Weight of Thorium.** By G. KRÜSS and L. F. NILSON (*Ber.*, 20, 1665—1676).—The accepted value for the atomic weight of thorium is 232.4, which is in accordance with the determinations of its specific heat.

In this paper, determinations are given of the equivalent of thorium and of the molecular weight of the chloride, and from these values, together with considerations of the position of the metal in the periodic system, the atomic weight is deduced.

The thorium oxide is prepared from the mixed sulphates obtained by dissolving thorite in sulphuric acid; from this solution, the hydrated oxides are precipitated by ammonia, subsequently dissolved in hydrochloric acid, and precipitated as oxalates. These last are converted into the sulphates, and from the mixed salts thorium sulphate is obtained by dissolving in ice-cold water, in which it is less soluble than the sulphates of the accompanying metals. This fractional crystallisation from ice-cold water is repeated several times. The sulphate crystallises with 8 mols.  $H_2O$ . From the anhydrous salt, the equivalent of the metal is determined by ignition and weighing the residual oxide; the mean value of eight concordant determinations is 57.997. The sp. gr. of the anhydrous sulphate is 4.2252.

Specimens of the chloride were obtained by heating the metal in a current of dry hydrochloric acid at a low red heat and subsequent resublimation of the salt. The percentage of chlorine found was 37.83 (theory requiring 37.89). Vapour-density determinations of different samples at temperatures varying from  $1057^\circ$  to  $1270^\circ$  gave values from 11.232 to 12.424; a determination at  $1400^\circ$  gave the value 9.835. The theoretical value for the chloride  $ThCl_4$  is 12.928. The previous determinations of Troost, which varied from 5.9 to 7.49, were probably vitiated by impurities in the samples used.

Then as thorium is quadrivalent, no place being found for a bivalent metal of atomic weight 116 in the periodic system, as also from the values found for the sp. gr. of the anhydrous sulphate and oxide, the corrected atomic weight is taken as 231.813 to 231.916 (mean 231.87), oxygen being taken as 15.96.

V. H. V.

**Potassium Germanium Fluoride.** By G. KRÜSS and L. F. NILSON (*Ber.*, 20, 1696—1700).—Germanium fluoride is readily obtained in solution by dissolving the oxide in hydrofluoric acid; on evaporating the solution with sulphuric acid and subsequent ignition the oxide is re-formed. On adding potassium hydrogen fluoride to the solution of germanium fluoride, the double salt is precipitated at first as a gelatinous precipitate, which gradually becomes crystalline;

on slowly evaporating the saturated solution, it separates in the form of tables or prisms. The salt can be heated to a red heat without alteration in weight. Its composition,  $K_2GeF_6$ , was determined by evaporating the salt with sulphuric acid and igniting, and weighing the residue of the oxide  $GeO_2$  and potassium sulphate. It is shown by crystallographic measurements ( $a : c = 1 : 0.8039$ ) that this salt is isomorphous with ammonium silicofluoride. In conclusion, it is remarked that the properties of potassium germanium fluoride agree with those predicted by Mendelejeff for the corresponding salt of ekasilicon.

V. H. V.

**Alkaline Vanadates.** By A. DITTE (*Compt. rend.*, **104**, 1168—1171).—When a mixture of lithium carbonate (1 mol.) and vanadic anhydride (1 mol.) is boiled with water, and the solution concentrated to a thick syrup in a vacuum, it deposits brilliant, silky needles of the composition  $Li_2O, V_2O_5 + 4H_2O$ , which lose water when heated, and form a brown liquid, which solidifies to a crystalline mass of the anhydrous normal vanadate.

If a solution of the normal vanadate is acidified with acetic acid and evaporated in a vacuum, it deposits red transparent crystals with a brilliant lustre, which have the composition  $Li_2O, 2V_2O_5 + 12H_2O$ . If crystallisation takes place in a warm solution, thin orange-red plates of the composition  $Li_2O, 2V_2O_5 + 8H_2O$  are obtained.

When lithium carbonate is boiled with an excess of vanadic anhydride, and the solution slightly acidified with acetic acid, and concentrated in a vacuum, it deposits orange-red crystals of the compound  $2Li_2O, 3V_2O_5 + 16H_2O$ .

All the hydrated acid salts when heated lose their water without melting and become deep red-brown. At a higher temperature, they melt to a brown liquid which solidifies to a crystalline mass on cooling.

If a solution of the normal vanadate is made strongly alkaline with lithia and concentrated in a vacuum, the syrupy liquid deposits silky, white needles of the compound  $2Li_2O, V_2O_5 + 6H_2O$ , which lose water when heated, then melt, and solidify on cooling to a white, crystalline, nacreous mass of the composition  $2Li_2O, V_2O_5$ . If the mother-liquor from these crystals is concentrated, it deposits crystals of the compound  $3Li_2O, V_2O_5 + 6H_2O$ .

Lithium carbonate solution saturated with vanadic anhydride, and mixed with a warm concentrated solution of lithia in large excess, almost immediately deposits the compound  $4Li_2O, V_2O_5 + H_2O$  in transparent, microscopic crystals, which if left in contact with the mother-liquor change to bulky, colourless, transparent, rhomboidal crystals of the composition  $4Li_2O, V_2O_5 + 14H_2O$ . They lose water when heated, but the white, anhydrous salt is infusible even at a red heat.

A comparison of the various alkaline vanadates (*Abstr.*, 1886, 671, and this vol., 639) shows that they are analogous in constitution, but contain different amounts of water of crystallisation according to the conditions under which they are formed. The normal salts are

colourless, the acid salts red with a more or less marked orange tint, and the basic salts are colourless. C. H. B.

**Reduction of Potassium Niobium Fluoride with Sodium.** By G. KRÜSS and L. F. NILSON (*Ber.*, **20**, 1691—1696).—By heating potassium niobium fluoride with sodium, the mixture being protected by a layer of sodium chloride, Marignac obtained a black insoluble powder; this was found to consist of a hydride of niobium,  $\text{NbH}$ , mixed with a small quantity of niobic acid. In this paper, the experiments of Marignac are repeated; the product obtained on heating the mixture of potassium niobium fluoride, sodium, and sodium chloride, was treated at first with alcohol, then with water, and finally washed with ether. The product was a glistening, hygroscopic, black powder, unattacked by hydrochloric and nitric acids or aqua regia, but soluble in concentrated hydrofluoric acid with evolution of hydrogen. It burns in a current of dry hydrochloric acid gas with formation of four different chlorides of niobium, two of which are the more and two the less volatile in the gas. Analysis showed the composition of the product to be as follows:— $\text{NbH} = 77.5$  per cent.;  $\text{Nb}_2\text{O}_5 = 21.53$  per cent.;  $\text{Fe}_2\text{O}_3 = 0.97$  per cent.

The following determinations are also given of the molecular heats of niobium hydride and oxide:—

|                     | Molecular heats at |           |           |         |
|---------------------|--------------------|-----------|-----------|---------|
|                     | 100—0°.            | 210.5—0°. | 301.5—0°. | 449—0°. |

**Earths and Niobic Acid from Fergusonite.** By G. KRÜSS and L. F. NILSON (*Ber.*, **20**, 1676—1690.)—In this paper, a description is given of the qualitative separation of the various earths present in the mineral fergusonite, a large quantity of which was operated on. The two samples used came from Arendal and Ytterby.

Among the oxides of the rare metals found were those of cerium, thorium, erbium, samarium, thulium, ytterbium, and the various components of didymium, and of Soret's X. Among the acid-forming oxides were those of titanium, tantalum, and niobium.

In order to prepare pure niobic acid from the mineral, the aqueous solution of crude potassium niobium oxyfluoride is heated for some time to separate the oxyfluoride of potassium and tantalum,  $2(2\text{KF}, \text{TaF}_5) \cdot \text{Ta}_2\text{O}_5$ ; on subsequent evaporation, the niobium oxyfluoride,  $2\text{KF}, \text{NbOF}_3$ , crystallises out, and from the determination of the ratio  $2\text{K}_2\text{SO}_4 : \text{Nb}_2\text{O}_5$  obtained from the salt, the atomic weight of niobium is taken as 93.8. From the oxyfluoride, a sample of the double fluoride  $\text{K}_2\text{NbF}_7$  was obtained, and from the ratio  $2\text{K}_2\text{SO}_4 : \text{Nb}_2\text{O}_5$  the value 93.96 is deduced; these numbers are practically equal to the atomic weight 94 taken by Marignac. When a solution of potassium niobium oxyfluoride is boiled, a double salt,  $2\text{KF}, 3\text{NbO}_2\text{F}$ ,

separates as a hard white powder consisting of minute crystals. The change which leads to its formation may be expressed thus :

V. H. V.

## Mineralogical Chemistry.

**Bismuthic Gold.** By R. W. E. MACIVOR (*Chem. News*, **55**, 191).—An analysis of bismuthic gold from Maldon, Victoria, gave gold 64.211; bismuth 34.398; siliceous matter 1.391 per cent. The proportions of gold and bismuth indicate the formula  $\text{Au}_2\text{Bi}$ .

R. R.

**Enargite from Montana.** By W. SEMMONS (*Min. Mag.*, **6**, 49—51; *Jahrb. f. Min.*, 1887, **1**, Ref., 416—417).—The mineral examined was of a lead-grey colour, with a black streak; sp. gr. 4.3, hardness 2.5. Crystals are rare and always small. The crystals are rhombic prisms with brachypinacoid and macropinacoid, brachydomes and macrodomes. Analysis gave the following results:—

|        | Cu.   | As.   | S.    | $\text{SiO}_2$ . | Fe.  | Total. |
|--------|-------|-------|-------|------------------|------|--------|
| I....  | 45.76 | 18.66 | 31.30 | 2.50             | 0.80 | 99.02  |
| II.... | 47.84 | 19.47 | 32.69 | —                | —    | 100.00 |

Analysis II gives the results calculated to 100, the silica and iron being considered as impurities. The mineral thus very closely resembles enargite in composition, but differs from it in cleavage, in hardness, and in behaviour before the blowpipe. It occurs with iron pyrites, bornite, covellite, and quartz in a number of mines in Montana, United States.

B. H. B.

**Artificial Production of Rose Spinel or Balas Ruby.** By S. MEUNIER (*Compt. rend.*, **104**, 1111—1112).—The bottom of a graphite crucible is covered with a layer of finely-powdered magnesia well rammed down, an intimate mixture of very finely-powdered aluminium chloride and cryolite is then introduced, and the crucible is filled up with alumina and magnesia, the latter being in excess. If a rose-coloured product is desired, a very small quantity of potassium dichromate is added. The crucible is heated for five or six hours in a good coke fire, and allowed to cool as slowly as possible. The product is a greyish gangue, full of vesicles which are lined with brilliant, rose-coloured crystals of balas ruby, identical with the natural crystals in form, colour, brilliancy, hardness, and optical properties. If cryolite is used without aluminium chloride, the product consists of rose-coloured lamellæ of corundum without any trace of spinel, even in presence of a large excess of magnesia.

Probably this is a further example of the mineralising action of fluorine recently described by Fremy (this vol., p. 556). The experiment may be varied in many ways, and the author has obtained a

series of products which includes the aluminates of zinc, iron, &c., together with secondary products.

C. H. B.

**Artificial Production of Magnetite.** By A. GORGEU (*Compt. rend.*, 104, 1174—1177).—When a mixture of ferric and ferrous sulphates is decomposed in a bath of fused sodium sulphate, crystals of ferric oxide only are formed, and no magnetite is obtained. The latter is only produced if some reducing agent is introduced at the moment when the whole of the iron has been oxidised to the ferric state. Ferric oxide answers quite as well as the mixed sulphates.

When iron wire or turnings is introduced into fused sodium sulphate, a small quantity of sulphurous anhydride is evolved, and some free soda is formed, but the main product is a magnetic ferrous ferrite, containing a much larger proportion of ferrous oxide than magnetite. If the action of heat is continued, the ferrite undergoes oxidation, the sulphite and sulphide are reoxidised to sulphate, and eventually the whole of the iron is converted into the crystalline magnetic oxide. If the substances taken are weighed, it is found that the increase of weight at the close of the experiment is sensibly equal to the oxygen absorbed by the iron, the sodium sulphate having absorbed from the air a quantity of oxygen equal to that which it gave up to the iron. Potassium sulphate gives similar results.

Iron sulphides act energetically on fused alkaline sulphates, with evolution of a large quantity of sulphurous anhydride, and ultimate formation of magnetite and an alkaline sulphate. The alteration in weight is due to the loss of the sulphur originally present in the sulphide, and the absorption of 1.33 times its weight of oxygen by the iron in the sulphide. The yield is better the greater the intermediate formation of a double alkaline ferrous sulphide, and is best of all when a mixture of sodium sulphide and sulphite is used instead of the sulphate.

Artificial magnetite very closely resembles the natural mineral. It crystallises in opaque, magnetic octahedra with a metallic lustre, which are sometimes modified by very small faces of the rhombic dodecahedron; hardness 6.0—6.5; sp. gr. 5.21—5.25. The hardness and sp. gr. of the natural mineral are 5.5—6.5 and 4.9—5.27 respectively. The artificial crystals are not affected by water and carbonic anhydride at a bright red heat, are not attacked by nitric or hydrochloric acid diluted with 10 vols. of water, and are only very slowly dissolved by the strong acids or aqua regia. When roasted in the air, they yield pure ferric oxide, and the residue is usually not magnetic, but if the magnetite has been prepared from native ferrous carbonate the residue is magnetic, a result which is doubtless due to the presence of foreign ferrites.

C. H. B.

**Australian Bat Guano and Minerals occurring therein.** By R. W. E. MACIVOR (*Chem. News*, 55, 215—216).—The author gives the results of his examination of bat guano obtained from caves situated in various parts of Victoria. The only important deposit is at the Skipton caves, about 30 miles from Ballarat. Disseminated

through these deposits are crystals of Struvite (I), and of Hannayite (II), and Newberyite (III), minerals previously described by the author, of which the following new analyses are given:—

|         | MgO.  | FeO. | MnO. | (NH <sub>4</sub> ) <sub>2</sub> O. | P <sub>2</sub> O <sub>5</sub> . | Water.  |
|---------|-------|------|------|------------------------------------|---------------------------------|---------|
| I....   | 16·07 | 0·81 | 0·16 | 10·57                              | 28·82                           | (43·57) |
| II....  | 18·54 | 0·31 | 0·09 | 8·10                               | 44·71                           | (28·25) |
| III.... | 22·37 | 0·85 | 0·21 | —                                  | 40·73                           | (35·84) |

Reference is made to two new ammonio-magnesium phosphates, Muellerite and Dittmarite, which will be described later.

A. J. G.

**Destinezite.** By G. CESÁRO (*Jahrb. f. Min.*, 1887, **1**, Ref., 412—413).—The author has made a chemical and crystallographical investigation of an almost white destinezite from Visé. On heating from 130° to 250°, 1 gram of the mineral lost 0·09 to 0·242 gram of volatile matter. At a red heat it lost 0·445 gram. Analysis gave the following results:—

| Insoluble<br>residue. | Fe <sub>2</sub> O <sub>3</sub> . | P <sub>2</sub> O <sub>5</sub> . | SO <sub>3</sub> . | H <sub>2</sub> O. | Hygro-<br>scopic H <sub>2</sub> O. | Total. |
|-----------------------|----------------------------------|---------------------------------|-------------------|-------------------|------------------------------------|--------|
| 1·40                  | 37·60                            | 16·76                           | 18·85             | 25·35             | 0·30                               | 100·26 |

From these results, the author calculates the formula  $P_2O_5, Fe_2O_3 + Fe_2O_3, 2SO_3 + 12H_2O$ . He concludes that the constitution of the substance is  $O[Fe_2(OH)(SO_4H) : PO_4]_2 + 10H_2O$ . Under the microscope, it is seen that destinezite forms small crystals at least 0·01 mm. in length. They are colourless, and isomorphous with gypsum.

B. H. B.

**Wollastonite from Sardinia.** By L. BUSATTI (*Jahrb. f. Min.*, 1887, **1**, Ref., 420).—The mineral examined was found at S. Vito, in the mining district of Sarrabus in Sardinia. It forms rosette-shaped aggregates of greyish-white fibres on a black Silurian clay slate. The substance is fusible with difficulty before the blowpipe, and gelatinises when heated with concentrated hydrochloric acid. Its hardness is  $4\frac{1}{2}$ , and its sp. gr. 2·7 to 2·8. From the analysis, the formula  $CaSiO_3$  was deduced. The analytical results were as follows:—

| SiO <sub>2</sub> . | CaO.  | MgO. | Fe <sub>2</sub> O <sub>3</sub> . | H <sub>2</sub> O. | Total. |
|--------------------|-------|------|----------------------------------|-------------------|--------|
| 49·78              | 45·12 | 1·20 | 2·20                             | 0·60              | 98·90  |

B. H. B.

**Griqualandite.** By G. HEPBURN (*Chem. News*, **55**, 240).—This mineral, from Griqualand West, South Africa, appears to be a pseudomorph after crocidolite, which it exactly resembles in structure. It has, however, the composition of a ferric silicate,  $6SiO_2, 4Fe_2O_3, 5H_2O$ . It occurs as opaque, asbestos-like fibres, non-elastic, and of a snuff or golden-brown colour. The analytical results were—

| SiO <sub>2</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | H <sub>2</sub> O<br>combined. | FeO. | MgO. | Moisture. | Total. |
|--------------------|----------------------------------|-------------------------------|------|------|-----------|--------|
| 56·75              | 37·64                            | 4·96                          | 1·09 | 0·10 | 0·27      | 100·81 |

R. R.

**The Meteorite of Karang-Modjo or Magetan in Java.** By J. BOSSCHA (*Jahrb. f. Min., Beilage* 5, 126—144).—The Leyden Museum possesses a fine meteorite, described in the catalogue as the Magetan meteorite. It fell on October 3, 1883, at Karang-Modjo, in the Magetan district of Java. On the same day, the Ngawi meteorite fell in the same settlement. It is consequently highly probable that both meteorites belong to the same fall. The Magetan meteorite weighed 1191.1 grams. Its sp. gr. was found to be 3.34. In macroscopic and microscopic structure the Magetan and Ngawi meteorites are identical.

**Sulphuretted Waters of Olette (Pyrénées Orientales).** By E. WILLM (*Compt. rend.*, 104, 1178—1180).—These springs are the hottest and most copious in the Pyrenees. There are also two which may be regarded as degenerated sulphuretted waters, since their general composition is the same, but they contain a larger proportion of sulphates, and no sulphides or thiosulphates. They also contain a notable quantity of nitrates.

| Name of spring .....                                | Sulphuretted. |            |            |        | Degenerated. |         |

All the waters contain traces of phosphoric and boric acids, iodine, and arsenic, but are free from ammonia. The nitrates were estimated by converting them into ammonia by means of the zinc-copper couple.

The nitric acid is probably due to the nitrification of air which has come in contact with the water at a great depth, the change being assisted by the high temperature and pressure. The increase in the proportion of the calcium carbonate may be attributed to the action of the carbonic anhydride of this air on the surrounding rocks. The similarity between the composition of the sulphuretted waters and of the degenerated waters shows that there has not been any infiltration of surface water.

## Organic Chemistry.

---

**Determination of the Relative Values of the Four Units of Chemical Activity of the Atom of Carbon.** By L. HENRY (*Compt. rend.*, 102, 1106—1109).—Hitherto there has been no actual determination of the relative values of the four units of chemical activity of the atom of carbon. Monocarbon-compounds of the type  $CX_4$  will of course exist only in one form whatever the relative values of the four units, but if these values are different, monocarbon-compounds which contain two radicles should show differences. To take the simplest case, if one combining unit differs in value from the three others, compounds of the type  $CX_3X'$  would exist in two forms, those of the type  $CX_2X'X''$  in three forms, and those of the type  $CXX'X''X'''$  in four. At present at least, the author's attention is confined to compounds of the type  $CX_3X'$ . The best known and most easily obtained of these are the mono-substitution-derivatives of methane. It is true that only one variety of each of these derivatives is at present known, but this fact is without value, since it is impossible to affirm that in different specimens formed under different conditions the radicles saturate different combining units.

It is essential to prepare the mono-substitution-derivatives  $MeX$  by a systematic series of reactions, such that it can be affirmed that the radicle  $X$  is united successively with each of the four units of activity of the carbon-atom. In other words, it is necessary to ascertain if the order of introduction of the radicle into the molecule of methane exerts any influence on the properties of the resulting compound. The compounds selected for this purpose are the nitromethanes and the acetonitriles, which are well known and can be prepared by means of reactions that do not involve the use of high temperatures. The author uses the letters  $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$  to denote the compounds in which the first, second, third, and fourth atoms of hydrogen respectively are replaced by the radicle  $NO_2$  or  $CN$ .

The  $\alpha$ -derivatives are obtained by the action of methyl iodide on potassium cyanide and silver nitrite respectively.

The  $\beta$ -nitro-derivative is prepared by the action of potassium nitrite on a salt of  $\beta$ -chloroacetic acid, which is obtained by the action of chlorine on acetic acid formed from  $\alpha$ -acetonitrile. The  $\beta$ -acetonitrile is prepared by the dry distillation of  $\beta$ -cyanacetic acid which is obtained by the action of potassium cyanide on  $\beta$ -chloroacetic acid.

The  $\gamma$ -derivative is prepared by similar reactions from  $\gamma$ -chloroacetic acid. This compound is formed by the dry distillation of  $\gamma$ -chloromalonic acid, which is obtained in the form of an ethyl salt by the action of chlorine on diethyl malonate, the malonic acid having been obtained from cyanacetic acid,  $CN\beta\cdot CH_2\cdot COOH\alpha$ .

The  $\delta$ -derivatives are formed in a similar manner from  $\delta$ -monochloroacetic acid, which is obtained by the action of heat on  $\delta$ -chloromethine-carboxylic acid,  $\text{CCl}(\text{COOH})_{\alpha\beta\gamma}$ , and this is prepared by the action of ethyl chlorocarbonate on ethyl monosodiummalonate.

The  $\alpha$ -,  $\beta$ -, and  $\gamma$ -derivatives have already been prepared by these methods and their properties investigated, but no differences could be detected. The  $\delta$ -derivatives are being prepared.

The whole argument is of course based on the principle of substitution and the stability of complex molecular structures throughout the course of a chemical reaction.

C. H. B.

**Action of Bromine on Isobutylene.** By L. M. NORTON and H. J. WILLIAMS (*Amer. Chem. J.*, **9**, 87—89).—During the preparation of isobutylene bromide from pure isobutylene, it was noticed that a considerable quantity of a tribromoisobutane was formed, boiling at  $173$ — $183^\circ$  at a pressure of 235 mm. When treated with alcoholic soda, it yielded a liquid boiling at  $158$ — $161^\circ$ ; probably an isobutylene bromhydrin.

For purposes of comparison, a known tribromoisobutane was prepared, namely, isobutylene bromide was converted by soda into isocrotyl bromide (b. p.  $91$ — $92^\circ$ ), and this saturated with bromine; the tribromide thus obtained boiled however at  $155$ — $161^\circ$  at a pressure of 235 mm., and when treated with soda yielded a dibromoisobutylene boiling constantly at  $154$ — $155^\circ$ , and by addition of bromine it yielded a crystalline tetrabromoisobutane, melting at  $205^\circ$ .

The two tribromoisobutylenes are therefore not identical; that derived from isocrotyl bromide is  $\text{CMe}_2\text{Br}:\text{CHBr}_2$ , and the only possible formula for that from isobutylene is  $\text{CMeBr}(\text{CH}_2\text{Br})_2$ . This tribromide is not formed by the direct action of bromine on isobutylene bromide.

H. B.

**Synthetic Acetonitrile.** By L. HENRY (*Compt. rend.*, **104**, 1181—1184).—Acetonitrile is obtained only in very small quantity by the action of methyl hydrogen sulphate on potassium cyanide. Much better results are obtained by the action of methyl iodide on potassium cyanide. Schlagdenhauffen has stated (*Compt. rend.*, **48**, 228) that these compounds will not react under ordinary pressure but only in sealed tubes at about  $100^\circ$ . This statement is not strictly correct. Methyl iodide, alone or dissolved in acetonitrile, has no action on potassium cyanide even at its boiling point, but if it be mixed with aqueous methyl or ethyl alcohol the reaction begins after a short time at the ordinary temperature, becomes more rapid, with continual development of heat, and the liquid soon enters into energetic ebullition. Only a very minute quantity of hydrocyanic acid, if any, is evolved, and the liquid remains colourless. The reaction is complete, and the yield is almost quantitative. The facility with which potassium cyanide is attacked by methyl iodide contrasts with the difficulty with which it is decomposed by ethyl iodide, and the simplicity of the chemical change is in contrast with the complexity of the corresponding reaction with the iodo-derivatives of the higher homologues.

The methyl iodide and potassium cyanide are mixed in equivalent proportions, and methyl alcohol of 85 per cent. is added in quantity equal to about one-third the volume of the methyl iodide. After the first product is distilled off, the distillate is mixed with a fresh quantity of potassium cyanide and methyl iodide, and the process is repeated until sufficient acetonitrile has been obtained. The product is treated with calcium chloride to remove the water and methyl alcohol, redistilled, and finally dried over phosphorus pentoxide. The pure product obtained is about 81 per cent. of the theoretical.

The acetonitrile prepared in this way is identical with that obtained by the dehydration of acetamide.

C. H. B.

**Dichlorethyl Alcohol.** By M. DE LACRE (*Compt. rend.*, **104**, 1184—1186).—This compound is obtained by means of a reaction similar to that which serves for the preparation of trichlorethyl alcohol. Zinc ethyl (1 mol.) dissolved in purified ether is placed in a flask filled with carbonic anhydride and surrounded by cold water, and dichloraldehyde (2 mols.) dissolved in ether is added very gradually. A violent reaction takes place, and a semi-solid substance of the composition  $(\text{CHCl}_2 \cdot \text{CH}_2 \cdot \text{O})_2 \text{Zn}$  separates. When this is decomposed by treatment with water and the liquid distilled, the products separated by fractionation are hydrated dichloraldehyde, dichlorethyl alcohol, and a crystalline solid which volatilises at a moderate temperature, the quantities obtained amounting respectively to 28, 38, and 15 per cent. of the dichloraldehyde used.

*Dichlorethyl alcohol*,  $\text{CHCl}_2 \cdot \text{CH}_2 \cdot \text{OH}$ , is a colourless thick viscous liquid with a characteristic odour and a pungent taste. It does not solidify in a mixture of sodium sulphate and hydrochloric acid, but boils without decomposition at  $146^\circ$  under a pressure of 764 mm.; sp. gr. at  $15^\circ = 1.145$ ; vapour-density 3.93. It is only slightly soluble in water, but dissolves readily in alcohol and ether, reduces ammonio-silver nitrate, and does not dissolve and is not affected by calcium chloride. It is attacked with some difficulty by fuming nitric acid, the product being dichloroacetic acid, which boils at  $191^\circ$ .

When treated with phosphorus pentachloride, dichlorethyl alcohol yields monochlorethylene chloride,  $\text{CHCl}_2 \cdot \text{CHCl}$ , boiling at  $114$ — $115^\circ$ . With phosphorus tribromide, it yields the corresponding bromine-derivative which boils at  $138^\circ$ , and is identical with the compound prepared by Henry (*Abstr.*, 1884, 571) by the action of antimony pentachloride on monobrom- or monochlor-ethylene bromide.

*Dichlorethyl nitrate*,  $\text{CHCl}_2 \cdot \text{CH}_2 \cdot \text{NO}_3$ , is obtained by the action of nitrosulphuric acid on the alcohol. It is a colourless liquid with a penetrating, ethereal odour and a sweet, aromatic taste. It is insoluble in water and boils at  $155$ — $156^\circ$  under a pressure of 767 mm.; vapour-density 5.56.

*Dichlorethyl acetate*,  $\text{CHCl}_2 \cdot \text{CH}_2 \cdot \text{OAc}$ , is obtained by the action of acetic chloride on the dichloralcohol. It is a colourless liquid with a strong pleasant odour, different from that of its isomeride ethyl dichloroacetate, and a very piquant taste. It boils at  $166$ — $168^\circ$  under a pressure of 766 mm.; vapour-density 5.74; sp. gr. at  $15^\circ = 1.104$ .

C. H. B.

**Normal Butyl Alcohol in Cognac Brandy: Higher Alcohols in Brandy and the Products of Fermentation of Sugar by Elliptical Yeast.** By E. CLAUDON and E. C. MORIN (*Compt. rend.*, 104, 1187—1189).—250 grams of the oils obtained by Ordonneau from brandy (Abstr., 1886, 436) were dried over potassium carbonate, distilled from barium oxide, and fractionated. The percentage composition of the fraction containing the higher alcohols was as follows:—

|                            | Claudon & Morin. | Ordonneau. |
|----------------------------|------------------|------------|
| Propyl alcohol .....       | 11·9             | 11·7       |
| Isobutyl alcohol .....     | 4·5              | 0·0        |
| Normal butyl alcohol ..... | 49·3             | 63·8       |
| Amyl alcohol .....         | 34·4             | 24·5       |

Ordonneau's figures are given for comparison. The normal butyl alcohol was recognised by its vapour-density and by converting it into the corresponding iodide. These results confirm those obtained by Ordonneau. The presence of butyl alcohol and butyric acid in this brandy may in all probability be attributed to the development of a bacillus in the wine from which the brandy was made. *Bacillus butylicus*, which converts glycerol, sugar, &c., mainly into normal butyl alcohol and butyric acid, will produce energetic fermentation even in a liquid containing as much as 10 per cent. of ethyl alcohol.

The following table shows the relative proportions of the higher alcohols in cognac brandy and in the corresponding product obtained from sugar fermented by elliptical yeast. The figures give the amounts of the higher alcohols in each hectolitre of the alcohol taken at 100°. The normal butyl alcohol present in the cognac is omitted.

|                        | Cognac.     | Sugar, with<br>elliptical yeast. |
|------------------------|-------------|----------------------------------|
| Propyl alcohol .....   | 48·1        | 3·1                              |
| Isobutyl alcohol ..... | 18·5        | 2·4                              |
| Amyl alcohol .....     | 139·5       | 80·0                             |
|                        | <hr/> 206·1 | <hr/> 85·5                       |

It is evident that elliptical yeast alone gives a much lower proportion of the higher alcohols than is contained in wine fermented in the ordinary manner, and hence the practice of "sugaring," at least from this point of view, cannot be injurious. C. H. B.

**Action of Sodium Amalgam on Arabinose.** By H. KILIANI (*Ber.*, 20, 1233—1235).—When arabinose is treated with sodium amalgam, with gradual addition of dilute sulphuric acid to prevent the reaction from becoming alkaline, and the product extracted with alcohol, a crystalline substance is obtained, which does not reduce Fehling's solution and has no specific rotatory power. This compound is probably a pentatomic alcohol,  $\text{OH}\cdot\text{CH}_2[\text{CH}\cdot\text{OH}]_3\cdot\text{CH}_2\cdot\text{OH}$ ; it is thus proposed to call it *arabitol*. It melts at 102°, and in this

property resembles sorbite, from which it differs in that it loses water neither at  $100^{\circ}$  nor when left in a vacuum. V. H. V.

**Sugar from Hesperidin and Naringin.** By W. WILL (*Ber.*, 20, 1186—1190).—When hesperidin is decomposed by dilute sulphuric acid and the sugar so obtained dissolved in alcohol and fractionally precipitated, well-formed crystals of isodulcitol were obtained. Glucose is also present. The two are readily separated by means of their phenylhydrazine-compounds. *Isodulcitolphenylhydrazine* crystallises in yellow needles melting at  $180^{\circ}$ ; it is insoluble in water, soluble in warm alcohol and glacial acetic acid; it is separated from the phenylglucazone by extracting with boiling acetone, in which it is soluble.

Crude maringin sugar, when treated with phenylhydrazine hydrochloride and sodium acetate, also yields the phenylhydrazine-derivatives of isodulcitol and grape-sugar, and is therefore identical with the sugar from hesperidin. N. H. M.

**Sodium Nitrate in Gun-cotton.** By F. NETTLEFOLD (*Chem. News*, 55, 241).—This paper gives weighings showing the hygroscopic effect of sodium nitrate in gun-cotton charges. R. R.

**Hydrazine (Diamidogen).** By T. CURTIUS (*Ber.*, 20, 1632—1634).—Ethyl diazoacetate, when treated with hot concentrated aqueous potash, is converted into the potassium salt of a new diazo-fatty acid, which crystallises in large yellow prisms, and differs from all diazo-fatty compounds hitherto described, since the addition of mineral acids does not bring about the evolution of nitrogen, but results in the separation of the diazo-acid in the form of glistening, golden-yellow tablets. These dissolve in water with a golden-yellow colour, and when the solution is digested for a short time with very dilute sulphuric acid, the colour disappears without evolution of nitrogen, and on cooling the sulphate of a new inorganic base, *hydrazine*,  $\text{NH}_2\cdot\text{NH}_2$ , is obtained in colourless, well-defined crystals.

*Hydrazine sulphate*,  $\text{N}_2\text{H}_4\cdot\text{H}_2\text{SO}_4$ , crystallises in anhydrous tables showing a vitreous lustre, and is sparingly soluble in cold, readily soluble in hot water, insoluble in alcohol. It is not decomposed at a temperature of  $250^{\circ}$ , but when heated over a flame, it melts with an explosive evolution of gas, accompanied with a partial reduction of the sulphuric acid to sulphur. The *hydrochloride*,  $\text{N}_2\text{H}_4\cdot 2\text{HCl}$ , obtained from the sulphate by treating it with barium chloride, forms large regular crystals, melts at about  $200^{\circ}$  with evolution of gas, and is readily soluble in cold water, less soluble in alcohol. With platinic chloride, it does not form a double salt, but is decomposed with the evolution of much gas.

*Diamidogen* or *hydrazine*,  $\text{NH}_2\cdot\text{NH}_2$ , is obtained when its salts are heated with aqueous soda. It is a very stable gas, is extremely soluble in water, turns red litmus-paper a deep blue, and gives white fumes with acid vapours. In the concentrated state, it has a very peculiar odour only slightly resembling that of ammonia, and, when breathed, it powerfully affects the nose and throat. When the

hydrochloride is heated with dilute aqueous soda, and the water which passes off by evaporation is constantly renewed, small quantities of hydrazine pass over with the steam even at the end of half an hour; and if, instead, the solution is allowed to concentrate, and finally is heated to the fusing point of sodium hydroxide, no formation of ammonia occurs, but the greater part of the base distils over with the steam. Hydrazine is a very powerful reducing agent, and in its reactions exhibits all the properties of its substitution derivatives. Fehling's solution and ammoniacal silver solution are at once reduced by it in the cold; from neutral copper sulphate a thick, red precipitate, from mercuric chloride a white precipitate, and from aluminium salts alumina are obtained, whilst with aromatic aldehydes and ketones it yields sparingly soluble, crystalline compounds. The solutions of the salts of hydrazine are decomposed by nitrites with much frothing.

W. P. W.

**Oxidation of Ricinoleic and Linoleic Acids.** By W. DIEFF and A. REFORMATSKY (*Ber.*, **20**, 1211—1212).—By oxidising ricinoleic and linoleic acids by means of potassium permanganate in alkaline solutions, trihydroxy- and tetrahydroxy-stearic acids respectively were obtained. The linoleic acid must therefore contain 18 and not 16 carbon-atoms.

N. H. M.

**New Reactions with Ethyl Sodacetoacetate and Ethyl Sodomalonate.** By A. MICHAEL (*Amer. Chem. J.*, **9**, 124—129).—Ethyl sodacetoacetate and benzaldehyde react to form a crystalline substance melting at 126—127°, and quite different from the compound described by Claissen. Ketones do not react until heated to 100°. Ethereal thiocarbimides react readily. Thus phenyl thiocarbimide and ethyl sodomalonate yield a crystalline substance,  $C_{14}H_{15}NaSNO_4$ , from which acids separate the thioanilide,

melting at 60°. Phenyl isocyanate reacts at once with ethyl sodacetoacetate, yielding two products, whilst with ethyl sodomalonate three products are obtained, the only one described being the sodanilide of methenyldiethyltricarboxylate,  $NNaPh \cdot CO \cdot CH(COOEt)_2$ , melting at 123—124°; from this, by treatment with acids, a compound,  $C_{12}H_9NO_3$ , melting at 172°, is obtained. Phthalic anhydride reacts readily, yielding a heavy oil of acid properties, having the formula  $C_{14}H_{14}O_6$ . Carbonic anhydride, carbon bisulphide, sulphurous anhydride, and phosphoric anhydride react readily with ethyl sodomalonate forming new compounds. The formation of coumarins by dehydrating a mixture of ethyl acetacetate and resorcinol has already been described; using ethyl sodacetoacetate, condensation takes place in the cold, and  $\beta$ -methylumbelliferone may be thus easily prepared. Sulphur seems to form ethyl thiotartrate with ethyl sodomalonate. The carbamides react to form ureides: thus sodium barbiturate is formed from urea and ethyl sodomalonate, and similarly a thiobarbiturate is obtained from thiocarbamide. Acetamide yields with ethyl sodomalonate a substance of the formula  $C_7N_2Na_2H_8O_4$ , and aldehyde ammonia and

ethyl sodacetoacetate yield long white needles of a compound of the formula  $C_8H_{12}NNaO_2$ .

H. B.

**Ethyl Propiopropionate.** By A. HANTZSCH and O. WOHLBRÜCK (*Ber.*, **20**, 1320—1325).—Ethyl propiopropionate, recently investigated by Israel (*Abstr.*, 1886, 334), is probably the ethyl salt of an  $\alpha$ -acid, and not of a  $\beta$ -acid, in that, like ethyl acetoacetate, it is decomposed by hydrolysis into a ketone and carbonic anhydride, the acid which is formed as an intermediate product being exceedingly unstable. When reduced with sodium amalgam, it is converted into a lactic acid,  $\alpha$ -methyl- $\beta$ -hydroxyvaleric acid,  $CH_3Me \cdot CH(OH) \cdot CHMe \cdot COOH$ , an uncrystallisable syrup, the sodium salt of which crystallises in leaflets. By phosphoric iodide, it is converted into methylpropylacetic acid,  $CH_3Me \cdot CH_2 \cdot CHMe \cdot COOH$ , which boils at 191—194°, and differs from primary caproic acid, in that it gives a flesh-coloured precipitate with ferric chloride. The monobromo-substitution derivative of ethyl propiopropionate is converted at 100° into a crystalline mass of an acid homologous with tetric acid, probably  $\alpha$ -propioacrylic acid,  $COEt \cdot CH : CH \cdot COOH$ , which crystallises in colourless tablets, melting at 106—108°. With nitrous acid, ethylic propiopropionate yields *ethyl  $\alpha$ -oximepropionate*,  $NOH : CMe \cdot COOEt$ , melting at 94°. Levulinic acid, under similar conditions, yields a substance of the composition  $C_{10}H_{14}N_4O_{11}$ , which may empirically be regarded as compounded of 2 mols. of di-isonitrosolevulinic acid with 1 mol. of water.

V. H. V.

**Synthesis of Diatomic Monobasic Acids from Ketones.** By S. REFORMATSKY (*Ber.*, **20**, 1210—1211).— $\beta$ -Dimethylethylenelactic acid (hydroxyvaleric acid) is obtained by the action of ethyl monochloracetate and zinc on acetone. The author proposes to investigate the reaction between ethyl sodacetate and zinc, and other ketones as well as aldehydes and the alkyl salts of monobasic acids.

N. H. M.

**Decomposition of Ethyl Acetomalonate and its Homologues.** By E. LIANG (*Ber.*, **20**, 1325—1328).—With a view of preparing higher homologues of ethyl acetoacetate, the decomposition of ethereal salts of substituted malonic acids by nitrous acid was investigated. It is found that by this reaction isonitroso-derivatives of ethyl acetoacetate are produced.

*Ethyl propiomalonate*,  $COOEt \cdot CH(COOEt) \cdot COOEt$ , is a colourless liquid boiling at 239—242°; *ethyl butyromalonate* boils with partial decomposition at 247—252°, and the *ethyl isonitrosobutyrouacetate*, derived from it, is a yellow oil, soluble in alkalis with red coloration.

V. H. V.

**Glycuronic Acid.** By H. THIERFELDER (*Zeit. physiol. Chem.*, **11**, 388—409).—This substance, which was first obtained from the urine of dogs by Schmiedeberg and Meyer (*Zeit. physiol. Chem.*, **3**, 422), was shown to exist in purree by Spiegel (*Abstr.*, 1883, 219, and this

vol., p. 498). It may be prepared in a pure state as follows:—Purree is mixed with water, and digested with hydrochloric acid, the excess of which is removed by filtering, and washing the precipitate with water; the euxanthic acid which is insoluble in water is dissolved in hot alcohol, and on cooling separates in yellow needles; it is purified by repeated recrystallisation. Spiegel's method of decomposing this acid into euxanthone and glycuronic acid by weak sulphuric acid not giving good results, it was found better to mix it with water and subject it to a temperature of 120—125° in a Papin's digester for some hours. On cooling, yellow needles of euxanthone form, and are filtered off. The filtrate is twice more subjected to the same process. The acid filtrate is then concentrated to a thin syrup by means of an air-pump. Large brown crystals of glycuronic anhydride separate; they are obtained colourless by recrystallisation. Free glycuronic acid is easily obtained by the action of sulphuric acid on the barium salt. The anhydride may also be obtained from this by heating its aqueous solution; the crystals belong to the monoclinic system, and have a sweetish, somewhat bitter, taste. The lead and barium salts were described by Schmiedeberg and Meyer. The potassium salt crystallises in colourless, strongly refracting needles with four prismatic faces, having the composition  $C_6H_9O_7K$ . The sodium salt is as easily obtained, and crystallises in fine needles arranged in a dendritic or radial manner. Attempts to crystallise the zinc, cadmium, copper, calcium, and silver salts failed. By mixing solutions of glycuronic anhydride with phenylhydrazine hydrochloride and sodium acetate, according to Fischer's method (Abstr., 1885, 53), brown drops form and sink to the bottom of the vessel, where they form a sticky, black mass; this is a compound of glycuronic acid with phenylhydrazine, but a similar product in a form available for analysis may be obtained by using a solution of potassium glycuronate instead of the anhydride. Yellow needles are then formed, of neutral reaction, melting point 114—115°, and composition  $C_{42}H_{48}N_{10}O_{10}$ . They reduce Fehling's solution on the application of heat. Attempts to obtain a benzoyl compound by Baumann's method (this vol., p. 228) failed.

The specific rotation of the anhydride is  $[\alpha]_D = +19.25$ ; Külz gives 19.4 (this vol., p. 498). Difference of temperature, however, probably accounts for the discrepancy, the present determinations being made at 18°, those of Külz at 21°. Experiments moreover showed that the specific rotation rises with the temperature of the solution.

Glycuronic acid reduces copper and bismuth salts in warm alkaline solutions; comparing its reducing power with that of dextrose, 1 part of the latter corresponds with 0.989 of glycuronic anhydride.

By the action of bromine, it yields saccharic acid. By the action of sodium amalgam, gluconic acid is obtained. By the action of mineral acids, lævulinic acid is not obtained but an acid containing two atoms of hydrogen less ( $C_5H_6O_3$ ).

W. D. H.

**Thiënethylamine.** By H. GOLDSCHMIDT and W. SCHULTHESS (*Ber.*, 20, 1700—1701).—As the method of preparation of amines from the

oximes has been shown to be applicable to the furfuran-derivatives, it is here applied to thiophen-compounds. Thus, acetothiënnoxime is converted on hydrogenation into *thiënethylamine*,  $C_4SH_3 \cdot CHMe \cdot NH_2$ . This reaction is best effected in a freezing mixture. The resultant compound is a colourless liquid, boiling at  $185-187^\circ$ ; it absorbs carbonic anhydride from the air, is decomposed on evaporation with hydrochloric acid; with acetic acid, it yields an acetate,  $C_6H_9SN \cdot OAc$ , crystallising in colourless, very soluble needles. Its benzoyl-derivative forms glistening, white needles melting at  $95^\circ$ , and gives the indophenine reaction.

V. H. V.

**Constitution of Benzene.** By A. CLAUS (*Ber.*, 20, 1422—1426).—The author considers that the introduction of three pairs of quinone-oxygen atoms in benzene (Nietzki and Kehrman, this vol., p. 473), can only be simply explained by his diagonal formula for benzene, and discusses the point raised against the diagonal formula, that it does not show a difference between ortho- and para-positions. The benzene formula lately suggested by J. Thomsen (*Ber.*, 19, 2944) is criticised, and R. Meyer's octahedral formula (*Ber.*, 15, 1825) referred to.

N. H. M.

**Aromatic Nitriles: Action of Sodium and Alcohol on  $\alpha$ -Naphthonitrile, Benzonitrile, and Tolunitrile.** By E. BAMBERGER and W. LODTER (*Ber.*, 20, 1702, and 1703—1710).—On hydrogenation of the aromatic nitriles two classes of substances are formed, namely, the corresponding hydrocarbon, or more generally its dihydro-derivative, thus:  $C_{10}H_7 \cdot CN + 2H_2 = C_{10}H_{10} + HCN$ , and the primary amine; and in part its tetrahydro-derivative, thus:  $C_{10}H_7 \cdot CN + 4H_2 = C_{10}H_{11} \cdot CH_2 \cdot NH_2$ .

*Dihydronaphthalene*,  $C_{10}H_{10}$ , formed as in the above reaction, is a strongly refractive oil, boiling at  $211^\circ$  under 713 mm. pressure, and solidifying at low temperatures in large, glistening tables which melt at  $15.5^\circ$ . It readily takes up bromine to form a dibromide,  $C_{10}H_{10}Br_2$ , which crystallises in colourless prisms of the monoclinic system, melting at  $73.5-74^\circ$ , and is readily converted into naphthalene with evolution of hydrobromic acid.

*Tetrahydronaphthobenzylamine*,  $C_{10}H_{11} \cdot CH_2 \cdot NH_2$ , also obtained in the above reaction, is a colourless, strongly refractive, viscid oil, of peculiar ammoniacal odour, boiling at  $269-270^\circ$  under 722 mm. pressure. It is monobasic, and shows a remarkable affinity for carbonic anhydride. Its *hydrochloride* crystallises in needles; its *platinochloride* is a pale-yellow, crystalline precipitate. On hydrogenation of benzonitrile, benzene, and benzylamine are obtained, and from paratolunitrile, a methylbenzylamine,  $C_6H_4Me \cdot CH_2 \cdot NH_2$  [Me :  $CH_2NH_2 = 1 : 4$ ], a colourless oil, resembling trimethylamine in odour, and absorbing carbonic anhydride. Its *hydrochloride* crystallises in flat needles, melting at  $234.5-235^\circ$ ; and the *platinochloride* in four-sided tables, sparingly soluble in water.

V. H. V.

**Constitution of Quinone-derivatives.** By A. HANTZSCH (*Ber.*, 20, 1303—1308).—When the sodium salt of quinonedihydroxy-dicarboxylate is treated with hydrobromic acid until carbonic

anhydride ceases to be evolved, and bromine is added to the product, paradibromodihydroxyquinone,  $C_6Br_2(OH)_2O_2$ , is formed. This is shown by its physical properties and crystallographic measurements, as also of its sodium and potassium salts, to be identical with brom-anilic acid. The rest of the paper is occupied by speculations on the constitution of bromanilic acid; it is suggested that it may be a paradibromotetraketohexamethylene. V. H. V.

**Isomeric Chloro- and Bromo-thymoquinones.** By K. SCHNITER (*Ber.*, 20, 1316—1319).—In the mono-substituted thymoquinones, the positions 3 and 6 are not identical in function, so that according to theory two mono-derivatives are possible. It is remarkable, however, that on addition of the halogen acid to thymoquinone and subsequent oxidation, the same chlorobromothymoquinone is formed whether the chlorine be introduced first and then bromine, or conversely, a result only to be explained by the substitution of different hydrogen atoms by the halogen in the two cases.

*α-Chlorothymoquinol*, prepared by adding thymoquinone to concentrated hydrochloric acid, crystallises in silky needles melting at 70°, soluble in alcohol and ether.

*α-Chlorothymoquinone*, prepared by oxidising the above with ferric chloride, was not obtained in a crystalline form.

*β-Bromothymoquinol* forms colourless needles melting at 53°; it is converted by oxidation into the *quinone*, which crystallises in yellow leaflets melting at 45°.

*α-Chloro-β-bromothymoquinol*, obtained either from the above *α*-chloro-derivative and hydrobromic acid, or from the *β*-bromo-derivative and hydrochloric acid, crystallises in needles melting at 63°; when oxidised it yields the corresponding quinone, crystallising in golden leaflets, and melting at 87°.

*β-Chlorothymoquinone*, formed from the *β*-bromo-derivative by substitution, was not obtained in a well-defined condition. The *β*-chloro-*α*-bromo-thymoquinone melts at 78°, and the corresponding quinol at 56°. V. H. V.

**Substitution of the Amido- by the Nitro-group in Aromatic Compounds.** By T. SANDMEYER (*Ber.*, 20, 1495—1497).—Nitrobenzene is prepared from aniline in the following way:—50 grams of crystallised copper sulphate and 15 grams of grape-sugar are dissolved in 100 c.c. of boiling water and at once treated with a cold solution of 20 grams of soda in 60 c.c. of water. The whole solidifies and then becomes quite liquid; it is quickly cooled and neutralised with acetic acid. 9 grams of aniline, 50 c.c. of water, and 20 grams of nitric acid (sp. gr. 1.4), are mixed, and gradually treated (being kept cool) with a solution of 15 grams of sodium nitrite in 50 c.c. of water; the whole is then added in portions to the solution first prepared contained in a two-litre flask. After two hours, it is distilled, the distillate treated with caustic soda and the nitrobenzene separated. The yield is 5 grams of almost pure nitrobenzene.

Parabromonitrobenzene is prepared in a manner similar to bromo-

benzene from 17 grams of parabromaniline, the amount of nitric acid, &c., being the same as given above; 3 grams of pure product were obtained.

$\beta$ -Nitronaphthalene is obtained by dissolving 7 grams of  $\beta$ -naphthylamine in a boiling mixture of 15 grams of nitric acid and 250 c.c. of water, cooling quickly, and adding 12 grams of sodium nitrite in 40 c.c. of water. After being treated with the cuprous oxide mixture, it is left for 20 minutes, and treated with alcohol; it is then kept cool for some hours and distilled. The yield of pure  $\beta$ -nitronaphthalene is  $\frac{1}{2}$  gram.

N. H. M.

**Conversion of the Higher Homologues of Phenyl into Amines.** By R. LLOYD (*Ber.*, 20, 1254—1262).—Merz and Weith have succeeded in converting phenol into aniline and diphenylamine by heating it with ammonium-zinc chloride; the conversion is more complete the higher the molecular weight of the phenol. In this paper, the examination of amines obtained from isobutyl- and isoamylphenols, thymol and carvacrol is described. Thus isobutylphenol yields mono- and di-isobutylphenylamine. *Isobutylphenylamine*,  $\text{NH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{C}_4\text{H}_9^\beta$ , is a brown oil, boiling at  $230\text{--}231^\circ$ , its acetyl-derivative crystallises in leaflets, melting at  $170^\circ$ . *Diisobutylphenylamine*,  $\text{NH}(\text{C}_6\text{H}_4 \cdot \text{C}_4\text{H}_9)_2$ , boils at  $305\text{--}315^\circ$ ; it gives at first a violet, then a blackish-blue coloration with nitric acid; its *platinochloride* crystallises in yellow needles, and its acetyl-derivative in glistening leaflets, melting at  $75^\circ$ , sparingly soluble in water, soluble in alcohol and benzene.

Similarly isoamylphenol yields mono- and di-isoamylphenylamine. *Isoamylphenylamine*,  $\text{NH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{C}_5\text{H}_{11}$ , boils at  $259\text{--}262^\circ$ . *Diisoamylphenylamine*,  $\text{NH}(\text{C}_6\text{H}_4 \cdot \text{C}_5\text{H}_{11})_2$ , is a thick oil, boiling at  $319\text{--}321^\circ$ ; its *platinochloride* forms golden-yellow crystals, and its acetyl-derivative glistening leaflets, melting at  $81^\circ$ .

From thymol were obtained thymylamine,  $\text{NH}_2 \cdot \text{C}_{10}\text{H}_{13}$ , and *dithymylamine*,  $\text{NH}(\text{C}_{10}\text{H}_{13})_2$ ; the latter is an oil of aromatic odour, boiling at  $340\text{--}345^\circ$ ; its acetyl-derivative crystallises in leaflets, melting at  $78^\circ$ ; the former has been investigated by Widman. Of the bases formed from carvacrol, *carvacrylamine*,  $\text{C}_{10}\text{H}_{13}\text{NH}_2$ , is a colourless oil, boiling at  $241\text{--}242^\circ$ , and solidifying at  $-16^\circ$ ; its *platinochloride* crystallises in prisms, its acetyl-derivative crystallises in white tablets melting at  $115^\circ$ , and the *benzoyl*-derivative in rhombic crystals melting at  $102^\circ$ . *Dicarvacrylamine* is a colourless oil boiling at  $344\text{--}348^\circ$ , its *hydrochloride* forms a white and the *platinochloride* a yellow precipitate; the acetyl-derivative crystallises in scales melting at  $78^\circ$ . In each case numbers are given showing the relative proportions of the primary and secondary base formed according as ammoniacal solutions of zinc ammonium chloride or bromide were used; the bromide gave a better yield than the chloride. The most satisfactory results were obtained in the case of carvacrol.

V. H. V.

**Dimethylbenzylamine.** By C. L. JACKSON and J. F. WING (*Amer. Chem. J.*, 9, 78—81).—This base has been prepared by

Schotten, but not fully described. *Dimethylbenzylamine* is prepared by the action of benzyl chloride on dimethylamine; the product in aqueous solution is treated with ether, which extracts the substance in question, but leaves dissolved in the water the excess of dimethylamine and also dibenzyltrimethylammonium chloride. It boils at 183—184°; its chloride and nitrate are deliquescent; the following three crystalline salts were analysed:  $(\text{NMe}_2 \cdot \text{C}_7\text{H}_7)_2, \text{H}_2\text{PtCl}_6$ ,  $(\text{NMe}_2 \cdot \text{C}_7\text{H}_7)_2, \text{H}_4\text{Fe}(\text{CN})_6$ , and  $(\text{NMe}_2 \cdot \text{C}_7\text{H}_7, \text{HCl})_2, \text{ZnCl}_2$ .

*Dimethyldibenzylammonium chloride*,  $\text{NMe}_2(\text{C}_7\text{H}_7)_2\text{Cl}$ , prepared as above described, is, after purification, a white crystalline solid, soluble in water and in chloroform; when it separates from aqueous solution it is obtained as an oil, which, however, soon solidifies. Its platino-chloride crystallises easily.

H. B.

**Action of Ethylenediamine on Catechol.** By V. MERZ and C. RIS (*Ber.*, 20, 1190—1197).—*Ethyleneorthophenylenediamine*,  $\text{NH} < \begin{smallmatrix} \text{C}_6\text{H}_4 \\ \text{C}_2\text{H}_4 \end{smallmatrix} > \text{NH}$ , is obtained by heating 3 grams of catechol with 3.2 grams of dried ethylenediamine hydrate at 200° to 210° for 15 hours. The product is treated with cold water, washed with water, and dried over sulphuric acid; it is then distilled in an atmosphere of hydrogen. It crystallises from ether in white, lustrous plates, melts at 96.5—97°, and boils at 287.5—288.5°. It dissolves readily in hot water, warm ether, and in cold alcohol, benzene, and chloroform. When the aqueous solution is heated with ferric chloride, it acquires a blue colour when dilute, violet when more concentrated; on adding hydrochloric acid, the blue colour changes to green or greenish-yellow, and then slowly (on heating quickly) to brown and red. The *oxalate* crystallises in colourless needles, sparingly soluble in alcohol, more soluble in water; it melts at 184° with decomposition. The *picrate* forms a yellow crystalline precipitate, readily soluble in alcohol; it melts just above 120°, with decomposition. When the diamine is oxidised with about five times its weight of potassium ferricyanide, and the product extracted with ether, quinoxaline is obtained. The yield is 64.4 per cent. of the theoretical. The quinoxaline melts at 27.5°, and distils at 225—226° (comp. Hinsberg, *Annalen*, 237, 333).

Quinoxaline can be reconverted into ethylene orthophenylenediamine by gradually treating the boiling alcoholic solution with sodium; the yield is about 40 per cent. of the weight of the quinoxaline. Other substances are formed in the reaction.

N. H. M.

**Nitrophenols and Phenylhydrazine.** By A. BARR (*Ber.*, 20, 1497—1500).—When orthonitrophenol is warmed with phenylhydrazine in presence of xylene as diluent for  $1\frac{1}{2}$  hours, orthamidophenol is obtained (comp. Merz and Ris, *Ber.*, 19, 1754); benzene, ammonia, and nitrogen are formed in the reaction.

Paranitrophenol reacts in like manner with phenylhydrazine;  $\alpha$ -dinitrophenol and phenylhydrazine yield benzene and ammonium dinitrophenol.

N. H. M.

**Thio-derivatives of Diethylaniline and Dimethylaniline.**

By E. HOLZMANN (*Ber.*, **20**, 1636—1643).—Sulphur monochloride forms with diethylaniline a *dithiodiethylaniline*,  $S_2(C_6H_4 \cdot NEt_2)_2$ ; in order to moderate the violence of the reaction, both substances are diluted to a considerable extent with petroleum. The compound crystallises in short, golden prisms, melting at  $69-72^\circ$ ; it is sparingly soluble in ether, more readily in alcohol and benzene; it is rapidly decomposed by excess of water. Its *picrate* and *platinochloride* are yellow, amorphous precipitates. By silver nitrate in ammoniacal solution, the sulphur compound is converted into *dioxydiethylaniline*,  $O_2(C_6H_4 \cdot NEt_2)_2$ , which crystallises in needles or prisms, melts at  $67^\circ$ , and is decomposed, when moist, in contact with air.

Similarly dimethylaniline reacts with sulphur dichloride to form *thiodimethylaniline*,  $S(C_6H_4 \cdot NMe_2)_2$ , which crystallises in pale yellow needles, melts at  $123.5^\circ$ , and is sparingly soluble in warm alcohol and benzene. Its *picrate* and *platinochloride* are similar to those of the above compound, from which, however, it differs in not being convertible into the corresponding oxygen compound. V. H. V.

**Sulphazides.** By H. LIMPRICHT (*Ber.*, **20**, 1238—1242).—In this paper, several sulphazides are described, a class of substances first investigated by König and Wiesinger, and obtained by passing nitrous acid into an alcoholic solution of the aromatic amines, saturated with nitrous acid.

*Metanitrophenylnitrobenzenesulphazide*,  $C_{12}H_{10}(NO_2)_2N_2SO_2$ , is a crystalline powder, melting at  $160-162^\circ$ , soluble in alcohol and acetone, insoluble in water; it slowly reduces Fehling's solution and ammoniacal silver solutions; when boiled with baryta-water, it is decomposed into nitrobenzene and *metanitrobenzenesulphinic acid*,  $NO_2 \cdot C_6H_4 \cdot SO_2H$ . This acid crystallises in glistening needles melting at  $95^\circ$ , and is soluble in ether, sparingly soluble in alcohol; its salts crystallise in prisms.

*Paranitrophenylnitrobenzenesulphazide*, melting at  $160^\circ$ , resembles the above compound; the corresponding sulphinic acid crystallises in leaflets melting at  $120^\circ$ , and is sparingly soluble in ether.

*Orthotolytoluenesulphazide*,  $C_{14}H_{16}N_2SO_2$ , crystallises in needles melting at  $140-142^\circ$ ; its sulphinic acid crystallises in pale-yellow needles melting at  $80^\circ$ .

*Nitrotolylnitrotoluenesulphazide* crystallises in prisms, melting at  $140-142^\circ$  with decomposition.

The reactions which lead to the formation of these compounds have been previously explained by Königs and Fischer.

V. H. V.

**Action of Aldehydes on Phenols.** By A. MICHAEL and J. P. RYDER (*Amer. Chem. J.*, **9**, 130—137).—Benzaldehyde and phenol, when heated with a few drops of hydrochloric acid, react with formation of a white, resinous substance,  $C_{26}H_{20}O_2$ , which yields a white amorphous acetate,  $C_{26}H_{18}O_2Ac_2$ . Benzaldehyde and pyrogallol, when heated with alcohol and a little hydrochloric acid, yield a white

crystalline substance, to which Baeyer gave the formula  $C_{26}H_{22}O_7$ , but which is really  $C_{26}H_{20}O_6$ ; it yields a crystalline acetate,  $C_{26}H_{14}O_6Ac_6$ . Benzaldehyde and phloroglucinol give a resinous compound, insoluble in alcohol; its composition is  $C_{26}H_{20}O_6$ . Benzaldehyde and orcinol give a white resin of the formula  $C_{22}H_{24}O_4$ , soluble in alcohol. The behaviour of a number of other phenols and aldehydes was examined; in some cases, a resinous substance was at once formed; in others there was no reaction, even on heating.

A solution of resorcinol in absolute alcohol (1:2) with a trace of hydrochloric acid is recommended as a reagent for aldehydes of monobasic acids; if no resin forms after some hours, it is poured into water, when a resinous or a crystalline substance will be precipitated. Ketones give no such reaction, and this reagent is therefore more characteristic than phenylhydrazine or hydroxylamine.

The action of chloral hydrate on resorcinol has been already described (Abstr., 1884, 598); by substituting orcinol for the resorcinol, a more stable product is formed; it can be obtained almost white by recrystallisation, has the formula  $C_{23}H_{24}O_8$ , and yields an acetate,  $C_{35}H_{34}O_{13}$ , melting at  $185^\circ$ . The resorcinol compound was again prepared, but it was still found impossible to obtain satisfactory analyses, owing to the ease with which it absorbs oxygen; the acetate is, however, easily obtained pure. When treated with permanganate, it yields a crystalline acid,  $C_{20}H_{16}O_8$ , which melts at about  $210^\circ$ .

H. B.

**Metamethylcinnamic Acid and its Derivatives.** By W. MÜLLER (*Ber.*, 20, 1212—1217).—*Metamethylcinnamic acid*,  $C_9H_9COOH$ , is obtained by boiling 30 grams of metaxylyl bromide with 35 grams of lead nitrate and 250 grams of water, in a reflux apparatus for 12 hours, a current of carbonic anhydride being passed through the apparatus all the time, in order to carry off the nitrogen oxide formed in the reaction. The product is extracted with ether, the oil so obtained treated with sodium hydrogen sulphite; the white flaky precipitate is separated from the liquid and washed with sodium hydrogen sulphite solution. It is then dissolved in water, separated from the oil which forms, and treated with sodium carbonate. *Metatoluic aldehyde* separates, and is extracted with ether. The aldehyde boils at  $199^\circ$ , and has an odour of benzaldehyde; when exposed to the air, it oxidises very readily to the corresponding acid; 1 part of aldehyde, 1 part of sodium acetate, and 3 parts of acetic anhydride are boiled for eight hours, the product treated with water and with sodium carbonate until alkaline, and steam distilled. The sodium metamethylcinnamate which remains is precipitated with hydrochloric acid, collected, dissolved in a little hot water, and again quickly filtered. It separates in white flakes. It resembles cinnamic acid in appearance, melts at  $107.5^\circ$ , distils with steam, and also alone when quickly heated. The *barium* and *silver salts* form white plates and white flakes respectively; both are almost insoluble. When oxidised with potassium permanganate, the acid is converted into metatoluic acid.

*Hydrometamethylcinnamic acid* (metamethylphenylpropionic acid),

$C_7H_7 \cdot C_2H_4 \cdot COOH$ , is prepared by the action of sodium amalgam on metamethylcinnamic acid. It forms white flakes which melt at  $40^\circ$ ; it dissolves in water, alcohol, and ether, and distils with steam.

*Metamethylcinnamic bromide*,  $C_9H_9Br_2 \cdot COOH$ , is formed when a solution of metamethylcinnamic acid in carbon bisulphide is treated with a solution of bromine in the same solvent. It melts at  $167^\circ$  with decomposition; it is readily soluble in ether.

*Metamethylphenylpropionic acid*,  $C_9H_7 \cdot COOH$ , is obtained by boiling the above bromide with alcoholic potash. The product is evaporated, dissolved in water, and precipitated with hydrochloric acid. It melts at  $109.5^\circ$ . When treated with silver nitrate, a white precipitate is formed, which is explosive. When the barium salt is distilled with lime, an oil is obtained (metamethylphenylacetylene), which gives a red precipitate with ammoniacal cuprous chloride solution; this explodes when heated.

*Metamethylcinnamene* is prepared by leaving powdered cinnamic acid for two or three days in contact with fuming hydrobromic acid. The product is filtered through glass-wool, washed with water, and treated with sodium carbonate. The oil is extracted with ether. It boils at  $164^\circ$ , and becomes solid when kept long.

*Metamethylbromocinnamene*,  $C_7H_7 \cdot CHBr \cdot CH_2Br$ , is obtained by the action of bromine on a cooled solution of metamethylcinnamene in chloroform. It melts at  $45^\circ$ .

*Metamethyl- $\alpha$ -bromocinnamene*,  $C_7H_7 \cdot CH : CHBr$ , is prepared by the action of bromine on sodium metamethylcinnamate dissolved in water; it has an agreeable odour, becomes thick when cooled, and boils with decomposition at  $242^\circ$ .

*Metamethyl- $\beta$ -bromocinnamene*,  $C_7H_7 \cdot CBr : CH_2$  is prepared by boiling metamethylbromocinnamene with alcoholic potash. It is an oil of an agreeable odour; it cannot be distilled, and blackens at the temperature of the water-bath.

N. H. M.

**Action of Phosphorus Pentachloride on Salicylic Acid.** By J. CHASANOWITCH (*Ber.*, **20**, 1164—1167).—When the product of the action of phosphorus pentachloride (1 mol.) on salicylic acid (1 mol.) is exposed to air, a solid substance is obtained, readily soluble in water, from which it separates in a crystalline form when kept over sulphuric acid. The compound is monorthocarboxylphenylorthophosphate,  $PO(OH)_2O \cdot C_6H_4 \cdot COOH + 3H_2O$ , identical with that obtained by Couper (*Annalen*, **109**, 370). The *lead salt*,  $(C_7H_4PO_6)_2Pb_3$ , and *silver salt*,  $C_7H_4PO_6Ag_3$ , were analysed. The first product of the reaction is the dichloride,  $POCl_2O \cdot C_6H_4 \cdot COCl$  (Anschütz, *Abstr.*, 1885, 1062). The latter distils with partial decomposition into chlorobenzoic chloride.

N. H. M.

**Homo-orthophthalimide.** By S. GABRIEL (*Ber.*, **20**, 1198—1205; compare this vol., p. 50).—Dimethylhomophthalimide is best prepared by warming 48 grams of finely powdered homo-orthophthalimide, 50 c.c. of water, 35 grams of powdered potassium hydroxide, and 200 c.c. of alcohol in a flask on a water-bath, until a clear solution is obtained; it is cooled down until lukewarm, and the flask fitted with

a reflux condenser; 87 grams of methyl iodide is gradually added, the whole left for one hour, and then boiled for about three-quarters of an hour. The contents of the flask are evaporated until free from alcohol, treated with hot water, filtered after some hours and then dried and distilled. The distillate is dissolved in soda solution, filtered, and precipitated with ammonia. It is crystallised from a mixture of water and glacial acetic acid (1 : 5). It boils without decomposition at  $318.5^{\circ}$ , under 770 mm. pressure.

Trimethylhomo-orthophthalimide boils at  $294.5^{\circ}$  under 770 mm. pressure. The compound  $C_9H_7Me_3O_3$  (*loc. cit.*) is best obtained from dimethylhomophthalimide (instead of the trimethyl compound) by digesting it with four parts of fuming hydrochloric acid at  $210-220^{\circ}$  for four to five hours. When the compound is dissolved in alcoholic potash in presence of a few drops of water, and the solution treated with 5 to 10 volumes of alcohol, and kept in a closed vessel, crystals of the *potassium salt*,  $C_9H_7Me_2O_3K_2 + H_2O$ , separate. Other salts were prepared. The *free acid*,  $COOH \cdot C_6H_4 \cdot CMe_2 \cdot COOH$ , is obtained by dissolving the anhydride in boiling soda, diluting, and supersaturating the cooled solution with hydrochloric acid. It separates in needles of a glassy lustre, soluble in ether, chloroform, and warm water. It melts at  $123^{\circ}$  when quickly heated, with separation of water. The same decomposition also takes place in hot solutions of the acid containing water.

When the anhydride is distilled with soda-lime, it is converted into isopropylbenzene. The two methyl-groups in dimethylhomophthalimide are therefore attached to the same carbon-atom, as shown in the formula previously ascribed to it (*loc. cit.*).

*Homophthalimide sodium*,  $C_9H_5O_2NNa$ , is prepared by adding a solution of 0.23 gram of sodium in 10 c.c. of alcohol to a solution of 1.7 gram of homophthalimide in 80 to 100 c.c. of boiling alcohol; it separates as a yellow, crystalline powder.

*Homo-orthophthalaminic acid*,  $COOH \cdot C_6H_4 \cdot CH_2 \cdot CONH_2$ , is formed when benzoylecyanideorthocarboxylic acid (W. Wislicenus, *Abstr.*, 1885, 532) is gradually added to 10 parts of sulphuric acid, and the whole warmed at  $70^{\circ}$  for half an hour; the product is precipitated by water. It crystallises from boiling alcohol in needles which melt at  $185-187^{\circ}$ , with evolution of gas; it then solidifies and melts at  $230^{\circ}$ , the melting point of homo-orthophthalimide. The *methyl salt* of the amido-amide melts at  $110-112^{\circ}$ .

*Benzalhomom-orthophthalimide*,  $C_{16}H_{11}NO_2$ , is obtained by boiling a mixture of homo-orthophthalimide with benzaldehyde for 10 minutes, and treating the product with hot alcohol. It crystallises from alcohol in needles which melt at  $173-174^{\circ}$ .

*Homo-orthophthalimidazobenzene*,  $C_9H_6NO_2 \cdot N_2Ph$ , is formed when 2.5 grams of homophthalide, dissolved in alcohol, is added to a solution of 5 grams of aniline previously treated with the necessary amount of hydrochloric acid and potassium nitrite to convert it into diazobenzene chloride. It crystallises from glacial acetic acid in orange-coloured needles melting at  $258-260^{\circ}$ . N. H. M.

**Derivatives of Ethyl Quinoneparadicarboxylate.** By A. HANTZSCH and A. ZECKENDORF (*Ber.*, 20, 1308—1315).—In continuation of the experiments of Hentzel and Loewy (*Abstr.*, 1886, 354 and 1028), it is shown that the product of the action of chlorine on ethyl dihydroxyquinonedicarboxylate is not represented by the formula  $C_6H_4Cl_2O_3$ , but by  $C_5H_5Cl_2O_3$ . The molecular formula should probably be doubled, and the constitution of the compound represented as  $C_2O_2(CCl_2\cdot COOEt)_2$ , *ethyl tetrachlorodiketoadipate*. This view is confirmed by its decomposition by ammonia into 1 mol. of oxamide and 2 mols. of dichloracetamide. The final product of the action of chlorine on ethyl quinonedihydrodicarboxylate and ethyl succinosuccinate is identical, namely, *ethyl dichloroquinonedicarboxylate*,  $C_6O_2Cl_2(COOEt)_2$ , which crystallises in greenish-yellow needles, melting at  $195^\circ$ ; the ready removal of both chlorine-atoms in this compound is remarkable, a change effected even by very dilute aqueous soda. By ammonia, it is converted into *ethyl diamidoquinonedicarboxylate*,  $C_6O_2(NH_2)_2(COOEt)_2$ , which crystallises in yellow glistening leaflets, decomposed at  $270^\circ$  without fusion; with aniline a *dianilido-derivative*,  $C_6O_2(NHPh)_2(COOEt)_2$ , is formed, which crystallises in glistening needles melting at  $246^\circ$ ; other primary amines give similar products. The above dichloro-compound yields on hydrogenation a compound,  $C_{12}H_{12}Cl_2O_6$ , probably ethyldichlorodihydroxyterephthalate, which crystallises in grouped needles melting at  $123^\circ$ .

V. H. V.

**Direct Conversion of Aromatic Sulphonates into the Corresponding Amido-compounds.** By C. L. JACKSON and J. F. WING (*Amer. Chem. J.*, 9, 75—78).—Although the haloid organic compounds, with the exception of benzoic chloride, do not act on sodamide or potassamide, yet the corresponding sulphonic acids do. Thus potassium benzenesulphonate fused with sodamide for a short time over a flame gives 10 per cent. of the theoretical yield of aniline; some diphenylamine melting at  $53$ — $54^\circ$  was also formed, probably because the sodamide contained an excess of sodium. Potassium benzenemetadisulphonate in like manner yields metaphenylenediamine, but the yield is much less, amounting only to about 5 per cent.

H. B.

**Oxidation of Benzene-derivatives with Potassium Ferricyanide.** By W. A. NOYES and C. WALKER (*Amer. Chem. J.*, 9, 93—99).—Orthotoluenesulphonamide, when treated with potassium ferricyanide, yields the corresponding acid (comp. *Abstr.*, 1886, 804), but with other oxidising agents similar substances have yielded sulphinides.

The action of potassium ferricyanide on paraxylenesulphamide is described. The product of the reaction was nearly acidified to precipitate unoxidised paraxylenesulphonamide, evaporated to remove potassium ferrocyanide, then acidified and extracted with ether and the acids converted into barium salts. The mixture of salts extracted with alcohol left barium sulphamineterephthalate insoluble, whilst a barium sulphamineparatoluate passed into solution. The free acid from the barium salts is identical with that described by Remsen and Hall. There appears to be formed also some of the isomeric  $\beta$ -acid.

*Sulphamineterephthalic acid*,  $C_6H_3(COOH)_2 \cdot SO_2NH_2$ , was extracted by dissolving the purified barium salt in hydrochloric acid and treating with ether; if, however, the salt is heated with hydrochloric acid, it is converted into hydrogen barium sulphoterephthalate,

Sulphamineterephthalic acid crystallises easily from hot water, and does not fuse at  $310^\circ$ . The monopotassium salt,

is sparingly soluble in cold water.

The barium salt (+  $H_2O$ ) when formed by boiling the acid with barium carbonate, dissolves easily, but once separated in the solid condition, it is difficult to redissolve; it forms nodular masses without any well-defined crystalline structure.

For the sake of comparison, terephthalic sulphinide and its barium salt were prepared; the acid potassium salt has been previously described. *Terephthalic sulphinide*,  $COOH \cdot C_6H_3 < \begin{smallmatrix} CO \\ SO_2 \end{smallmatrix} > NH$ , is easily soluble in hot water, and fuses at  $297-299^\circ$ ; it gives a precipitate with silver nitrate almost insoluble in dilute nitric acid; sulphamineterephthalic acid does not give a similar reaction. The barium salt with  $3H_2O$  forms scales very sparingly soluble in water. H. B.

**Conversion of  $\beta$ -Naphthaquinone into Indonaphthene-derivatives.** By T. ZINCKE (*Ber.*, 20, 1265—1272).—In a former paper, Zincke has shown that dichloro- $\beta$ -naphthaquinone is converted by alkalis into an acid,  $C_{10}H_6Cl_2O_3$ , which may be regarded as a dichloro-derivative of phenyleneacetyleneglycollic acid,

(this vol., p. 54). On oxidation, the acid is converted into a ketone,  $< \begin{smallmatrix} C_6H_4 \\ C_2Cl_2 \end{smallmatrix} > CO$ , an analogue of diphenylene ketone. These compounds can also be considered as derivatives of indonaphthene, the former as a *dichlorohydroxyindonaphthenecarboxylic acid*, the latter as a *dichloroindonaphthene ketone*. The ketone crystallises in yellow, glistening needles, melting at  $89-90^\circ$ , resembling quinone not only in odour, but also in its reactions in that it combines with hydroxylamine and the amines. The hydroxylamine-derivative or oxime,

crystallises in needles melting at  $120^\circ$ , the *methylamine*-derivative in dark-red needles melting at  $195^\circ$ , and the *dimethylamine*-derivative in quadratic tablets melting at  $140^\circ$ . These amine-derivatives are decomposed by acids or alkalis with regeneration of the amine and formation of *phenylenechlorohydroxyacetylene ketone*,  $C_6H_4ClO \cdot OH$ ,

which crystallises in leaflets melting at  $114^{\circ}$ ; it is soluble in alkalis with a red coloration, and is converted by phosphoric chloride into a compound, crystallising in leaflets, and differing from the original ketone. It readily takes up chlorine and bromine, yielding colourless, crystalline compounds which no longer possess a quinone character.

V. H. V.

**Synthesis of Indonaphthene-derivatives.** By W. ROSER (*Ber.*, **20**, 1273—1274).—This paper is a preliminary communication with regard to the synthesis of indonaphthene-derivatives from those of cinnamic acid. Thus, dibromocinnamic acid when heated with concentrated sulphuric acid yields *phenylenedibromoacetylene ketone* or *dibromoketoindonaphthene*,  $C_6H_4 \begin{smallmatrix} \text{---CO---} \\ \text{C}_2Br_2 \end{smallmatrix}$ , crystallising in orange yellow

needles melting at  $123^{\circ}$ . With hydroxylamine, it forms an oxime crystallising in needles melting at  $195^{\circ}$ , and with aniline an anilide melting at  $170^{\circ}$ . The ketone combines directly with bromine to form a tetrabromo-additive product, which may be regarded as a derivative of hydrindonaphthene; this compound crystallises in prisms melting at  $124^{\circ}$ .

V. H. V.

**Nitrosamines.** By O. FISCHER and E. HEPP (*Ber.*, **20**, 1247—1253).—In a former paper (this vol., p. 244), it has been shown that the nitrosamines derived from aromatic amines are converted by alcoholic hydrogen chloride into paranitroso-derivatives corresponding with paranitrosodimethylaniline. Thus, from phenyl- $\alpha$ -naphthyl-nitrosamine a paranitroso-product,  $C_{16}H_{12}N_2O$ , is obtained, which crystallises in leaflets or needles melting at  $150^{\circ}$ , and soluble in concentrated sulphuric acid with brown coloration. Similarly from paranitroso- $\alpha$ -dinaphthylamine, a compound,  $C_{20}H_{14}N_2O$ , is obtained, crystallising in brownish-red needles melting at  $169^{\circ}$ , and from  $\beta$ -naphthylethyl-nitrosamine a base,  $C_{12}H_{10}N_2$ , which crystallises from methyl alcohol in short prisms containing 1 mol. MeOH, melting at  $75^{\circ}$ . The hydrochloride crystallises in colourless needles, and the platinochloride in yellow needles containing 3 mols.  $H_2O$ , the picrate in yellow needles. This substance probably belongs to the anhydro-bases, and its constitution is that of an ethenyl- $\beta$ - $\beta$ -naphthalenediamine.

The base obtained from tetrahydroquinolinenitrosamine separates in greenish-yellow flocks, melting at  $134^{\circ}$ .

It has been observed that the above paranitroso-derivatives dissolve readily in dilute alkalis, and are again reprecipitated on passing in carbonic anhydride. The sodium salt of paranitrosomethylaniline separates in yellow needles of the composition  $C_7H_8N_2O + NaOH$ , but the formation of such a salt is not in accordance with the formula proposed for those substances by Baeyer and Caro.

V. H. V.

**Azonium Bases.** By O. N. WITT (*Ber.*, **20**, 1183—1186).—Phenylorthonaphthylene-diamine (this vol., p. 590) is prepared by mixing a solution of 10 grams of sulphobenzene-azo- $\beta$ -naphthylphenylamine in 100 c.c. of alcohol and 10 c.c. of glacial acetic acid, with a solution of 12 grams of stannous chloride dissolved in 20 c.c. of glacial acetic acid. After a short time, pure hydrochloric acid is added until the

red colour of the solution has entirely disappeared. The hydrochloride of the diamine separates in white needles; these are collected and washed with alcohol and ether, and dried at  $110^{\circ}$ . The base is obtained by treating the alcoholic solution with potash. It forms transparent, flat prisms, which melt at  $136\text{--}137^{\circ}$ , and gradually redden when exposed to air. When dry, it can be heated at  $110^{\circ}$  without decomposition, but in presence of water it rapidly becomes red.

*Phenyl-naphthophenanthrazonium nitrate*,  $\text{C}_{30}\text{H}_{19}\text{N}_3\text{O}_3$ , is formed when a solution of equal parts of phenanthraquinone and the diamine in glacial acetic acid is boiled for a short time; alcohol and nitric acid (sp. gr. 1.3) are added to the cooled product. It separates after a day in long needles, which are crystallised several times from alcohol; it melts at  $110^{\circ}$ . The crystals are dichroic. It is almost insoluble in water, but more soluble in alcohol, with a yellowish-red colour. The alcoholic solution when treated with boiling water dyes cotton and wool a salmon colour. The other salts of the base are much more soluble; the *platinochloride* is a red precipitate. The *free base* is soluble in ether; the solution is yellow; it has the constitution

$\text{C}_{14}\text{H}_8 \begin{array}{c} \text{N} \cdot \text{C}_{10}\text{H}_6 \\ | \\ \text{NPh}(\text{OH}) \end{array}$ , and is therefore the analogue of the hypothetical phenylphenazonium hydroxide, of which the author considers saffranine to be the asymmetrical diamido-derivative (*Ber.*, 19, 3121).

N. H. M.

**Azo-derivatives of Phenyl- $\beta$ -naphthylamine.** By T. ZINCKE and A. T. LAWSON (*Ber.*, 20, 1167—1176).—*Benzene-azo- $\beta$ -naphthylphenylamine* is obtained by converting 20 grams of aniline into diazobenzene chloride, diluting the liquid with an equal weight of alcohol, and adding it to a warm solution of 47 grams of phenyl- $\beta$ -naphthylamine in 900 to 1000 c.c. of alcohol. The azo-compound separates in a crystalline form, and after being filtered, washed, and extracted with alcohol, is pure enough for most purposes. It crystallises from hot acetic acid in small lustrous needles of an intense red colour and dark metallic lustre, and melts at  $141\text{--}142^{\circ}$  (not  $128\text{--}129^{\circ}$ ; Henriques, *Abstr.*, 1885, 168). When boiled with glacial acetic acid (5—6 parts) and hydrochloric acid ( $1\text{--}1\frac{1}{2}$  part), it is converted into naphthaphenazine,  $\text{C}_{10}\text{H}_6\text{N}_2 \cdot \text{C}_6\text{H}_4$ , and aniline. This reaction supports the view that the azo-derivatives of  $\beta$ -naphthylamine are hydrazimides; the constitution of benzeneazo- $\beta$ -naphthylphenylamine would therefore be  $\text{C}_{10}\text{H}_6 \begin{array}{c} \text{NPh} \\ | \\ \text{N}(\text{NHPh}) \end{array}$ . Bromine acts on the compound dissolved in warm glacial acetic acid with formation of phenyl- $\beta$ -naphthylamine tetrabromide, melting at  $202\text{--}203^{\circ}$ ; the latter is identical with the compound obtained by Streiff (*Annalen*, 209, 158).

*Amido- $\beta$ -naphthylphenylamine*,  $\text{NH}_2 \cdot \text{C}_{10}\text{H}_6 \cdot \text{NHPh}$ , is obtained by reducing the azo-compound with stannous chloride. The *hydrochloride* forms long, colourless, lustrous needles, very sparingly soluble in water, more soluble in alcohol; it becomes violet when exposed to air. The *sulphate* resembles the hydrochloride. The

free base crystallises from alcohol in wide needles or plates, which melt at 138—140°, and readily become violet.

*Diphenylnaphthaleneazammonium hydroxide*,  $C_{10}H_6 \begin{array}{c} \diagup N \\ | \\ \diagdown N \end{array} NPh_2 \cdot OH$ , is

prepared by dissolving the azo-derivative of  $\beta$ -phenylnaphthylamine in hot glacial acetic acid (10 parts), heating almost to boiling, and gradually adding to it a hot concentrated solution of potassium dichromate until the solution acquires a brownish-red colour. It is then boiled for a few minutes and diluted with an equal volume of hot water; on cooling, the *chromate* of the base separates in yellow needles. The free base was only obtained in solution; it shows a green fluorescence, precipitates metallic salts, and liberates ammonia. The *chloride*,  $C_{22}H_{16}N_3Cl$ , crystallises in well-formed lustrous prisms readily soluble in alcohol, less soluble in water. The *platinochloride*,  $(C_{22}H_{16}N_3Cl)_2PtCl_4$ , forms a crystalline, reddish precipitate sparingly soluble in water; the *sulphate* and *nitrate* form lustrous prisms and long, flat, lustrous needles respectively. The *picrate* crystallises in small needles of an intense yellow colour; it melts at 243°, and is very sparingly soluble in water.

N. H. M.

**Orthamidoazo- and Hydrazimido-compounds.** By T. ZINCKE and A. T. LAWSON (*Ber.*, 20, 1176—1183).—When a solution of orthodiazazotoluene (prepared by treating a solution of 5 grams of orthamidoazotoluene in 50 grams of alcohol and 5 grams of strong hydrochloric acid with 1.6 gram of sodium nitrite dissolved in 5 parts of water) is mixed with an alcoholic solution of 3 grams of  $\alpha$ -naphthol, and treated with concentrated aqueous soda, a deep red precipitate consisting of the sodium salt of the compound  $C_7H_7 \cdot N_2 \cdot C_7H_7 \cdot N_2 \cdot C_{10}H_6 \cdot OH$  is formed. The latter is obtained by decomposing the sodium salt with acetic acid; it crystallises from aniline in brownish-red needles melting at 210°, is sparingly soluble in neutral solvents, but dissolves in dilute alcoholic soda with violet-red coloration. When reduced with stannous chloride in alcoholic solution it yields tolueneazimidotoluene,  $C_7H_6 : N_3 \cdot C_7H_7$ , melting at 126°, and amido- $\alpha$ -naphthol hydrochloride together with a small quantity of a substance, probably orthotoluylenediamine.

Orthodiazazotoluene reacts with  $\beta$ -naphthol with formation of a compound isomeric with that described above. In the case of  $\beta$ -naphthol, the free diazo-compound, and not the sodium salt, separates on the addition of soda. It may be crystallised from chloroform or benzene, when it is obtained in long, deep red prisms of an intense green metallic lustre. It melts at 177°, dissolves readily in chloroform, benzene, and xylene, sparingly in alcohol, acetone, and light petroleum. Alcoholic soda dissolves it only slightly. When reduced, it is converted into the azimide,  $C_7H_6 : N_3 \cdot C_7H_7$ , and the hydrochlorides of  $\beta$ -amidonaphthol and para- and ortho-toluidine.

Orthodiazazotoluene reacts readily with  $\beta$ -naphthylamine with formation of the compound  $C_7H_7 \cdot N_2 \cdot C_7H_6 \cdot N_2 \cdot C_{10}H_6 \cdot NH_2$ . This crystallises from hot alcohol in deep red, lustrous plates melting at 201—203°; it is readily soluble in chloroform and benzene. When reduced,

it behaves like the naphthol-derivatives, yielding the azimide  $C_7H_6:N_3:C_7H_7$ , and probably also orthonaphthylenediamine; when boiled with hydrochloric acid in alcoholic solution, the azimide is also formed.

The diazo-compounds of paramidoazotoluene are prepared in a manner similar to those of the ortho-compound.

*Paradiazotoluene nitrate* crystallises in slender, brownish-yellow needles, rather readily soluble in water and alcohol; the *perbromide* forms a yellow, crystalline precipitate which changes to slender, violet needles, melting at  $96^\circ$ .

*Paradiazotoluene imide* is obtained by treating the perbromide with an excess of alcoholic ammonia in long, slender, slightly yellow plates melting at  $58-60^\circ$ ; it can be crystallised from alcohol, but decomposes when heated or when in contact with sulphuric acid.

When the diazo-salts are reduced with zinc-dust and glacial acetic acid or with stannous chloride, orthotoluidine and orthometatoluenediamine are formed; when sodium sulphite is used, *sodium diazoazotoluene sulphonate*,  $C_7H_7 \cdot N_2 \cdot C_7H_6 \cdot N_2 \cdot SO_3Na$ , is obtained; this is a reddish crystalline precipitate, readily soluble in alcohol, sparingly in water.

The diazo-salts combine readily with the naphthols; the  $\beta$ -naphthol-*derivative* forms deep red needles melting at  $186^\circ$ ; it is readily soluble in hot alcohol and benzene. When reduced with stannous chloride, it yields  $\beta$ -amidonaphthol, orthotoluidine, and orthometatoluylenediamine.

The diazo-salts of paramidoazotoluene, as well as the perbromide, correspond, therefore, only partially with the compounds of orthamidoazotoluene which yield hydrides when reduced. N. H. M.

**Naphtholcarboxylic Acids.** By R. NIETZKI and A. L. GUITERMANN (*Ber.*, 20, 1274—1277).—The naphtholcarboxylic acids are readily decomposed into carbonic anhydride and the corresponding naphthol; in this respect, the  $\beta$ -acid is more unstable than the  $\alpha$ -acid. On adding diazobenzene chloride to a solution of  $\alpha$ -naphtholcarboxylic acid in dilute alkali, a crystalline precipitate is obtained, but analyses show that it is not homogeneous. On hydrogenation, however, there was obtained an amidonaphtholcarboxylic acid,  $OH \cdot C_{10}H_6(NH_2) \cdot COOH$ , as a colourless, crystalline powder, decomposing at  $230^\circ$  with evolution of carbonic anhydride. The amidonaphthol obtained from it on oxidation yielded  $\alpha$ -naphthaquinone, and thus its constitution was that of a 1 : 4-derivative. Then since the  $\alpha$ -naphtholcarboxylic acid is obtained by Kolbe's process from  $\alpha$ -naphthol, and in that in the reaction only 1 : 2- and 1 : 4-derivatives are formed, and as the introduced amido-group takes up the second 4-position in the naphtholcarboxylic acid, the OH and COOH groupings are probably in the 1 : 2 positions respectively. V. H. V.

**$\beta$ -Naphthylaminesulphonic Acid.** By F. BAYER and C. DUISBERG (*Ber.*, 20, 1426—1432).— $\beta$ -Naphthylamine- $\delta$ -sulphonic acid,  $NH_2 \cdot C_{10}H_6 \cdot SO_3H$ , is prepared by the action of much sulphuric acid on  $\beta$ -naphthylamine at  $150^\circ$  for  $1\frac{1}{2}$  hour. The hot solution is poured at

once on to ice, left for some time, and the residue collected and extracted with boiling water several times; it is then further purified by means of the barium or sodium salt. It is sparingly soluble in hot water, and crystallises on the addition of hydrochloric acid to the hot dilute solution of the sodium salt in long, lustrous needles (with 1 mol.  $\text{H}_2\text{O}$ ); when boiled for a long time, it separates as a sandy powder (anhydrous). The *barium salt* (with  $4\frac{1}{2}$  mols.  $\text{H}_2\text{O}$ ) crystallises in groups of slender plates readily soluble in hot water; the *magnesium salt* forms white needles (with 1 mol.  $\text{H}_2\text{O}$ ), which show a blue fluorescence. The *sodium* (with 4 mols.  $\text{H}_2\text{O}$ ) and *potassium salts* crystallise respectively in small white needles and groups of needles. The acid is distinguished from the  $\alpha$ -acid by the solubility of its sodium salt in alcohol, from the  $\beta$ -acid by the solubility of the free acid in boiling water, and from the  $\gamma$ -acid by the sparing solubility of the barium salt. The acid reacts with tetrazodiphenyl with formation of  $\delta$ -purpurin G, and with tetrazoditoyl chloride with formation of  $\delta$ -purpurin 5B, a splendid red product.

The  $\delta$ -acid is formed by heating the pure  $\gamma$ -acid or  $\alpha$ -acid with sulphuric acid at  $160^\circ$  for  $1\frac{1}{2}$  hour.

$\beta$ -Naphthol- $\delta$ -sulphonic acid is obtained by heating to boiling an aqueous solution of the diazo-compound of  $\beta$ -naphthylamine- $\delta$ -sulphonic acid with sulphuric acid, and neutralising with barium carbonate; it is then collected and extracted with sodium carbonate solution. The barium salt is sparingly, the sodium salt readily soluble; the chloride melts at  $114^\circ$  (the chlorides of Bayer's and Schaeffer's acids melt at  $61.5^\circ$  and  $135^\circ$  respectively). The acid is identical with that already prepared by Cassella by heating salts of naphthalene- $\alpha$ -disulphonic acid with alkali.

N. H. M.

**Purpurogallin.** By R. NIETZKI and T. STEINMANN (*Ber.*, **20**, 1277—1280).—Girard and others have described a substance, purpurogallin, obtained by the oxidation of pyrogallol; a somewhat similar substance, pyrogalloquinone, was obtained by the action of quinone on pyrogallol. In this paper, these two substances are examined, and found to be identical and of the formula  $\text{C}_{20}\text{H}_{16}\text{O}_9$ ; the acetyl-derivative has the formula  $\text{C}_{20}\text{H}_{12}\text{O}_9(\text{Ac})_4$ . Naphthalene is obtained when purpurogallin is distilled with zinc-dust.

V. H. V.

**Oxidation of Santonin.** By H. WAGNER (*Ber.*, **20**, 1662—1665).—Santonin is for the most part unaffected by ordinary oxidising agents; on prolonged treatment with nitric acid, it yields succinic, acetic, and hydrocyanic acids, together with carbonic anhydride; with less complete treatment, oxalic acid is also formed. Other oxidising agents burn only a small proportion of santonin with formation of carbonic anhydride.

V. H. V.

**Amyrin.** By A. VESTERBERG (*Ber.*, **20**, 1242—1246).—The crystalline product amyrin, extracted from elemi-resin, has formed the subject of several investigations, but the formulæ assigned to this substance are most discordant. In order to purify the amyrin, it was

converted into the acetyl-derivative; but it was observed that on frequent fractionations of the latter two substances of different crystalline form were obtained, the one, in aggregates of prisms, melting at  $235^{\circ}$ ; the other, in leaflets melting at  $220^{\circ}$ . The corresponding alcohols,  $C_{30}H_{48} \cdot OH$ , obtained by hydrolysis, are provisionally called  $\alpha$ - and  $\beta$ -amyrin; the former crystallises in delicate needles melting at  $180-181^{\circ}$ ; its *acetate*, mentioned above, melts at  $220^{\circ}$ , and the benzoate at  $192^{\circ}$ . When heated with phosphoric chloride, it yields a hydrocarbon,  $\alpha$ -amyrilene  $C_{30}H_{48}$ , crystallising in rhombic prisms,  $a : b : c = 0.667 : 1 : 0.4049$ , and melts at  $134-135^{\circ}$ ; its specific rotatory power  $[\alpha]_D = 109.84$  ( $C = 4$ ).

$\beta$ -Amyrin melts at  $193-194^{\circ}$ , its derivatives are less soluble and fusible than those of the  $\alpha$ -compounds; its benzoate crystallises in rectangular leaflets melting at  $230^{\circ}$ .  $\beta$ -Amyrilene crystallises in rhombic prisms,  $a : b : c = 0.916 : 1 : 0.540$ , melts at  $175-178^{\circ}$ ;  $[\alpha]_D = 112.19$  ( $C = 1.515$ ). It is probable that amyrin is allied to cholesterin, and that amyrilene belongs to the class of polymeric terpenes.

V. H. V.

**Composition of Lac-dye.** By R. E. SCHMIDT (*Ber.*, 20, 1285—1303).—Before the introduction of the azo-dyes, the lac-dye obtained from lac was a product of some commercial importance; it is produced on the boughs of various trees of the East Indies and Malay Archipelago as an exudation following the puncture by an insect, *Coccus lacca*. The statements in the various technological books are, however, very discordant, and the description of the methods used for the extraction of this dye seems incorrect. From the analytical results obtained with the ash, it would appear that the dye is precipitated from the crude material by the addition of lime, and that the product obtained consists of 10 to 13 per cent. of the dye itself, 9 to 11 per cent. of moisture, 15 to 18 per cent. of mineral constituents, and 57 to 68 per cent. of organic matter and water given off above  $100^{\circ}$ . A full description is given of the method used to extract and purify the colouring matter; the crystalline substance finally obtained is frequently recrystallised from alcohol and ether. The formula deduced from not very concordant results is  $C_{16}H_{12}O_8$ , and it is proposed to call the substance *laccic acid*; it crystallises in microscopic, rhombic tables of a yellowish-red colour soluble in the alcohols, acetone, and acetic acid. Alkalis produce with it a characteristic red coloration, and the changes of tint caused by the addition of various reagents are described in full.

In many of its chemical properties, as also in its absorption spectrum, laccic acid resembles carminic acid. The salts can only be obtained as amorphous precipitates. When heated with concentrated nitric acid, it yields picric and oxalic acids together with resinous substances, and with hydrochloric acid in sealed tubes it yields, in addition to a gas burning with a green flame, a substance,  $C_{26}H_{16}O_{11}$ . Laccic acid when fused with alkali yields two products, the one of phenolic odour volatile in steam, the other contains a non-volatile, crystalline substance, probably an aromatic hydroxycarboxylic acid giving a red coloration with ferric chloride, an acid, probably para-

hydroxymetatoluic acid, which gives no coloration with ferric chloride, and, lastly, a very soluble substance which gives a black precipitate with ferric chloride.

In conclusion, it is noted that laccaic acid and other naturally occurring dyes contain 16 atoms of carbon in the molecule.

V. H. V.

**$\beta$ -Methyltetramethylenediamine and  $\beta$ -Methylpyrrolidine.** By H. OLDBACH (*Ber.*, 20, 1654—1659).—On hydrogenation of the nitrile of pyrotartaric acid,  $\beta$ -methyltetramethylenediamine,  $\text{NH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CHMe}\cdot\text{CH}_2\cdot\text{NH}_2$ , is formed; it is a colourless liquid boiling at  $172\text{--}173^\circ$ , fuming in the air and absorbing water and carbonic anhydride; its *platinochloride* forms small, yellow crystals, the *aurochloride*, prisms; and the *mercurochloride*, small prisms. If the hydrochloride is distilled in small quantities,  $\beta$ -methylpyrrolidine,  $\text{C}_5\text{H}_{11}\text{N}$ , is formed with separation of ammonium chloride; it is best purified by distillation with potash, conversion into the nitroso-derivative, and decomposition of the latter with hydrogen chloride. The free base boils at  $103\text{--}105^\circ$ , fumes in the air, and resembles in odour its isomeride piperidine; sp. gr. = 0.8654. Its hydrochloride is very deliquescent; the *platinochloride* crystallises in long prisms, the *aurochloride* in four-sided tables, the bismutho-iodide,  $3\text{C}_5\text{H}_{11}\text{N}\cdot\text{HI}\cdot 2\text{BiI}_3$ , in red needles. The  $\beta$ -methylpyrrolidine, above described, is not identical with a base found by Brieger in the culture of the *Tetanus bacillus*.

V. H. V.

**Action of Amines on Ethylenedibenzoylorthocarboxylic Acid.** By J. BAUMANN (*Ber.*, 20, 1486—1493).—Ethylenedibenzoylcarboxylic acid is prepared by heating 50 grams of succinic acid, 50 grams of phthalic anhydride, and 17 grams of finely-powdered dry sodium acetate for two hours at  $210\text{--}220^\circ$ , breaking up the product and extracting with boiling water, and then several times with boiling alcohol (96 per cent.). The crude ethylenediphthalide is boiled for a few minutes in a reflux apparatus with excess of alcoholic potash (25 grams of substance to 17 grams of potash); the product is treated with water and the alcohol evaporated; more water is added, the whole filtered, and the filtrate carefully treated with dilute hydrochloric acid until a precipitate is formed. It is again filtered and an excess of hydrochloric acid added, when ethylenebenzoylcarboxylic acid separates; this is purified by crystallisation from alcohol. The yield is about 18 grams.

*Phenylpyrrolenedibenzoic acid*,  $\text{NPh} < \begin{smallmatrix} \text{C}(\text{C}_6\text{H}_4\cdot\text{COOH}) : \text{CH} \\ \text{C}(\text{C}_6\text{H}_4\cdot\text{COOH}) : \text{CH} \end{smallmatrix} >$ , is obtained by heating 5 grams of ethylenedibenzoylcarboxylic acid with 15 grams of aniline in a water-bath for about half an hour; the product is heated with an excess of hydrochloric acid, filtered, washed with water, extracted, and washed with boiling alcohol. It is crystallised from nitrobenzene, from which it separates in slightly yellow crystals melting at  $295^\circ$  (uncorr.); it is very sparingly soluble in boiling alcohol and glacial acetic acid; rather more soluble in boiling alcohol; insoluble in water, benzene, ether, and chloroform. The *silver salt* forms a white, voluminous precipitate; the *ethyl salt* crys-

tallises in lustrous, yellowish-white needles which melt at  $122^{\circ}$ ; it is readily soluble, except in water.

*Ethylpyrrolinedibenzoic acid*,  $C_{20}H_{17}NO_4$ , is prepared by heating ethylenedibenzoylcarboxylic acid with 33 per cent. aqueous solution of ethylamine and some alcohol for one hour at  $100^{\circ}$ , evaporating the alcohol, and treating with an excess of hydrochloric acid. It is crystallised from dilute alcohol, and forms bright yellow plates melting at  $220^{\circ}$ , sparingly soluble in ether, benzene, and carbon bisulphide, more soluble in alcohol, nitrobenzene, and glacial acetic acid. The *silver salt* was prepared.

*Methylpyrrolinedibenzoic acid*,  $C_{19}H_{15}NO_4$ , prepared in manner similar to the ethyl compound, forms splendid, deep yellow plates, melts at  $231^{\circ}$ , and resembles the ethyl-derivative in solubility.

*Paratolylpyrrolinedibenzoic acid*,  $C_{25}H_{19}NO_4$ , is prepared from ethylenedibenzoylcarboxylic acid (5 grams) and paratoluidine (12 grams); it is purified by dissolving the product in ammonia, filtering, and treating with hydrochloric acid. It crystallises from dilute alcohol in yellowish needles melting at  $253^{\circ}$ ; it is readily soluble.

*Diphenylpyrroline*,  $NH<\begin{smallmatrix} CPh:CH \\ CPh:CH \end{smallmatrix}>$ , is obtained by distilling pyrrolinedibenzoic acid mixed with lime (20 parts) in a partial vacuum. It crystallises from alcohol in yellowish-white, microscopic needles melting at  $143.5^{\circ}$ ; it is insoluble in water and alkalis, very sparingly soluble in dilute hydrochloric acid (the solution is rose-coloured), readily soluble with red colour in strong sulphuric acid; it is also readily soluble in ether, benzene, &c.

*Triphenylpyrroline*,  $NPh<\begin{smallmatrix} CPh:CH \\ CPh:CH \end{smallmatrix}>$ , is prepared in a manner similar to the diphenyl compound from phenylpyrrolinedibenzoic acid, using barium oxide instead of lime. It may be recrystallised from glacial acetic acid; it melts at  $226^{\circ}$ , is almost insoluble in alcohol and ether, sparingly in benzene and glacial acetic acid, and very readily soluble in nitrobenzene and chloroform; it dissolves in sulphuric acid without coloration.

*Tolylldiphenylpyrroline*,  $C_{23}H_{19}N$ , is obtained by distilling paratolylpyrrolinedibenzoic acid (2.8 grams) with barium oxide (30 grams). It crystallises from nitrobenzene in groups of bright yellow needles, melts at  $201^{\circ}$ , dissolves very sparingly in alcohol and glacial acetic acid, is more soluble in benzene and ether, and is readily soluble in nitrobenzene and chloroform.

When 2 grams of ethylenedibenzoylorthocarboxylic acid is heated with 1.3 gram of hydroxylamine hydrochloride, some drops of hydrochloric acid, and 10 c.c. of alcohol for one hour at  $100^{\circ}$ , long, yellow needles separate which may be crystallised from nitrobenzene. The new compound is the internal anhydride of ethylenebenzoylcarboxylic acid dioxime, and has the constitution

It melts at  $270^{\circ}$ , and is sparingly soluble except in nitrobenzene.

N. H. M.

**The Cinnamene of the Pyridine Series.** By A. LADENBURG (*Ber.*, 20, 1643—1644).—In order to prepare the analogue of cinnamene in the pyridine series, a mixture of ethylene and pyridine was passed through a red-hot tube. Besides subsidiary products not further examined, there was obtained a small quantity of *α*-vinylpyridine as a colourless liquid of pleasant odour boiling at 160°. When oxidised with potassium permanganate, it is converted into picolinic acid, and on hydrogenation with sodium and alcohol into *α*-ethylpiperidine.

V. H. V.

**Constitution of Aldehydecollidine.** By E. DÜRKOPF and M. SCHLAUGK (*Ber.*, 20, 1660—1661).—It is generally assumed that the collidine obtained from aldehyde is an *α*-ethyl-*β*-methylpyridine (*Abstr.*, 1885, 257); subsequent investigations have shown this view to be incorrect. On oxidation, the collidine yields a methylpyridine-carboxylic acid, convertible on distillation with potash into *α*-picoline. It thus becomes necessary to determine the constitution of the dicarboxylic acid obtained as the final product of oxidation of the collidine.

V. H. V.

**Reactions of Quinolinic Acid.** By A. BERNTHSEN and H. METTEGANG (*Ber.*, 20, 1208—1210).—*Quinolinic anhydride*,

is readily obtained by the action of acetic anhydride on free quinolinic acid. It crystallises in prisms melting at 134·5°. When heated with resorcinol, *fluorazein*,  $\text{C}_5\text{NH}_3 < \begin{array}{c} \text{C}(\text{C}_{12}\text{H}_8\text{O}_3) \\ \text{CO}-\text{O} \end{array} >$ , is formed which resembles ordinary fluorescein.

*β*-Benzoylpicolinic acid,  $\text{C}_5\text{NH}_3 \cdot \text{Bz} \cdot \text{COOH}$ , is obtained by the action of benzene on quinolinic anhydride in presence of aluminium chloride. It crystallises in prisms which melt at 147°, and is soluble in water. When heated, it is converted, with evolution of carbonic anhydride, into *phenylpyridylketone*,  $\text{C}_5\text{NH}_4\text{Bz}$ . The latter boils at 307° (uncorr.). The *phenylhydrazine-derivative* melts at 143·5°. The *platinochloride*,  $(\text{C}_{12}\text{H}_9\text{NO})_2 \cdot \text{H}_2\text{PtCl}_6$ , was prepared. The base is converted by oxidation into nicotinic acid.

N. H. M.

**Quinoline.** By E. LELLMAN and G. LANGE (*Ber.*, 20, 1446—1451; compare this vol., p. 502).—A mixture of 5 grams of metamido-benzoic acid, 4 to 5 grams of nitrobenzene (better nitrophenol), 20 grams of glycerol, and 25 grams of sulphuric acid, is heated in a reflux apparatus over a free flame until the violent reaction becomes more moderate, when it is kept for six hours at 155—160°. It is cooled to 80°, treated with water, steam distilled, and made alkaline with baryta. It is then filtered, and after the excess of baryta has been removed by means of carbonic anhydride, treated with animal charcoal. The free acid, the yield of which was unsatisfactory, is identical with that obtained by La Coste and Valem by sulphonating quinoline.

When the sodium salt of the sulphonic acid is distilled with potassium cyanide, and the cyanide so obtained is saponified according to Fischer and Körner's method (*Ber.*, **17**, 765), by heating with hydrochloric acid for one day at  $140^{\circ}$ , a carboxylic acid is obtained identical with that prepared by Lellman and Alt (*loc. cit.*), from metamidobenzoic acid. Hence the sulphonic acid obtained from metamidobenzoic acid belongs to the ana-series, inasmuch as it yields a carboxylic acid having the 4 (ana) position. N. H. M.

**Quinoline-derivatives.** By L. RÜGHEIMER and C. G. SCHRAMM (*Ber.*, **20**, 1235—1238).—In previous investigations, it has been shown that quinoline-derivatives are formed by the action of phosphoric chloride on salts of malonic acid or its homologues with aromatic amines. Thus from aniline and paratoluidine malonates, trichlorinated quinoline or toluquinoline is produced, and from orthotoluidine malonate a dichlorohydroxytoluquinoline. So, too, from aniline ethyl malonate a *chlorethylhydroxyquinoline*, ( $\text{Cl} : \text{Et} : \text{OH} = 2' : 3' : 4'$ ), is produced. This compound crystallises in colourless needles melting at  $248^{\circ}$ . As a subsidiary product of the above reaction, a compound,  $\text{C}_{17}\text{H}_{17}\text{N}_2\text{O}_2\text{Cl}$ , is formed, which melts at  $101.5\text{--}104.5^{\circ}$ , and is probably an additive product of  $\alpha$ -chlorohydroxybutyranilide and phenyl carbamide, both of which substances are formed by heating the compound with sodium carbonate.

Similarly from orthotoluidine, ethyl malonate, and phosphoric chloride, a *chlorethylhydroxytoluquinoline* is produced, which crystallises in glistening, silky needles, melts at  $225\text{--}225.5^{\circ}$ , and is converted by hydrochloric acid into a *hydroxyethyltolucarbostyryl*, crystallising in needles and melting at  $222\text{--}223.5^{\circ}$ . V. H. V.

**Orthohydroxyquinolinecarboxylic Acid.** By R. SCHMITT and F. ENGELMANN (*Ber.*, **20**, 1217—1220).—*Sodium hydroxyquinolinecarboxylate*,  $\text{OH}\cdot\text{C}_9\text{NH}_5\cdot\text{COONa}$ , is formed quantitatively when sodium quinoloxide and carbonic anhydride are heated in an autoclave for 7 to 8 hours at  $140\text{--}150^{\circ}$ . To obtain the *free acid*, the salt is dissolved in warm, moderately dilute hydrochloric acid; on cooling, hydrochloride of the acid separates in long, lustrous needles. This is filtered and brought into contact with much water, when it gives up the hydrogen chloride, the free acid remaining suspended in the water as a yellow, crystalline mass. When warmed in the slightly acid liquid, it dissolves and separates on cooling in yellow prisms an inch long (with 1 mol.  $\text{H}_2\text{O}$ ), the anhydrous substance melts at  $235^{\circ}$  with evolution of carbonic anhydride and formation of orthohydroxyquinoline, and dissolves sparingly in cold water, alcohol, and benzene; it gives a violet-red to deep-brown coloration with ferric chloride. When the hydrochloride of the acid is boiled with hydrochloric acid and tin, the compound,  $\text{OH}\cdot\text{C}_9\text{NH}_5\cdot\text{COOH}\cdot\text{HCl}$ , is obtained. This crystallises from water in short, thick prisms. The *free acid*, prepared by treating the hydrochloride with the necessary amount of sodium carbonate, forms small, colourless prisms, very sparingly soluble.

*Methyltrihydro-orthohydroxyquinolinecarboxylic acid*,

is readily obtained by heating the tetrahydro-acid above described with methyl iodide dissolved in methyl alcohol at 120°. The anhydrous acid melts at 211°; it is readily soluble in hot water and in alcohol.

N. H. M.

**Homologue of Isoquinoline.** By S. GABRIEL (*Ber.*, 20, 1205—1208).—8 grams of dimethylhomophthalimide and 24 c.c. of phosphorus oxychloride were heated for 5 hours at 200—210°, the product treated with 4 to 5 vols. of alcohol, filtered after some hours, and washed with alcohol until the product is almost colourless. It is recrystallised from alcohol, from which it separates in long, almost colourless needles, which melt at 165—166°. Analyses point to the formula  $C_{11}H_9NCl_2$ . The reaction is analogous to that which takes place between homophthalimide and phosphorus oxychloride (this vol., p. 61).

When the compound  $C_{11}H_9NCl_2$  is boiled with an equal weight of red phosphorus and 10 parts of hydriodic acid (b. p. 127°), and then distilled with steam, the compound  $C_{11}H_{10}NCl$  is obtained. The latter softens at 70° and melts at 78—80°; it is a feeble base.

When 6 grams of the dichloro-compound, 1·4 gram of red phosphorus, and 24 c.c. of hydriodic acid are heated for 3 hours at 200—210°, the product treated with alkali and steam-distilled, an oily and then a clear distillate is obtained, which is heated with 10 c.c. of hydrochloric acid, and then treated with a solution of 4 grams of chromic acid. When cold, it is filtered from the orange-red needles; these are washed and digested with dilute aqueous soda until the red colour has disappeared, when an oil is obtained, which solidifies on cooling. The new base, which has the formula  $C_{11}H_{11}N$ , melts at 63·5—65° and boils at 274—275° under 763·5 mm. pressure; it has an odour resembling that of quinoline. The *platinochloride*,

forms flat, orange-yellow needles. The *picrate* is sparingly soluble.

The constitution of the dichloro-derivative is probably

N. H. M.

**Xanthine-derivatives in Urine.** By G. SALOMON (*Zeit. physiol. Chem.*, 11, 410—416).—The presence of hypoxanthine in human urine has been until now a matter of uncertainty. 50 litres of urine was treated with ammonia, and the earthy phosphates filtered off; the filtrate was treated with silver nitrate, and the precipitate washed by decantation, treated with hydrogen sulphide, filtered, and the filtrate evaporated to a small bulk. Ammonia was again added, and the rest of the phosphates removed, silver nitrate again added, and the carefully washed precipitate dissolved in hot nitric acid. On cooling, silver hypoxanthine crystallised out, was purified by recrystallisation, decomposed with hydrogen sulphide, and filtered. On evaporating the filtrate, after adding ammonia, hypoxanthine separated out. This was identified by its reactions, and by elementary analysis.

The xanthine-derivatives of the urine of a dog under the toxic influence of phosphorus was also qualitatively investigated. They were found to be the same as in normal dog's urine. In addition to hypoxanthine prepared in the way above described, heteroxanthine (Abstr., 1886, 266) was also prepared from the mother-liquor from which the silver hypoxanthine had crystallised out. By Weidel's test, an intense red colour was produced. No paraxanthine was present. Hitherto heteroxanthine has been found exclusively in human urine.

W. D. H.

**The Piperideïne Series.** By A. LADENBURG (*Ber.*, 20, 1645—1647).—The members of the piperideïne series, containing two atoms of hydrogen less than the piperidine series, can be regarded as tetrahydro-derivatives of pyridine. Two bases of the former have been isolated, namely, dimethylpiperideïne and coniceïne; in this paper, other members are described.

*Pipecoleïne* or  $\alpha$ -methylpiperideïne,  $C_{10}H_{11}N$ , is obtained from  $\alpha$ -pipercoline hydrochloride by treatment with bromine and sodium, and purification of the base formed by means of its ferrocyanide. It is a liquid boiling at  $125-127^\circ$ , of unpleasant odour; sp. gr. = 0.8801.

$\alpha$ -Ethylpiperideïne,  $C_7H_{13}N$ , obtained in a similar manner from  $\alpha$ -ethylpiperidine, is a liquid boiling at  $149-151^\circ$ , resembling conine in odour, and soluble in water; its salts are very soluble.

$\alpha$ -Isopropylpiperideïne, prepared from isopropylpiperideïne, boils at  $163.5^\circ$ , and is of unpleasant odour; its platinochloride crystallises in tables melting at  $189^\circ$ , with decomposition.

V. H. V.

**Duboisine.** By A. LADENBURG and F. PETERSON (*Ber.*, 20, 1661).—Duboisine is identical with hyoscyamine, as shown by the crystallographic form and melting point of the aurochloride.

**Constitution of Tropine.** By A. LADENBURG (*Ber.*, 20, 1647—1654).—The former researches of the author have led to the conclusion that tropine is a tetrahydro-derivative of pyridine, in which one of the hydrogen-atoms is replaced by hydroxyethyl, and another by the methyl group. In order to decide this point, hydrotropidine,  $C_8H_{15}N$ , is taken as a starting point; this base, on distillation in a current of hydrochloric acid, is converted into a new base, *norhydrotropidine*,  $C_7H_{13}N$ . The latter is purified by means of its nitroso-derivative, which forms large crystals, melting at  $116-117^\circ$ , readily soluble in benzene and ether, and decomposed by hydrochloric acid, with formation of the free base; this is a colourless, transparent, crystalline substance, boiling about  $161^\circ$ , but not of very definite melting point. The hydrochloride melts at  $281^\circ$ , with decomposition, and the platinochloride crystallises in prisms, which carbonise above  $225^\circ$  without fusion. A solution of the hydrochloride gives precipitates with auric and mercuric chlorides and picric acid. Norhydrotropidine on distillation with zinc-dust, yields a base, shown to be identical with  $\alpha$ -ethylpyridine. Tropine is therefore a hydroxyethylmethylpyridine,  $C_8H_7Me \cdot C_2H_4 \cdot OH$ , a formula to be preferred to that,  $OH \cdot C_8H_6EtMe$ , proposed by Fischer as bringing out the analogies of tropine with

neurine and the triacetonalkamines. Further, the ethyl group, as such, is seldom present in naturally occurring substances.

V. H. V.

**Ecgonine.** By A. EINHORN (*Ber.*, **20**, 1221—1229).—*Anhydroecgonine*,  $C_9H_{13}NO_2$ , is prepared by boiling ecgonine hydrochloride (20 grams) with phosphorus oxychloride (100 grams) for two hours in a reflux apparatus. The product is poured into water, converted into periodide (by adding a solution of iodine in hydriodic acid), filtered, washed with water, and steam-distilled. Iodine is given off, and anhydroecgonine hydrochloride remains. The latter is recrystallised from absolute alcohol, dissolved in water, and treated with silver oxide. It is purified by precipitation from its alcoholic solution with ether. It is a colourless, crystalline substance melting at  $235^\circ$  with evolution of gas; it dissolves very readily in water and alcohol, and is almost insoluble in ether, chloroform, benzene, and light petroleum. The *hydrochloride* is obtained by treating the hydriodide with silver chloride; it crystallises from absolute alcohol in compact, white needles which melt at  $240$ — $241^\circ$ . The *platinochloride* forms yellowish-red prisms melting at  $223^\circ$  with decomposition. The *aurochloride* (Merck, this vol., p. 284) forms sulphur-coloured prisms. The *hydrobromide* is orange-coloured, and melts at  $154$ — $155^\circ$  with decomposition. The periodide,  $C_9H_{13}NO_2 \cdot HI \cdot I_2$ , crystallises from glacial acetic acid in brownish-violet plates melting at  $185$ — $186^\circ$ . It gives up its iodine in presence of sulphurous acid, ammonia, and mercury.

Anhydroecgonine forms salts with bases; the *sodium salt* was prepared. *Ethyl anhydroecgonine*,  $C_9H_{12}NO_2Et$ , is obtained by passing dry hydrogen chloride through a solution of anhydroecgonine hydriodide in absolute alcohol. It forms an oil. It dissolves very readily in hydrochloric acid, yielding a compound crystallising in needles; it melts at  $243$ — $244^\circ$ . The *platinochloride*,  $C_9H_{12}NO_2Et \cdot H_2PtCl_6$ , forms yellow prisms melting at  $211^\circ$ . The *perbromide* is very unstable. The formation of this ether points to the presence of a carboxyl-group in anhydroecgonine. This and the fact that a dilute aqueous solution of anhydroecgonine decolorises potassium permanganate, whilst ecgonine does not, makes it probable that anhydroecgonine contains the group  $-CH:CH:COOH$ . This view is confirmed by the formation of a *bromide* isomeric with the perbromide already mentioned, but more stable. The latter is obtained by heating anhydroecgonine hydrobromide with a slight excess of bromine for  $1\frac{1}{2}$  hours at  $100^\circ$ . It melts at  $165^\circ$  with decomposition. *Anhydroecgonine dibromide hydrochloride*,  $C_9H_{12}NBr_2 \cdot COOH \cdot HCl$ , is readily obtained by heating 1 gram of anhydroecgonine hydrochloride with 2.5 grams of bromine dissolved in glacial acetic acid for two hours at  $100^\circ$ . It crystallises from alcohol in prisms which melt at  $183$ — $184^\circ$ . When bromine is added to an aqueous solution of anhydroecgonine hydrochloride, *anhydroecgonine hydrobromide perbromide* is formed; it crystallises from glacial acetic acid in orange-coloured needles which melt at  $154$ — $156^\circ$ . The hydrochloride of the perbromide appears not to exist. When the product of the action of bromine on anhydroecgonine hydrochloride and the bromide, melting at  $165^\circ$ , are treated with sodium carbonate, an oil is obtained having the properties of a compound corresponding

with bromo- $\alpha$ -cinnamene. The presence of an acrylic acid group is thus proved. Merck (*loc. cit.*) has shown that both ecgonine and also anhydroecgonine contain a methyl group attached to nitrogen; anhydroecgonine is therefore tetrahydropyridylacrylic acid,

ecgonine is methyltetrahydropyridyl- $\beta$ -hydroxypropionic acid,

cocaine is methylic methyltetrahydropyridyl- $\beta$ -benzoylhydroxypropionate,  $C_5NH_7Me \cdot CH(OBz) \cdot CH_2 \cdot COOMe$ . N. H. M.

**Ptomaines from Pure Cultivations of "Vibrio Proteus."** By O. BOCKLISCH (*Ber.*, 20. 1441—1446).—Finkler's bacillus decomposes beef with formation of ammonia and cadaverine which was isolated, the picrate prepared and analysed. Choline and creatinine are present in the fresh beef.

Beef was kept in contact with *Vibrio proteus* mixed with some putrefactive bacteria which always accompany it when in the forward intestines. Creatinine and methylguanidine were obtained together with a small amount of cadaverine.

Cadaverine has all the properties of pentamethylenediamine (Ladenburg, this vol., p. 125), except that the mercurchloride of pentamethylenediamine contains 3 mols.  $HgCl_2$ , whilst that of cadaverine has 4 mols. The author prepared and analysed the latter compound, and obtained numbers pointing to the formula with 4 mols.  $HgCl_2$ .

*Cadaverine oxalate*,  $C_5H_{14}N_2 \cdot H_2C_2O_4 + 2H_2O$ , is obtained by mixing the cadaverine base with oxalic acid dissolved in alcohol; it crystallises in needles which melt at about  $160^\circ$  with evolution of gas. When treated with an alcoholic solution of oxalic acid, the salt,  $C_5H_{14}N_2(H_2C_2O_4)_2 + H_2O$ , is obtained. This crystallises in quadratic plates which melt with decomposition at  $143^\circ$ . N. H. M.

**The Acids of Pig's Bile.** By S. JOLIN (*Zeit. physiol. Chem.*, 11, 417—420).—In addition to the well-known hyoglycocholic acid first obtained by Strecker from pig's bile, a small quantity of another acid,  $\beta$ -hyoglycocholic acid, is also present. The two acids can be separated by the use of sodium sulphate, which readily precipitates Strecker's  $\alpha$ -acid, but not the  $\beta$ -acid. By the use of an ice-cold saturated solution of sodium sulphate, which contains less salt than a warm one, the  $\alpha$ -acid is precipitated, and the  $\beta$ -acid remains in solution. When this solution is concentrated by heat, the sodium salt of the  $\beta$ -acid separates in the form of oily drops of a dark brown colour; on cooling these set to a sticky mass. It is soluble in alcohol, and can be freed from fat, cholesterolin, and pigment by ether. It is then a white, curdy substance, easily soluble in alcohol and in water; it is incompletely precipitated by saturating the aqueous solution with sodium sulphate. With barium salts, a barium compound is formed which precisely resembles that obtained from the  $\alpha$ -acid. The acids themselves are both insoluble in water, and behave to most reagents in a similar way; the  $\beta$ -salts, as a rule, melt more easily, and their

taste is less bitter than that of the  $\alpha$ -salts. Both give Pettenkofer's reaction. The cholic acid from both has the same properties. The nitrogen of the two acids is about equal in amount. The carbon is rather less in the  $\beta$ -acid than in the  $\alpha$ -acid; but on account of the difficulty of crystallising the compounds of the  $\beta$ -acid, it is not easy to make trustworthy analyses. W. D. H.

## Physiological Chemistry.

**Absorption in the Stomach of the Horse.** By H. GOLDSCHMIDT (*Zeit. physiol. Chem.*, 11, 421—437).—The amount of absorption which takes place from the stomach is difficult to estimate accurately, especially because it is difficult to make allowance for the composition and particularly for the proteid constituents of the various digestive juices. The result can only be taken as comparative, and not absolutely correct. The general method of the analysis may be seen from the following example:—Horse killed  $1\frac{1}{2}$  hours after food; the stomach contained 120·17 grams of cellulose, which correspond with 1442·6 grams of oats which contain 142·24 grams of proteid and 924·562 grams of constituents free from nitrogen, and about 200 grams of water. In the stomach, 3200 grams of juice was present which, deducting the 200 grams of water in the oats, leaves 3000 grams as the weight of saliva and gastric juice; 3000 grams of saliva contain 0·548 per cent. of proteid—that is about 16·4 grams in all. In the stomach, the analysis of the contents gave the following results:—

|                       | Proteid.        | Substances free<br>from nitrogen. |
|-----------------------|-----------------|-----------------------------------|
| Undigested .....      | 67·35 grams     | 652·48                            |
| In solution .....     | 43·00 „         | 125·31                            |
| Total in stomach....  | 110·35 „        | 777·79                            |
| In oats and saliva .. | 158·64 „        | 924·562                           |
| Absorbed.....         | 48·29 „         | 146·772                           |
|                       | or 34 per cent. | or 16 per cent.                   |

Eight similar investigations were made in which the general results may be tabulated as follows:—

| Horse. | Hours killed.<br>after death. | Percentage of<br>proteids absorbed. | Percentage of<br>non-nitrogenous<br>substances<br>absorbed. |
|--------|-------------------------------|-------------------------------------|---|
| No. 1. | $1\frac{1}{2}$                | 34                                  | 16  |
| „ 3.   | $2\frac{1}{2}$                | 19                                  | 13  |
| „ 4.   | $3\frac{1}{2}$                | 39                                  | 28  |
| „ 5.   | $4\frac{1}{2}$                | 29                                  | 23  |
| „ 6.   | $6\frac{1}{2}$                | 49                                  | 43  |
| „ 7.   | 8                             | 64                                  | 51  |
| „ 8.   | 10                            | 64                                  | 59  |
| „ 9.   | 12                            | 61                                  | 51  |

In the horses numbered 1, 4, 7, absorption was great; and in those numbered 3, 5, 6, 8, and 9, not so marked: this corresponds with the activity of digestion in the individual cases. The greatest part of the digested non-nitrogenous stuffs and an important part of the nitrogenous are absorbed during and after the sixth hour after food.

On account of the difficulty in these estimations arising from the want of knowledge concerning the composition of the digestive juices, some analyses were made to serve as data on which to correct the first series of observations; the various juices in the stomach, the duodenum, the middle of the small intestine, the ileum, the cæcum, the ventral colon, and the dorsal colon were investigated in two horses A and B. The percentages of proteïds were as follow:—

| Stomach. | Duo-<br>denum. | Jejunum. | Ileum. | Cæcum. | Colon.   |         |
|----------|----------------|----------|--------|--------|----------|---------|
|          |                |          |        |        | Ventral. | Dorsal. |
| A. 0·594 | 1·567          | 1·006    | 0·594  | 0·854  | —        | —       |
| B. 1·238 | 5·088          | 1·856    | 1·675  | 0·656  | 1·476    | 1·638   |

The following conclusions are drawn:—

1. That the intestinal juice becomes poorer in proteïds, non-nitrogenous constituents, total solids, and ash towards its ileal end.
2. That the amount of water correspondingly increases.
3. That the proteïds throughout are present in important quantities.

Somewhat similar investigations by Ellenberger and Hofmeister (*Archiv. f. prakt. u. Wissensch. Thierheilkunde*, 10, 328) in three horses gave an average result closely corresponding with that obtained in horse A.

W. D. H.

**Digestion and Digestive Secretions of the Horse.** By ELLENBERGER and HOFMEISTER (*Bied. Centr.*, 1887, 229—232).—This is a review of the long researches of the authors on this subject, of which many abstracts have been given in this Journal, and in the course of which many interesting particulars relating to the digestion of vegetable substances by men and animals have been treated.

The action of saliva in the process of mastication is shown to be more mechanical than chemical. The quantity of saliva used depends on the dryness and roughness of the food rather than its contents in starch, and the authors think that the chemical activity of saliva owes much to spores, which floating in the atmosphere, mix with the food and assist in the fermentation process.

A digestive action of the mixed food takes place in the stomach when the acidity due to hydrochloric or lactic acid does not exceed 0·03 to 0·04 per cent. The left section of the stomach of the horse does not secrete a gastric juice, this is the function of the right portion. The pure gastric fluid of the horse contains lactic, fatty, and amylaceous ferments, the latter in small quantities.

Cellulose is not digested in the stomach of the horse, but muscle, fat, gelatin; and flesh generally are easily digested, bone and elastic tissues more slowly. Pepsin operates actively only when acids are present, about 2 per cent. of lactic acid or 0·2 per cent. of hydrochloric acid being necessary; the activity of pepsin does not increase in proportion to its quantity after reaching a certain point, but it rather becomes injurious.

The acid which appears first in the digestive process is lactic acid and later hydrochloric; at the time of greatest activity, lactic acid is present in the upper and lower extremities of the digestive tract, hydrochloric acid being found in the intervening part.

The digestion of starch in the stomach of the horse lasts for about two hours, that of albuminous matter takes place later, and occupies three or four hours after the eating of the food; the drinking of water immediately after food does not appear to hinder digestion.

The secretions of the intestinal canal unite in themselves all the properties of the gastric juice, and can act as a substitute for it, and are particularly energetic in the decomposition of fats.

The duration of the digestive process in the horse is long, lasting almost three days.

A very active lactic fermentation of sugar takes place in the stomach and intestines, but the authors do not say that all the sugar which is lost in the course of passage is lost in that way, it is more probably reabsorbed. J. F.

**Changes in Milk produced by Freezing.** By KAISER and SCHMIEDER (*Bied. Centr.*, 1887, 267—269).—The matter is of importance to milk dealers in cold countries, where the contents of their cans become frozen.

Two samples were experimented with, one was frozen slowly, the other quickly, and afterwards partially thawed, in the former case the ice contained the greater part of the fat and the fluid portion most of the casein, milk-sugar, and salts.

In the quickly frozen and partially thawed sample, the fat was equally distributed between the solid and fluid portions; the author explains this by the fat globules rising to the top when the process of freezing is gradual, they thus become imbedded in the flakes of ice, whilst in quickly frozen samples this cannot take place, and the fat is more evenly distributed.

If a dealer whose milk has been frozen pours off the clear fluid which underlies the ice, he is liable to the suspicion of adulteration on the one hand, or will deliver milk above the standard on the other. Milk which has been frozen should be well thawed and shaken up, and not sold whilst any ice is visible. J. F.

**Frozen Milk.** By O. HENZOLD (*Bied. Centr.*, 1887, 269—270).—The experiment shows different results, as in the quickly frozen sample, the ice contained a much larger proportion of fat than the ice of the slowly frozen, but the *modus operandi* was different, as during the process of slow freezing the milk was frequently agitated. J. F.

## Chemistry of Vegetable Physiology and Agriculture.

**Fermentation of Sugar by Elliptical Yeast.** By E. CLAUDON and E. C. MORIN (*Compt. rend.*, **104**, 1109—1111).—The yeast was obtained from a white wine of Rouillac, and was purified by successive cultivations. Fermentation took place at a temperature of 18—20°, and foreign germs were excluded. On distillation, the product was separated into an alcoholic liquid, an acid liquid, and a residue consisting of glycol, glycerol, and non-volatile products. The products from 100 kilos. of sugar were as follows—

|                            |               |
|----------------------------|---------------|
| Aldehyde.....              | traces.       |
| Ethyl alcohol.....         | 50615·0 grams |
| Normal propyl alcohol..... | 2·0 „         |
| Isobutyl alcohol.....      | 1·5 „         |
| Amyl alcohol.....          | 51·0 „        |
| Ethyl cœnanthylate.....    | 2·0 „         |
| Isobutylene glycol.....    | 158·0 „       |
| Glycerol.....              | 2120·0 „      |
| Acetic acid.....           | 205·3 „       |
| Succinic acid.....         | 452·0 „       |

The proportion of propyl and isobutyl alcohols is unusually low, and amyl alcohol constitutes almost the whole of the higher alcohols. The bases usually present in fusel oils are absent, and so also are normal butyl alcohol and butyric acid, which were found by Ordonneau in brandy (*Abstr.*, 1886, 436). C. H. B.

**Formation of Nitrogen during Putrefaction.** By A. EHRENBERG (*Zeit. physiol. Chem.*, **11**, 438—471).—This research follows up the author's previous observations (this vol., p. 172), and is devoted to the question as to whether free nitrogen is formed during the processes of nitrification induced by low organisms. The apparatus previously described was used. Earth containing the necessary organisms was added to a 2 per cent. solution of ammonium chloride, to a mixture of calcium sulphate, calcium carbonate, and ammonium chloride, in the presence of pure oxygen, and to a mixture of peptone, sodium chloride, sodium phosphate, saltpetre, and cane-sugar, in the presence of carbonic anhydride; but in none of these instances was any nitrogen given off, nor was nitric acid formed. In other experiments, in which putrefactive processes were more intense, in which urine, fæces, blood, and other organic matter was used and in which there was formation of nitrates, free nitrogen was formed as well; the details of the several experiments are given. In the absence of oxygen, and also in the presence of a large quantity of this gas, free nitrogen is not formed; in the first case, methane and carbonic anhydride, and in the latter case carbonic anhydride alone are the gaseous products. In cases where nitrates and free nitrogen are formed, there is also at first a formation of methane.

W. D. H.

**Absorption of Aniline Colours by Living Cells.** By W. PFEFFER (*Ann. Agronom.*, 13, 176—179).—The author has worked with very dilute solutions (1 in 100,000 or 1,000,000) of methylene-blue, methyl-violet, Bismarck-brown, magenta, &c., with a view of throwing light on the accumulation of such substances as sugar, nitre, &c., in particular organs of plants. The results show that the protoplasmic layer of living cells behaves very differently towards these colouring matters under different circumstances. Some colours are absorbed, some are not; those which are absorbed, generally accumulate in the cell sap; all colour the protoplasmic layer in traversing it, except methylene-blue. Arriving in the cell sap, the colouring matter may behave in three different ways; it may accumulate in solution, may form a precipitate, or may attach itself to a pre-formed substance, generally tannic acid. In *dead* cells, the colour is absorbed by the nucleus.  
J. M. H. M.

**Presence of Choline in Germinating Plants.** By E. SCHULZE (*Zeit. physiol. Chem.*, 11, 365—372).—Employing Brieger's method for the separation of nitrogenous bases, it is possible to obtain choline from germinating pumpkin sprouts. The base was identified by its reactions, and by the characters and elementary composition of its aurochloride and platinochloride. The quantity present is very small; from a kilogram of the dried sprouts, only about 3 grams of the aurochloride was obtained.  
W. D. H.

**Composition of Potatoes.** By M. A. SCOVELL and A. E. MENKE (*Amer. Chem. J.*, 9, 103—107).—The following numbers are the maxima and minima obtained in the analyses of 20 varieties of potatoes:—Specific gravity, 1·0923—1·0731; dry substance, 22·91—20·20; starch, 16·05—12·05; sugar, gum, &c., calculated as glucose, 1·49—0·74. The specific gravity cannot be used for calculating the percentage of starch. The addition of various fertilisers has no appreciable influence on the proportions of the various constituents. The albuminoids are most readily acted on by dilute hydrochloric acid; the percentage of albuminoids varied from 2·19 to 2·69, that of peptones from 0·0294 to 0·0418: tyrosine formed about 0·008 per cent.; leucine and asparagine were not estimated.  
H. B.

**Effects of Deep or Shallow Sowing on Cereals.** By E. STÖSSNER (*Bied. Centr.*, 1887, 236—244).—The author has been making experiments in sowing the seeds of wheat, rye, barley, and oats at different depths, and gives a *résumé* of his conclusions, from which the following are selected:—

The depth at which the seed is sown is of great importance, an improper depth reducing the weight of the crop sometimes by one-half.

In loamy humous soils, both winter and summer wheat, rye, and oats should not be sown deeper than 4 cm., whilst summer barley will bear a covering of 10 cm. When a large yield of straw is desired, the seed may be planted at a greater depth than when the heaviest grain crop is desired. In good soil, well pulverised and rolled, the

covering may be only 2 cm. provided it is retentive of moisture. Seeds should, if possible, be procured from the previous year's crop, and never used when over two years old.

There are other recommendations well known in agricultural practice.  
J. F.

**Manurial Experiments with Sugar-beets.** By A. PAGNOUL (*Bied. Centr.*, 1887, 223—227).—The experiments were made in vessels containing about 1200 litres filled with a sand freed from lime and organic matter, but containing traces of alumina, iron, phosphoric acid, and potash.

The manures employed were Chili saltpetre (15.5 per cent. N), ammonium sulphate with 20 per cent. N, ammonium nitrate, and dried blood; potassium chloride 50 per cent.; superphosphate; Thomas slag with 7 per cent. phosphoric acid, and finely ground natural phosphate of 20 per cent., with addition of carbonate of lime.

The growth of the beets sown without any manure, and those manured without phosphoric acid was slow and weak. The ground raw phosphate and the Thomas slag produced very good effects, and the addition of carbonate of lime increased the crop in every case. The best results were obtained from a mixture of 600 parts of Chili saltpetre, 600 of superphosphate, and 300 of potassium chloride, and with another mixture of 500 parts of dried blood, 300 Chili saltpetre, 300 calcium chloride, 660 superphosphate, and 1000 carbonate of lime.

The average weight of the roots, however, shows that sand to which is added theoretically correct quantities of manures, does not produce as favourable results as natural soils.

One of the vessels was manured with crushed oil-cake placed at a certain distance from the seeds. The plants were longer in developing, but the crop of leaves was as large as in the case of the complete manure, the roots attained an abnormal length, and they passed in a slanting direction so as to reach the oil-cake, which was not thoroughly mixed with the soil as in the case of soluble manures. The sugar contents of the juice was considerably influenced by the nature of the manure; the absence of potash sensibly diminished the yield of sugar, and in one case where both soda and potash were absent the actual weight of the whole roots was diminished one-half. Soda appears to have more affinity for organic salts than potash, and forms larger quantities of those salts which are considered impurities of beet-juice. It is also shown that when manured with substances containing both soda and potash, the latter is absorbed in preference to the former.

## Analytical Chemistry.

---

**Weil's Method for Determining Sulphur.** By C. FRIEDHEIM (*Ber.*, 20, 1483—1485).—The author made determinations of sulphur by Weil's method, and obtained results which confirm the statement previously made by him (this vol., p. 396) that a correct result can only be obtained when the error in one direction happens to equal that in the other. This remark applies to the results since given by Weil (this vol., p. 618).  
N. H. M.

**Detection of Sulphites in Presence of Thiosulphates and Sulphates.** By A. VILLIERS (*Compt. rend.*, 104, 1177—1178).—When a solution of a normal alkaline sulphite is mixed with excess of barium chloride, barium sulphite is precipitated, and the liquid which was originally strongly alkaline becomes neutral to litmus. If the barium chloride is added to an alkaline hydrogen sulphite, normal barium sulphite is precipitated, and free sulphurous acid remains in solution. A solution which contains a mixture of a normal alkaline sulphite and a hydrogen sulphite has a distinctly alkaline reaction even when the proportion of normal salt is very small, but after addition of barium chloride the solution becomes acid and contains free sulphurous acid.

To detect sulphites in presence of thiosulphates, the solution is neutralised with hydrochloric acid, care being taken to avoid excess, and the liquid is mixed with barium chloride, when its reaction becomes acid to litmus. If the liquid is distilled, the sulphurous anhydride passes over with the first portion of the distillate, and can be detected in the usual way. The filtered liquid can also be tested for sulphurous acid by means of iodine, without distillation.

This method is also applicable in presence of the thionic acids.

C. H. B.

**New Method for the Quantitative Determination of Hydroxyl.** By C. L. JACKSON and G. W. ROLFE (*Amer. Chem. J.*, 9, 82—87).—As an improvement on the ordinary method of determining hydroxyl groups in organic compounds, parabromobenzoic chloride or anhydride is substituted for acetic or benzoic chloride, and in the ethereal salts formed with the compound in question, the bromine is estimated by Carius' method. The differences to be looked for are almost twice as great as in the analyses of the acetyl or benzoyl compounds, and the parabromobenzoyl compounds are easily prepared and purified.

The method of preparing parabromobenzoic acid is described; the yield amounts to 40—70 per cent. *Parabromobenzoic chloride*,  $C_6H_4Br \cdot COCl$ , has been previously prepared, but not described. It melts at  $30^\circ$ , and boils at  $245\text{--}247^\circ$ ; it is not dissolved or acted on by cold water, but dissolves in benzene and in alcohol, being then converted into its ethereal salt. *Parabromobenzoic anhydride*,

is very insoluble in ordinary reagents, is crystalline, and melts at 212—213°. Its best solvent is chloroform.

*Parabromobenzamide*,  $C_6H_4Br\cdot CONH_2$ , was prepared from the chloride, it is nearly insoluble in cold water, is crystalline, and melts at 186°.

As an example of the application of the method, the preparation of the two following compounds is described. *Phenyl parabromobenzoate*,  $C_6H_4Br\cdot COOC_6H_5$ , was obtained by heating at about 200° phenol, with either parabromobenzoic chloride or anhydride. It forms crystals resembling naphthalene, melting at 117°, insoluble in water, but soluble in other solvents. *Pyrogallol triparabromobenzoate*,  $(C_6H_4Br\cdot COO)_3C_6H_3$ , was made by heating pyrogallol with the chloride at 100°; the excess of chloride was removed by light petroleum and the pyrogallol by sodium carbonate. The substance crystallises easily from hot benzene, and melts at 140°. The corresponding pyrogallol tribenzoate is resinous, and hardly capable of purification.

H. B.

**Quantitative Estimation of Glycerol.** By R. DIEZ (*Zeit. physiol. Chem.*, **11**, 472—484).—The methods hitherto employed for the estimation of glycerol in wine and beer consist in dissolving it out usually by alcohol and ether from a mixture of the beverage with chalk, and finally weighing the glycerol. Neubauer and Borgmann (*Abstr.*, 1879, 404) found that the glycerol so obtained contained 2 per cent. of mineral constituents and 0.4 per cent. of nitrogen. Champion and Pellet (*this Journ.*, 1873, 1165) devised a method in which the glycerol was obtained as nitroglycerol, and weighed in this form, but this and other methods are also liable to error. The present method is one in which the compounds of glycerol with benzoyl are weighed. There are three benzoates of glycerol, according as to whether one, two, or three atoms of the hydrogen of the latter are replaced by the group  $C_7H_5O_2$ . The following gives the method of procedure:—Glycerol was diluted to a known extent with water (0.1 gram in 10 or 20 c.c.); 5 c.c. of benzoic chloride and 35 c.c. of sodium hydroxide added; this mixture was cooled and shaken for 10 to 15 minutes. The benzoyl compound which separated was collected on a weighed filter, washed with water, dried at 100°, and weighed. A mean of eight estimations gave the amount of the compound as 0.385 gram. In a second series of four estimations, the number obtained was rather higher, the mean being 0.395 gram; in these cases, the alkaline filtrate was shaken a second time with benzoic chloride and sodium hydroxide; the second filtrate contained hardly a trace of glycerol. These numbers formed a basis for the subsequent analyses, and showed that the compound formed in this way was chiefly the tribenzoate; theoretically the amount of that compound for 0.1 gram of glycerol would be 0.439 gram. Tables of the amount of glycerol in various forms of beer and wine, estimated by this method, are given, the numbers obtained being somewhat less than those given by Borgmann. The method has the following advantages: the substance weighed is solid and not hygroscopic, and admixture with inorganic and nitrogenous substances is avoided.

W. D. H.

**New Sugar Reactions.** By D. LINDO (*Chem. News*, 55, 230 and 239).—With reference to the new reactions for sugar described by Molisch (Abstr., 1886, 923), the author has found that a 1 per cent. starch or gum solution gives this reaction with thymol, as does also one part of cane-sugar in 200,000 of distilled water, and that all samples of normal human urine do so also, even when diluted with 50 vols. of water. He considers, however, that this fails to prove the presence of sugar is normal urine, which as a complex fluid must be acted on by the sulphuric acid. He finds that nitrates give the same characteristic colour reactions and precipitate on dilution, and that similar results are obtained when menthol is substituted for thymol; menthol has also the advantage of not giving with nitrates or nitrites any reaction that could be mistaken for that of sugar. Chlorides or hydrochloric acid do not impair the delicacy of either test, but sugar cannot be detected by either, in the presence of notable quantities of nitrates or nitrites. R. R.

**Analyses of Sugar-cane and Beet Juices.** By C. A. CRAMP-  
TON (*Chem. News*, 55, 207—209).—The paper details the author's method of analysing sugar juices. By working with a smaller quantity and using the same solution, first for polarisation and then for reduction by Fehling's solution, with filtration by means of Wiley's tubes, he is enabled to expedite the process. The paper contains an extended table for calculating the results from the different factors obtained. R. R.

**Separation of Acetic Acid from Formic Acid.** By D. S. MACNAIR (*Chem. News*, 55, 229).—For the quantitative estimation of acetic acid in presence of formic acid, the author recommends that the substance be distilled with dilute sulphuric acid, and the distillate boiled for 10 minutes in a reflux apparatus, with an equal bulk of chromic acid mixture, made by dissolving 12 grams of potassium dichromate in 30 c.c. of sulphuric acid, diluted with 100 c.c. of water. Acetic acid only remains unchanged, and when the liquid is distilled, passes over and can be titrated in the distillate. R. R.

**Analysis of Milk.** By F. G. SHORT (*Amer. Chem. J.*, 9, 100—103).—About 2 c.c. of the milk is weighed into a very thin, tared glass capsule, containing a quantity of asbestos, and dried at 110° for two hours. For the determination of the fat, the capsule is wrapped in a piece of cheese cloth, crushed and pushed tightly into the tube of a continuous ether extraction apparatus, and extracted for two hours with 50 c.c. of ether; the ether then evaporated, and the flakes heated in the drying oven for three hours before weighing. The same method can be used for butter analysis; the sample is placed in a jar or bottle, the whole melted and then vigorously shaken until solid. The drying and extraction of fat is carried out as before. In place of the glass capsules, porcelain ones may be used and the dried fat and asbestos transferred by a piece of cloth to the extraction apparatus, the little dish being washed with a few drops of ether. A large

number of analyses may be conducted at once, and very concordant results are obtained. H. B.

**Determination of Butter in Milk.** By H. N. MORSE and C. PIGGOT (*Amer. Chem. J.*, 9, 108—112).—20 grams of anhydrous copper sulphate is made to cover the bottom of a mortar, and 10 c.c. of the sample carefully run into the powder. In a few minutes, when dry, the contents are ground up with a little sand, and transferred to an extraction tube plugged with cotton-wool, where it is extracted with 10 portions of 10 to 15 c.c. of light petroleum; the fat solutions are concentrated to 10 c.c. or less, and 20 c.c. of decinomal potash solution (in 95 per cent. alcohol) added; after warming for a quarter of an hour, the excess of alkali is estimated by standard acid and phenolphthaleïn. To saponify one gram of butter, 0.230 gram of potassium hydroxide is required. The results agree with those obtained by other methods, and 25 to 30 analyses can be made in the day. H. B.

**Colour Tests for Strychnine and other Alkaloids.** By C. L. BLOXAM (*Chem. News*, 55, 155).—Strychnine is dissolved in a drop of dilute nitric acid, and gently heated; to the warm solution a very minute amount of potassium chlorate is added, when an intense scarlet coloration is obtained. Ammonia changes this to brown, and gives a brownish precipitate; the mixture is then evaporated to dryness, when it leaves a dark-green residue, dissolved by a drop of water to a green solution, changed to orange-brown by potash, and again turned green by nitric acid. A table is given showing the colour-changes given by brucine, narcotine, morphine, quinine, cinchonine, and caffeine on like treatment. The reactions given by various alkaloids, when boiled with a mixture of potassium chlorate and hydrochloric acid, are also described. A. J. G.

**Guaiacum Resin.** By H. HAGER (*Zeit. anal. Chem.*, 26, 261).—To distinguish the purified from the natural resin, the latter alone being suitable as a test for ozone, 0.15 gram is dissolved in 5 c.c. of absolute alcohol, and to the solution, filtered in the shade, 10 drops of oil of turpentine are added. If in the course of half an hour the solution turns bluish, the resin has either been purified or has been altered by heat or sunlight. Natural resin gives a solution which remains yellow for several hours. M. J. S.

---

## General and Physical Chemistry.

---

**Index of Refraction of Ice.** By G. MEYER (*Ann. Phys. Chem.* [2], 31, 321—322).—Hitherto the measurements of this index which have been made do not refer to light of any fixed wave-length. The writer therefore communicates some preliminary determinations, both for the ordinary and also the extraordinary ray, for the light from sodium, lithium, and thallium flames. C. S.

**Refractive Index and Compressibility of Cyanogen.** By J. CHAPPUIS and C. RIVIÈRE (*Compt. rend.*, 104, 1433—1435).—This is a continuation of the authors' work on the refractive power of cyanogen at various pressures. They find that for temperatures between 0° and 30° and pressures between 1 atmos. and 4 atmos., the relation  $\frac{n-1}{d} = \text{constant}$ , holds good for this gas as for carbonic anhydride and air, and the values obtained by means of this expression differ from those given by the formula  $\frac{n_2-1}{(n_2+2)d}$  by quantities which are not greater than the errors of experiment. The numbers calculated by the first formula agree closely with the observed numbers.

C. H. B.

**Molecular Refractive Energies of Derivatives of Carbon Bisulphide.** By R. NASINI and A. SOALA (*Gazzetta*, 17, 72—78).—Determinations are given of the refractive indices for various rays and the specific molecular refractive energies, according to the formulæ of Landolt and of Lorentz and Lorenz, of allyl sulphide and of various ethereal salts of xanthic acid. The principal results are given in the table below.

|                                 | $d_4$ . | $P \frac{\mu_a - 1}{d}$ . | $P \frac{\mu_a^2 - 1}{(\mu_a^2 + 2)d}$ . |
|---------------------------------|---------|---------------------------|--|
| Allyl sulphide .....            | 0·88765 | 61·74                     | 36·73                                    |
| Methyl ethyl xanthate .....     | 1·11892 | 65·67                     | 38·15                                    |
| Diethyl xanthate .....          | 1·07400 | 71·96                     | 42·13                                    |
| Ethyl dioxithiocarbonate .....  | 1·26043 | 118·28                    | 67·09                                    |
| Methyl propyl xanthate .....    | 1·08409 | 73·34                     | 42·75                                    |
| Ethyl propyl xanthate .....     | 1·05054 | 81·39                     | 47·66                                    |
| Propyl dioxithiocarbonate ..... | 1·19661 | 133·81                    | 74·46                                    |

As regards these results, it is noted that in the case of allyl sulphide the found and calculated values are concordant; but in the derivatives of carbon bisulphide the values are not concordant if it is supposed that the atomic refractive energy of the sulphur-atoms is the same as

those in carbon bisulphide. If, however, it is supposed that one of the sulphur-atoms functions as in carbon bisulphide, whilst the other changes its functions and assumes that of a sulphur-atom in the sulphides or mercaptans, then the found and calculated values are concordant.

It would also appear that one of the sulphur-atoms in the dioxythiocarbonates has an atomic refractive energy of 17.42. The difference observed in other cases for the addition of the grouping  $\text{CH}_2$  to the molecule is also verified for the homologous ethereal salts of xanthic acid; the isomeric diethyl and methyl propyl xanthates have not, however, identical molecular refractive energies. V. H. V.

**Molecular Refractive Energies of the Thiocyanates and Thiocarbimides.** By R. NASINI and A. SCALA (*Gazzetta*, 17, 66—72).—In this paper a series of determinations are given of the refractive indices for various rays, and the specific molecular refractive energies of the thiocyanates and their isomerides, the thiocarbimides. The latter values are also compared with those calculated according to Brühl's data, although there remains some uncertainty as to the atomic refraction of sulphur in the thiocyanates, and of nitrogen in the cyanogen compounds generally. The following are the principal results obtained:—

|                           | $d_4$ . | $\frac{p^{\mu_a} - 1}{d}$ . | $P \frac{\mu_a^2 - 1}{(\mu_a^2 + 2)d}$ . |
|---------------------------|---------|-----------------------------|--|
| Methyl thiocyanate.....   | 1.06935 | 31.75                       | 18.87                                    |
| Ethyl thiocyanate.....    | 1.00715 | 39.94                       | 23.76                                    |
| Methyl thiocarbimide..... | 1.06912 | 35.54                       | 20.77                                    |
| Ethyl thiocarbimide.....  | 0.99525 | 41.26                       | 25.98                                    |
| Allyl thiocarbimide.....  | 1.00572 | 50.76                       | 29.71                                    |
| Phenyl thiocarbimide..... | 1.12891 | 76.48                       | 43.06                                    |
| Thiophen.....             | 1.05928 | 41.4                        | 24.13                                    |

It will be seen from the above results that the thiocarbimides have a greater refractive (as also dispersive) power than their isomerides; it is also shown that whereas for the first three thiocarbimides the values found for the molecular refractive energies agree with those calculated according to Brühl's data, yet for the phenyl-derivative there is a considerable difference, about 7 per cent. Further, the authors note that their results do not confirm Thomsen's hypothesis that the refractive energy and the heat of combustion are correlative quantities. V. H. V.

**Dispersion in Rock-salt.** By E. KETTELER (*Ann. Chim. Phys.* [2], 31, 322—326).—The recent researches of Langley on the spectrum of radiant heat afford sufficient data for the calculation of the constants of Ketteler's dispersion formula,

$$n^2 = -k\lambda^2 + a^2 + D\lambda^2 n / (\lambda^2 - \lambda_n^2).$$

By forming a table of the values of  $n$ , the accuracy of the formula is proved for a considerable range of wave-length.  $k$  in the case of rock-salt is found to be extremely small = 0.000858. If the substances for which  $k$  is known be arranged according to decreasing values of  $k$ , the order will be that of the diathermancy of the substances, rock-salt concluding the list.

The physical meaning of the term  $-k\lambda^2$  is, therefore, that it represents the absorption of radiant heat, and no dispersion formula wanting this term can be correct.

C. S.

**Red Fluorescence of Chromiferous Gallium.** By L. DE BOISBAUDRAN (*Compt. rend.*, 104, 1584—1585).—The author has previously found (this vol., p. 409) that gallium oxide which contains chromium shows a red fluorescence in a vacuum. The spectrum of this fluorescence shows a very distinct line homologous with the bright lines in the spectrum of the fluorescence of chromiferous alumina and of spinel. The wave-length of this line is  $\lambda 6897$ — $6898$ , and it rapidly diminishes in brilliancy as the substance becomes heated by the action of the discharge. The centre of the band in the spectrum of this fluorescence is at  $\lambda 6619$ ; it is very nebulous at both ends, and extends through  $\lambda 1080$ — $1180$  according to the intensity of the light.

C. H. B.

**Specific Rotation of Optically Active Substances in very Dilute Solution.** By R. PRIBRAM (*Ber.*, 20, 1840—1850).—Three explanations may be given of the influence of a solvent on the rotatory power of many active substances. 1. The molecules of the substance in solution may be aggregates of simple molecules which undergo dissociation by dilution. 2. The active substance may form hydrates of different, perhaps opposite, rotatory power, the relative quantities of which depend on the amount of water present (Bremer, *Abstr.*, 1885, 622). 3. The solvent may alter the constitution (distance or arrangement of atoms) of the active molecules (Landolt, van t'Hoff). In the first two cases, the rotatory power might be expected to reach a limiting value when the solvent is in sufficient excess; in the last no such limit is probable.

In this third case the author gives a picture of the possible action by imagining four groups to be arranged round an unsymmetrical carbon-atom, at the solid angles of an irregular tetrahedron. A line drawn through them in the order of their magnitude represents the direction of rotation. If the plane containing groups 2 and 3 be supposed to rotate round an axis passing through the carbon-atom, and lying in the plane containing groups 1 and 4 and the carbon-atom, this line will be either a right- or left-handed spiral or a plane curve. The latter position represents an inactive state of the substance.

Recent improvements in the polaristobometer by Lippich and Landolt have enabled the author to measure accurately the rotation of very dilute solutions of tartaric acid, nicotine, and cane-sugar, with the following results.

**Tartaric Acid.**—Arndtsen (*Ann. Chim. Phys.* [3], 54, 403) expresses the rotatory power at  $25^\circ$  by the formula  $[\alpha]_D = 1.950 + 0.1393q$ , in

3 e 2

which  $q$ , the percentage of water, may vary from 50 to 95. The author gives a number of measurements of rotatory power for solutions containing from 4.7161 down to 0.3471 per cent. of acid. The value of  $[\alpha]_D^{20}$  increases from  $14.198^\circ$  to  $16.284^\circ$ . The increase is thus continuous up to the highest dilution.

*Nicotine*.—The specific rotation (left-handed) of pure nicotine,  $[\alpha]_D^{20} = 161.55^\circ$ ; and Landolt (Abstr., 1878, 1) found that that of the base in solution diminishes rapidly, but irregularly, with increasing dilution. The heat developed when nicotine is mixed with water points to the formation of a hydrate, as does also the following:—When water is added to a solution containing less than 20 per cent. of base, the mixture becomes turbid, and clears only on long standing. When the turbid mixture is heated to  $40^\circ$  it clears rapidly; but again becomes turbid on cooling or on further heating to  $50^\circ$ . Between  $50^\circ$  and  $60^\circ$  the turbidity amounts to milkiness, but still disappears on cooling below  $50^\circ$ . At  $70^\circ$  the nicotine separates as a layer. Furthermore, the rotation of a freshly prepared solution increases with time, and becomes constant only after 48 hours. The author finds the value of  $[\alpha]_D^{20}$  to rise from  $77.03^\circ$  for a 4.0289 per cent. solution to  $79.319^\circ$  for a 0.8826 per cent. solution. Thus no limit has been reached.

*Cane-sugar*.—The rotatory power has been measured by Schmitz (this Journal, 1877, ii, 876) and Tollens (*ibid.*, 875). The latter detected a slight increase when the percentage in solution falls from 70 to 18.86, but a decrease for weaker solutions. Subsequent special experiments by Tollens (Abstr., 1884, 1285) tended to confirm this view. The author's observations show that this decrease is well-marked and tolerably regular. In the table  $p$  = percentage of sugar,  $d$  density.

|                         |                |                |                |                |                |
|-------------------------|----------------|----------------|----------------|----------------|----------------|
| $p$ .....               | 3.6589         | 2.0536         | 1.0131         | 0.3201         | 0.2222         |
| $d^{20}$ .....          | 1.01256        | 1.00633        | 1.00224        | 0.99956        | 0.99919        |
| $[\alpha]_D^{20}$ ..... | $66.531^\circ$ | $66.382^\circ$ | $66.002^\circ$ | $65.415^\circ$ | $65.213^\circ$ |

Tollens' formula,  $[\alpha]_D = 66.386 + 0.015035p - 0.0003986p^2$ , gives results for these weak solutions differing considerably from the author's.

All the results described are at least in harmony with the third hypothesis stated above.

CH. B.

**Electric Couple with Carbon Elements.** By D. TOMMASI and RADIGUET (*Bull. Soc. Chim.*, 47, 85—88).—The positive element consists of a stick of carbon covered with a layer of lead peroxide and is contained in a canvas bag. The negative element consists of a hollow cylinder of carbon pierced with holes, into this the positive element is thrust, and the whole is placed in a glass cell which is then packed with lumps of gas carbon, and finally a concentrated solution of sodium chloride poured in until the level of the liquid is about half way up the cell. The electromotive force of this couple is from 0.6 to 0.7 volt, and no action occurs in it until the circuit is closed: it,

however, polarises rapidly, and is only suitable for intermittent work, but when thus used it lasts for an almost illimitable time, being in as good condition after two years as when first put up. The chemical action which occurs is an oxidation of the carbon at the negative pole and a reduction of the lead peroxide at the positive pole. A. P.

**Nickel and Carbon Elements.** By C. v. NEUMANN (*Dingl. polyt. J.*, 264, 47).—The author has constructed a battery with nickel and carbon as galvanic elements. The exciting solution is either dilute nitric acid or aqua regia or sulphuric acid, whilst lead dioxide is the depolarising agent. The E.M.F. of this battery is said to be 0.75 volt. D. B.

**Galvanic Element.** By R. EISENMANN (*Dingl. polyt. J.*, 263, 540).—The author recommends the use of tungstic acid as an exciting agent for galvanic elements. Its action is similar to that of chromic acid but it has the advantage of being rapidly oxidised after reduction, whilst the addition of a small amount of phosphoric acid suffices to keep the tungstates in solution in the acid liquid. D. B.

**Polarisation of Copper by the Extension of the Surface in Contact with a Liquid Conductor.** By KROUCHKOLL (*Compt. rend.*, 104, 1436—1437).—A spiral of copper immersed in water or in water containing 2 per cent. of sodium sulphate becomes negative at the moment when the surface in contact with the liquid is increased. With a certain degree of polarisation, the phenomenon is reversed, and the copper becomes positive with extension of surface, and with an intermediate degree of polarisation variations in the surface of the metal in contact with the liquid have no effect on the electromotive force. C. H. B.

**Conductivity of Amalgams.** By C. L. WEBER (*Ann. Phys. Chim.* [2], 243—250).—Experiments were made with amalgams of mercury with each of the following metals: tin, bismuth, lead, cadmium. The measurements being made at high temperatures, so as to secure a homogeneous conductor. The resistance of the amalgam contained in a U-tube was found by the method given by Thomson for the determination of small resistances. The electrodes were of iron on account of corrosion. To avoid the influence of thermoelectric effects, the mean of the resistances with the direct and reversed current was taken. An india-rubber tube was attached to the arm of the U-tube, and by suction and compression the amalgam was kept well mixed.

Taking as ordinate the specific resistance and as abscissa the percentage of metal in the amalgam, curves are traced showing the variation of the specific resistance with the composition of the amalgam. All the curves concur in showing that the effect of adding a small quantity of metal to the mercury is to cause a rapid decrease of resistance, and that the conductivity of the amalgam is not the mean conductivity of its constituents. In other respects the amalgams separate into two groups, those of like atomic weight going together. In the tin and cadmium amalgams the resistance, although falling rapidly at

first with increasing percentage of metal, gradually slackens its rate of decrease, and more and more nearly approaches a fixed limit. On the other hand the bismuth and lead amalgams have their resistance decreasing down to a minimum and then rising to a maximum.

The initial character of the curves for these amalgams is therefore different to that of the curves of the alloys of Class 2 which have been investigated by Mathiessen.

In both amalgams and alloys points of maxima and minima occur corresponding to definite chemical combinations. The alloys of mercury with bismuth and lead, however, have this special peculiarity, that they conduct better than either of their constituents.

C. S.

**Conductivity of Acids and Salts in Dilute Solutions.** By E. BOUTY (*Compt. rend.*, **104**, 1611—1614).—The conductivity of dilute solutions of acids and of salts other than normal salts does not follow the simple law which has been found to hold good for normal salts (*Compt. rend.*, **102**, 1097, 1372), a result similar to that obtained in the electrolysis of the same solutions. The resistance at constant temperature is, however, sensibly proportional to a factor  $1 + Km\frac{1}{3}$ , but the limit and the coefficients in the equation (*loc. cit.*) vary for different substances. Determinations of the conductivity of very dilute solutions of sulphuric, nitric, and hydrochloric acids shows that their molecular resistance varies with the temperature, although within somewhat narrow limits. If the resistance of sulphuric acid is taken as unity at each temperature, the resistances of the other acids in the highest possible degree of dilution are represented by the following numbers:—

|                      | 0°.   | 16°.  | 32°.  |
|----------------------|-------|-------|-------|
| Nitric acid .....    | 1·042 | 1·026 | 1·017 |
| Hydrochloric acid... | 1·053 | 1·025 | 1·009 |

When the resistance of solutions of these acids is compared with that of solutions of their normal salts, it is found that the ratio between the two quantities depends mainly on the temperature, and varies greatly at different temperatures.

C. H. B.

**Electric Conductivity of Compounds of Potassium and Sulphur in Solution, of Sodium Sulphide and of Boric Acid.** By O. BOCK (*Ann. Phys. Chem.* [2], **30**, 631—638).—The author has measured the conductivity of mixtures of alkaline hydroxide and alkaline hydrosulphide represented by the formulæ  $3\text{KOH} + \text{KSH}$ ,  $\text{KOH} + \text{KSH} = \text{K}_2\text{S} (+ \text{H}_2\text{O})$ ,  $\text{KOH} + 3\text{KSH}$ ,  $\text{KSH}$  and  $\text{Na}_2\text{S}$ . The conductivities and temperature coefficients are given in tables for many different concentrations in each case. For these the original paper must be referred to.

The conductivity of KOH, like that of NaOH, is diminished by the addition of hydrogen sulphide. Each mixture of hydroxide and hydrosulphide shows an independent maximum of conductivity for some particular strength of solution, which increases with the amount of hydrosulphide present.

When the solutions are dilute, the conductivities of KOH,  $\text{K}_2\text{S}$ , and

KHS are to each other nearly as  $1 : \frac{2}{3} : (\frac{2}{3})^2$ . Thus each addition of an electrochemical sulphur molecule,  $S/2$ , to one of potassium (or sodium) diminishes the conductivity by one-third. Similarly, the author finds the conductivities of the pentasulphides,  $K_2S_5$  and  $Na_2S_5$ , in solution to be about one-third of that of the corresponding sulphide solutions.

The conductivity of various solutions of pure boric acid is also given. This acid is one of the worst known conductors. The trace of sodium present in the commercial acid increases the conductivity threefold.

CH. B.

**Nobili's Rings and Allied Electrochemical Phenomena.** By A. ELSAS (*Ann. Phys. Chem.* [2], 30, 620—630).—The author believes, in opposition to Voigt, that Nobili's rings are mainly due to currents which traverse the electrolysed liquid nearly parallel to the metal plate. The colours obtained are not in all cases colours of thin plates; but the rings are sometimes deposits of different chemical and physical constitution. In fact, electrochemical decomposition takes place not only at the surfaces of the electrodes, but at every point throughout the liquid traversed by the current. This is proved as follows. Plaster of Paris moistened with copper sulphate solution is poured on a metal plate, and a copper wire plunged into the still soft mass with its end very close to the plate. The plaster is allowed to set firmly, and a current is passed from wire to plate. On removing the cake, four or five coloured rings are seen on its surface, corresponding rings being found on the plate. The plaster also adheres to the metal more or less firmly in different zones, and is also distorted. The central area opposite the wire is green ( $CuH_2O_2?$ ), and is surrounded by rings successively white, blue, white, red (Cu) and again blue. When the current is long continued, coloured deposits are also found throughout the mass of the gypsum. The colours of the rings are independent of the nature of the metal plate, when the latter does not directly act on the electrolyte.

When the anode wire is of platinum, the electrolyte becomes acid and pure copper is nowhere deposited. When it is of iron, rust-coloured rings are found in the gypsum plate, showing that transference of the ions takes place even in the solid. If the metal plate is made the anode, a blue circle appears round the cathode, surrounded by an intensely blue ring.

When a current is passed between two wires immersed in a plate of gypsum, prepared as above on a plate of glass, circular coloured rings are formed round each wire. The isochromatic lines do not correspond either with the equipotential lines or the lines of equal current-intensity. If in this experiment a metal plate is substituted for the glass, rings also appear on its surface. These appear to coincide with the equipotential lines only at some distance from the wires.

Theoretical views follow as to the distribution of potential in the last case. But the appearances cannot be explained by reference to this alone, as Guébbard imagines.

CH. B.

solubility of the respective salts,  $\text{KNO}_3$  and  $\text{NaNO}_3$  solutions becoming, so to speak, more dilute at high temperatures. H. K. T.

**Tellurium.** By BERTHELOT and C. FABRE (*Compt. rend.*, 104, 1405—1408).—The different varieties of tellurium were finely powdered and dissolved in bromine and water saturated with bromine, the thermal disturbance being measured. The precipitated varieties were washed and dried in an atmosphere of nitrogen. The following mean numbers were obtained:—

|  |             |
|--|-------------|
| Crystallised tellurium, prepared by volatilisation in hydrogen .....                               | +66·66 Cal. |
| Tellurium precipitated by sulphurous acid.....   | +42·584 „   |
| Tellurium precipitated from alkaline tellurides by the action of air or other oxidising agents.... | +66·78 „    |
| Tellurium precipitated from hydrogen telluride by oxidising agents .....                           | +67·01 „    |

The tellurium precipitated from hydrogen telluride and alkaline tellurides is identical with the crystalline variety, and the mean heat of solution in bromine and water is +66·776 Cal.

From these results it follows that the conversion of crystallised tellurium into the amorphous variety develops +24·192 Cal., and that tellurium, like sulphur and selenium, exists in two perfectly distinct states. Molten tellurium thrown into cold water and then treated as above gives numbers varying from 44 to 56 Cal., which indicate that it is a mixture of the crystalline and amorphous varieties.

It is worthy of note that the change from amorphous to crystalline tellurium absorbs heat, the corresponding change for selenium develops heat, whilst the similar change in the case of sulphur gives rise to no sensible thermal disturbance at the ordinary temperature, but is positive at a high temperature, and doubtless becomes negative at a low temperature.

It is also of interest that tellurium precipitated in alkaline liquids and from hydrogen telluride, is identical with the crystalline variety, whilst that precipitated by sulphurous acid constitutes a distinct modification. Similar phenomena are observed in the case of sulphur.

C. H. B.

**Heats of Combustion of Organic Substances.** By J. THOMSEN (*Ber.*, 20, 1758—1759).—The author quotes results obtained in the estimation of the heats of combustion of organic substances by Berthelot and Vielle by combustion with oxygen in the calorimetric bomb, and by Stohmann by combustion with potassium chlorate, and points out that the results obtained by the latter are always far lower than those obtained by the former. This he attributes to Stohmann's use of an indirect and an inaccurate method.

A. J. G.

**Heats of Combustion.** By BERTHELOT and RECOURA (*Compt. rend.*, 104, 1571—1574).—These determinations were made by means of the calorimetric bomb.

*Glucose.*—Heat of combustion per gram 3·762 Cal.; per gram-mole-

cule + 677.2 Cal. This value is sensibly equal to the heat of combustion of lactose, and is identical with half the heat of combustion of saccharose (+ 677.5 Cal.). These results agree with those previously obtained by Berthelot and Veille. The heat of formation of glucose is + 300.8 Cal. The union of carbon in the form of diamond ( $C_6$ ) with water ( $6H_2O$ ) to form glucose would absorb - 113.2 Cal., a result which explains the development of heat during alcoholic fermentation and the reserve energy associated with the carbohydrates which plays such an important part in vital processes.

*Quinone*.—Heat of combustion per gram 6.102 Cal.; per gram-molecule + 659.02 Cal. Heat of formation + 45.2 Cal. The union of  $C_6$  with  $2H_2O$  to form quinone would absorb - 92.8 Cal., an absorption relatively greater than that which accompanies the formation of glucose.

*Naphthalene*.—Heat of combustion per gram 9.6888 Cal.

*Benzoic Acid*.—Heat of combustion per gram 6.345 Cal.; per gram-molecule + 773.1 Cal. at constant volume; 772.8 Cal. at constant pressure. Heat of formation + 92.2 Cal. The union of  $C_6H_6$  with  $CO_2$  would absorb - 30 Cal.

*Salicylic Acid*.—Heat of combustion per gram 5.326 Cal.; per gram-molecule + 734.99 Cal. at constant volume and constant pressure. This value agrees with that calculated from the heat of combustion of phenol, and the heat of transformation of salicylic acid into phenol and carbonic anhydride.

C. H. B.

**Heats of Combustion.** By BERTHELOT and LOUGUININE (*Compt. rend.*, 104, 1574—1577).—These results were obtained by means of a calorimetric bomb smaller than that used by Berthelot and Recoura (preceding Abstract).

*Naphthalene*.—Heat of combustion per gram 9.6961. The general mean of this and the previous results is + 9.700 Cal. Heat of combustion per gram-molecule + 1241.6 Cal. at constant volume; 1242.7 at constant pressure. Heat of formation from its elements - 26.7 Cal.

*Phenol*.—Heat of combustion 7.8105 Cal., which agrees with the previous determination by Berthelot and Vieille.

*Benzoic Acid*.—Heat of combustion 6.3221 Cal.

*Cumic Acid*.—Heat of combustion per gram 7.5533 Cal.; per gram-molecule + 1239.3 at constant volume, + 1237.7 at constant pressure. The excess over the heat of combustion of benzoic acid is + 464.9, or + 155  $\times$  3 Cal.

*Quinone*.—Heat of combustion 6.00613 Cal.

*Quinol*.—Heat of combustion per gram 6.2295 Cal.; per gram-molecule + 685.24 Cal. at constant volume; 684.9 Cal. at constant pressure. Heat of formation + 86.1. Heat of formation from hydrogen and quinone + 40.9 Cal.

*Pyrogallol*.—Heat of combustion per gram 5.0262 Cal.; per gram-molecule + 633.3 Cal. at constant volume and constant pressure. Heat of formation + 137.7 Cal.

The practical identity of the two last numbers is of considerable interest. The first two changes are not exactly of the same character.

C. H. B.

**The Continuous Transition from the Liquid to the Gaseous State of Matter at all Temperatures.** By W. RAMSAY and S. YOUNG (*Phil. Mag.* [5], 23, 435—458).—For perfect gases at constant volume, the pressure varies directly as the absolute temperature, or  $p = cT$ . This law is at best only approximate, because the actual molecules of gas occupy space, and may be assumed to be incompressible, and because they exercise attraction on one another. If volume be kept constant, however, these two factors are in all probability invariable. Hence it might be expected that at constant volume a gas or a liquid under any conditions of temperature and pressure should exhibit simple relations between temperature and pressure. It has been proved by the authors that this relation is expressible by the formula  $p = bT - a$ , where  $b$  and  $a$  are two constants, functions of volume. Amagat from imperfect data has stated a similar relation for gases, but not for liquids. In the paper a full proof of these relations is given from the behaviour of ether and carbonic anhydride. The constants of the former are deduced from measurements by the authors; for the latter Dr. Andrews' data have been employed. Here are three methods of expressing relations between temperature, pressure, and volume; by means of isobars, isotherms, and *isochors* (lines of equal volume). From the above formula it follows that the isochors are straight. They therefore admit of extrapolation without error, and by means of such extrapolation those portions of the isothermals which elude measurement can be mapped. Such isothermals form a sinuous curve, cutting the line representing the observed vapour-pressure, as was predicted by Prof. James Thomson, in three points, and enclosing two areas, one above and the other below the vapour-pressure line. These areas have proved to be equal, thus furnishing a striking confirmation of the correctness of the formula  $p = bT - a$ , and of the accuracy of the experimental results.

There are three curves obtainable, all representing relations between temperature and pressure: (1) that furnished by the lower apices of the sinuous curves; (2) that furnished by the upper apices; and (3) the ordinary vapour-pressure curve. These three curves cut at the critical point. The critical temperature and pressure are thus given directly. With ether the calculated temperature is  $193.83^\circ$ ; that observed was  $193.8^\circ$ . The calculated pressure is 27075 mm. The value of  $b$  corresponding with the critical volume is the tangent to the ordinary vapour-pressure curve at the critical temperature. But since no equation is known exhibiting the relations of  $a$  and  $b$  to the volume (those of Van der Waals, Clausius, and Sarrau being either not convertible into the simpler equation  $p = bT - a$ , or not repre-

senting facts with sufficient accuracy), the volume corresponding with this value of  $b$  can be obtained only by a graphical method. It is for ether, 4.06 c.c. per gram.

W. R.

**Vapour-tension of Liquid Cyanogen.** By J. CHAPPUIS and C. RIVIÈRE (*Compt. rend.*, **104**, 1504—1505).—The pressures observed are given in mm., the first number being Bunsen's determination. In order to remove nitrogen, the liquefied cyanogen was made to congeal by its own evaporation in a vacuum, the gas being removed by means of a mercury pump.

|                |        |      |      |      |      |
|----------------|--------|------|------|------|------|
| Temperature..  | −20.7° | 0°   | 5°   | 10°  | 15°  |
| Pressure ..... | 750    | 1800 | 2150 | 2570 | 3070 |

C. H. B.

**Vapour-tensions of Saline Solutions.** By R. EMDEN (*Ann. Phys. Chem.* [2], **31**, 145—189).—There are two important questions to be considered, the relation of vapour-tension (1) to temperature, (2) to the amount of salt dissolved. In each case a law of simple proportionality has been enunciated. Thus Babo found that with several salts the vapour-tension was proportional to the tension of the vapour of pure water at the same temperature. The later and more perfect researches of Wüllner, Pauchon, Tammann, and others, do not yield results in accordance with Babo's law. It must be noted, however, that the results of these researches are not concordant, and different conclusions are arrived at with regard to the same salt.

The author's object was to clear the matter up by using a method which had already proved trustworthy. Konovaloff's arrangement (*Ann. Phys. Chem.* [2], **14**, 34) was employed, because it permits the solution to be introduced into the apparatus completely free from air.

To test the exactness of the method, the apparatus was first used to determine the vapour-tension of pure water. The numbers obtained were in close agreement with those of Magnus, and the differences served as some sort of measure of the accuracy of the method.

From the observations by means of Magnus' formula for the vapour-tension—

$$P = a10^{\frac{b}{c+t}},$$

the constants  $a$ ,  $b$ ,  $c$ , were calculated. The values were very nearly the same as those Magnus has already given.

Determinations were next made of the vapour-tensions of solutions of varying degrees of concentration of eight different salts (NaCl, KCl, NaNO<sub>3</sub>, KNO<sub>3</sub>, K<sub>2</sub>SO<sub>4</sub>, CaCl<sub>2</sub> + 6H<sub>2</sub>O, ZnSO<sub>4</sub> + 7H<sub>2</sub>O, CuSO<sub>4</sub> + 5H<sub>2</sub>O).

The author points out the importance of avoiding any small constant error of experiment, and alludes to such an error which is to be found in some determinations of vapour-tension by Regnault, who supposes that his thermometers were the cause of it.

In the researches of Wüllner and Tammann, cathetometers were

used. The error might be caused by the barometer-tube being inclined to the plane glass face of the water tank, or by the condensation of the vapour on the sides of the tube.

A formula similar to that given by Magnus may be supposed to hold for a salt solution, so that—

$$p = a'10^{\frac{bt}{c' + t}}.$$

It easily follows analytically that, if Babo's law holds,  $b = b'$  and  $c = c'$ . The observations may then be used to determine the value of  $a'$ , and a table of the values of  $p$  may be constructed. The differences between the values of  $p$  as observed and as given by the formula were found to be within the limits of experimental error already determined. It was therefore concluded that for a range of temperature from  $20^\circ$  up to  $95^\circ$ , Babo's law was true.

Wüllner asserts that the alteration of vapour-tension is proportional to the amount of salt dissolved. This law, however, is not in accordance with the results of experiments of Pauchon, Tammann, and others. The present observations prove that Wüllner's law is incorrect. In conclusion, the formula for  $p$  is extended to the calculation of the boiling points of the solutions. C. S.

**Apparatus for Vapour-density Determinations.** By D. S. MACNAIR (*Chem. News*, 55, 289).—The apparatus is a simplification of Hofman's, and consists of a syphon barometer-tube, filled with mercury, and suspended in an outer tube, in which some liquid of constant boiling point is heated, so as to surround the syphon tube by its vapour. A weighed quantity of the substance is passed round the bend of the syphon, and rises through the mercury to the slightly widened upper end of the tube, where its vapour soon depresses the mercury. Observations of the volume occupied, the temperature, and the barometer, complete the necessary data for calculating the vapour-density. A determination of the density of toluene vapour gave 46.3, the theoretical number being 46.0. R. R.

**Hydrates of Barium and Strontium Hydroxides.** By W. MÜLLER-ERZBACH (*Ber.*, 20, 1628).—A repetition of the experiments on the vapour-tension of hydrated barium and strontium hydroxides at temperatures between  $15^\circ$  and  $70^\circ$  has confirmed the results previously obtained (comp. this vol., p. 208), inasmuch as barium hydroxide was always found combined with one, two, seven, and eight molecules, and strontium hydroxide with one, seven, and eight molecules of water. At  $15^\circ$  the vapour-tension of  $\text{BaH}_2\text{O}_2 + 8\text{H}_2\text{O}$  amounted to 11.4 mm.; of  $\text{BaH}_2\text{O}_2 + 3$  to  $7\text{H}_2\text{O}$  to 2.46 mm.; of  $\text{BaH}_2\text{O}_2 + 2\text{H}_2\text{O}$  to 1.3 mm. (at first 1.5 mm.); of  $\text{BaH}_2\text{O}_2 + \text{H}_2\text{O}$  to *nil*; of  $\text{SrH}_2\text{O}_2 + 8\text{H}_2\text{O}$  to 9.4 mm.; of  $\text{SrH}_2\text{O}_2 + 2$  to  $7\text{H}_2\text{O}$  to 3.2 mm., and of  $\text{SrH}_2\text{O}_2 + \text{H}_2\text{O}$  to *nil*. This difference between barium hydroxide and strontium hydroxide is not altered when the respective hydrates containing 1 mol. of  $\text{H}_2\text{O}$  are placed in a moist atmosphere until each has taken up 2 mols. of  $\text{H}_2\text{O}$ , since the hydrated strontium hydroxide lost the absorbed water at a constant vapour-

tension, whilst the barium compound gave off water at a tension of 2.5 mm. until it acquired the composition  $\text{BaH}_2\text{O}_2 + 2\text{H}_2\text{O}$ , and lost the second mol. of  $\text{H}_2\text{O}$  at a tension of 1.3 mm. W. P. W.

**Hydrates of Barium Chloride.** By H. LESCŒUR (*Compt. rend.*, 104, 1511—1513).—The following are the vapour-tensions at 100°:—

|   |  |  |
|---|--|--|
| Saturated solution.                       | $\text{BaCl}_2 + 2\text{H}_2\text{O}$ .    | $\text{BaCl}_2 + 1.9\text{H}_2\text{O}$ .  |
| About 664 mm.                             | 620 mm.                                    | 626 mm.                                    |
| $\text{BaCl}_2 + 1.2\text{H}_2\text{O}$ . | $\text{BaCl}_2 + 0.94\text{H}_2\text{O}$ . | $\text{BaCl}_2 + 0.18\text{H}_2\text{O}$ . |
| 615 mm.                                   | 272 mm.                                    | 270 mm.                                    |

These results indicate the existence of a dihydrate and monohydrate. The latter is not formed at 100°, since dehydration becomes complete at this temperature, but is readily obtained by heating the dihydrate at 60—65°. In presence of moist air the dihydrate takes up some water, the vapour-tensions at +10 being—

|   |  |  |  |
|---|--|--|--|
| $\text{BaCl}_2 + 2\text{H}_2\text{O}$ . | $\text{BaCl}_2 + 2.25\text{H}_2\text{O}$ . | $\text{BaCl}_2 + 2.40\text{H}_2\text{O}$ . | $\text{BaCl}_2 + 2.61\text{H}_2\text{O}$ . |
| 2.7 mm.                                 | 7.5 mm.                                    | 7.5 mm.                                    | 7.4 mm.                                    |

These results indicate the existence of a higher hydrate, which, however, has not yet been isolated, but the fact that the addition of barium chloride to a supersaturated solution of calcium chloride determines the separation of the hexahydrate,  $\text{CaCl}_2 + 6\text{H}_2\text{O}$ , seems to point to the existence of a hexahydrate of barium chloride.

C. H. B.

**Amount of Water of Crystallisation contained in some Salts.** By C. R. SCHULZE (*Ann. Phys. Chem.* [2], 31, 204—233).—The method of investigating the constitution of a salt by measuring the vapour-tension by the barometric method seems free from objection, but there are very considerable practical difficulties in carrying it out. Müller-Erbach has proposed a somewhat easier plan, namely, to measure the relative vapour-tension. The present research was directed to test the accuracy of Müller-Erbach's method.

Twelve tubes of three different sizes with spherical bulbs blown at their ends were used. Some were filled with zinc sulphate in the shape of powder, and others with small crystals of zinc sulphate, whilst three were filled with water. By determining the loss of weight from day to day the relative tension was obtained. The tabulated results prove that the quantity of water evaporated is not proportional to the cross section of the tubes. The tubes containing the crystals give much higher values of the tensions than those containing the powder. It is inferred that Müller-Erbach's method is untrustworthy.

Müller-Erbach supposed that the relative tension increased with the temperature, but the author adduces observations made by Wiedemann to show that it is very nearly constant. This last result is of importance, because it enables us to deduce the vapour-tension for a salt from the corresponding tension of water-vapour.

Müller-Erbach has deduced from his observations the existence of a sulphate of zinc having the formula  $\text{ZnSO}_4 + 5\text{H}_2\text{O}$ , but Schulze proves that Müller-Erbach is hardly consistent in his mode of interpretation of the results of his experiments.

Wiedemann had discovered a modification of magnesium sulphate with 6 mols.  $\text{H}_2\text{O}$  produced at a temperature of  $93^\circ$ , which differs from the crystals produced between  $50^\circ$  and  $60^\circ$  by having a greater density. The author by measurements with the specific gravity bottle confirms the existence of this modification. C. S.

**Decomposition of Acetates by Water.** By G. FOUSSEREAU (*Compt. rend.*, 104, 1265—1267).—When aqueous solutions of zinc, copper, and lead acetates are allowed to remain at the ordinary temperature the resistance gradually increases, and this indicates a partial dissociation of the salt, since the resistance of free acetic acid is higher than that of its salts. The resistance increases with a rise of temperature and diminishes with a fall of temperature, tending towards a definite limit in each case. The dissociation is greatest in the case of cupric acetate, and somewhat less in the case of zinc acetate. Lead acetate shows similar changes in a very much lower degree.

In concentrated solutions the dissociation is very slightly marked even at high temperatures, and when the solution is diluted the resistance at first increases with the dilution, attains a maximum, and then decreases when the solutions become very dilute. The phenomena consequent on dilution are therefore different from those observed in the case of chlorides. C. H. B.

**Velocity of Saponification.** Part III. By L. T. REICHER (*Annalen*, 238, 276—286).—Urech (*Abstr.*, 1885, 480) has recently stated that when two substances A and B act on each other, the rate of saponification is influenced to a different extent by an excess of A than by an excess of B. The author has repeated his experiments on the saponification of ethyl acetate, and proves that the rate of saponification remains the same whether excess of sodium hydroxide or excess of ethyl acetate is doubled. W. C. W.

**Action of Heat on Potassic Chlorate and Perchlorate.** By E. J. MILLS (*Phil. Mag.* [5], 23, 375—378).—The author investigates as instances of cumulative resolution the results obtained by Teed, and by Frankland and Dingwall (*Proc.*, 1885, 105; 1886, 141; 1887, 24 and 25) on the decomposition by heat of potassic chlorate and perchlorate.

Representing the reaction by the equation  $2n\text{KClO}_3 - (n - 2)\text{O}_2 = (n + 1)\text{KClO}_4 + (n - 1)\text{KCl}$ , and taking  $r$  = specific measure of the change =  $\frac{\text{p. c. KCl in KClO}_3}{\text{p. c. O in KClO}_3}$ , then  $r \times \frac{\text{O}_2}{\text{KCl}} = \frac{n - 1}{n - 2}$ .

The value of  $n$  calculated from the results of the above experimenters is always rational, and approximates to  $r$ , a result which reduces the change to a mass action. For potassic perchlorate the equation  $(n + 1)\text{KClO}_4 - (2n - 1)\text{O}_2 = 2\text{KClO}_3 + (n - 1)\text{KCl}$  is

taken, and the values for  $n$  calculated as before. From these values the ratio  $\frac{\text{KCl}}{\text{KClO}_3} = p$  is calculated from the equation  $p \times \frac{\text{KClO}_3}{\text{KCl}} = \frac{n-1}{2}$ , and the values compared with those obtained from analytical data. They agree well in two cases out of three; in the third case the value for  $n$  was large.

If the weight of chloride = that of oxygen, then  $r = 1$ . If the values for  $n$  be now calculated from the two equations they are found to be reciprocal, hence the perchlorate reaction is the exact inverse of the chlorate reaction.

**Influence of Temperature on the Coefficient of Speed of Inversion of Cane-sugar by Hydrochloric Acid.** By F. URECH (*Ber.*, 20, 1836—1840).—The author shows that this influence as deduced from his experiments (Abstr., 1883, 174; 1885, 41) is not expressed by the formula arrived at by Spohr (Abstr., 1886, 502),  $K = a^{t+b}$ , in which  $t$  is reckoned from  $0^\circ$  and  $b$  is arbitrary. In the series of experiments quoted, the calculated value of  $a$  is nearly constant throughout, whilst  $b$  increases rapidly both with the temperature and with the concentration of the acid. On the other hand, Van t'Hoff's formula,  $\log K = -\frac{A}{T} + BT + C$ , expresses the results for any particular strength of acid fairly well when the constants  $A$ ,  $B$ , and  $C$  are determined from observations at wide intervals of temperature. These constants, however, vary for acids of different strengths, and even for any particular concentration their values depend on the temperatures for which they are calculated.

CH. B.

**The Spheroidal State.** By GOSSART (*Compt. rend.*, 104, 1270—1272).—The author has repeated Luvini's experiments (*Il Nuovo Cimento*, 17) with an apparatus so modified that the volume of the liquid, the temperature, and the pressure remained constant, and the two latter can be accurately measured.

Below  $33^\circ$  the temperature of the spheroid is higher than the boiling point of the liquid at the particular pressure. From  $33^\circ$  to  $50^\circ$  the two numbers are practically identical, the differences being sometimes positive and sometimes negative. From  $50^\circ$  up to  $90^\circ$  the temperature of the spheroid is always lower than the boiling point of the liquid under the existing pressure. At low temperatures the differences increase somewhat regularly, but at high temperatures the variations are comparatively irregular.

Under a pressure of 0.5 mm. a drop of water weighing 2 grams was completely frozen whilst in the spheroidal state, and was kept in this condition for 15 minutes, notwithstanding the fact that the dish on which it was supported was heated by means of a blowpipe.

C. H. B.

**Decrease of the Compressibility of Ammonium Chloride Solutions with Increase of Temperature.** By F. BRAUN (*Ann. Phys. Chem.* [2], 31, 331—335).—The measurements were made with

an Oersted's piezometer, the solution being contained in a dilatometer. Care was taken to expel as far as possible all air from the solution, and to diminish errors arising from this source, large pressures were employed. A rise of temperature of about  $18^{\circ}$  produced a diminution of about 3 per cent. in the compressibility, whether the liquid surrounding the dilatometer was water or ammonium chloride solution. This alteration cannot be ascribed to errors of experiment, and it is shown that the thermal effect of compression would not produce so large a change, although it would affect the absolute value of the coefficient. The comparison of the author's results with those obtained in the recent research of Schumann shows that the coefficients found are smaller, but that in each case the temperature coefficient of compressibility has the same sign.

C. S.

**Lecture Experiments.** By A. MERMET (*Bull. Soc. Chim.*, **47**, 306—310).—Silicon hydride may be conveniently prepared in small quantity for a lecture experiment by placing a piece of magnesium ribbon in a glass tube about 6 cm. long, and closed at the lower end, and heating in a Bunsen flame; after cooling, a few drops of hydrochloric acid are poured on the small globule of the silicon and aluminium compound formed, when an evolution of silicon hydride takes place, the bubbles burning in the air with decrepitation, and leaving a cloud of silica. If it be wished to prepare the gas in larger quantity it may be done by twisting one end of a stout wire round the rim of a steel thimble, and fixing the other end in a suitable support; a mixture of silica or sand and magnesium powder is then heated in this small improvised crucible, and the experiment conducted as before.

Potassium ferrate may be prepared in quantities sufficient to demonstrate its properties by adding excess of a concentrated solution of potash to 0.5 c.c. of a strong solution of ferric chloride, then a good pinch of bleaching powder, and finally a fragment of potassium hydroxide of the size of a pea, the solution is next filtered through asbestos, and the reddish-violet solution obtained contains sufficient potassium ferrate with which to demonstrate all the characteristic reactions of that salt. The author further calls attention to a violent explosion which took place when preparing hypochlorous anhydride, with use of a mixture containing liquid methyl chloride to condense the gas.

**Methods for obtaining Sulphurous Anhydride and Oxygen by the Use of a Kipp's Apparatus.** By G. NEUMANN (*Ber.*, **20**, 1584—1585).—Sulphurous anhydride can be generated in a Kipp's apparatus by the action of ordinary concentrated sulphuric acid on cubes prepared by Winkler's method (this vol., p. 442) from a mixture of 3 parts of calcium sulphite and 1 part of gypsum. Economy in

the use of the cubes is effected, if only the number required for the generation of the amount of gas needed are wetted with the acid at the commencement of the operation.

To prepare oxygen in a Kipp's apparatus, cubes consisting of a mixture of 2 parts of barium dioxide, 1 part of manganese dioxide, and 1 part of gypsum are used with hydrochloric acid (sp. gr. = 1.12) diluted with an equal volume of water. The oxygen evolved contains traces of chlorine, and must therefore be washed with an alkali.

It is not advisable to replace the gypsum in the cubes by starch or other similar cementing material.

W. P. W.

**Vapour-density of Tellurium Tetrachloride: Valency of Tellurium.** By A. MICHAELIS (*Ber.*, 20, 1780—1784).—Tellurium tetrachloride boils constantly at 380°. The vapour-density was determined in V. Meyer's apparatus at the temperature of boiling sulphur (448°) and of boiling phosphoric sulphide (530°). The density found in each case was that required by the formula  $\text{TeCl}_4$ , so that the vapour of tellurium sulphide does not suffer much dissociation even at 150° above its boiling point. From this result it follows that tellurium is at least tetravalent. The result is the more important, seeing that sulphur tetrachloride is only stable in the liquid state at -21°, and that selenium tetrachloride gives at 218° a vapour-density showing dissociation into selenium chloride and free chlorine ( $\text{Se}_2\text{Cl}_2 + 3\text{Cl}_2$ ). The densities determined for tellurium tetrachloride were—

| At 448°. |       | At 530°. |       | Calculated for<br>$\text{TeCl}_4$ . |
|----------|-------|----------|-------|-------------------------------------|
| 9.028    | 9.224 | 8.859    | 8.468 | 9.32                                |

A. J. G.

**Nitrogen Fluoride.** By H. N. WARREN (*Chem. News*, 55, 289).—Oily-looking drops found on the negative pole on electrolysing a solution of ammonium fluoride were supposed to be nitrogen fluoride. When connected with the positive electrode (a thin gold wire) these drops exploded with great violence, and the same thing occurred when they were brought into contact with glass, silica, or organic matter. No analyses seem to have been attempted.

R. R.

**Regeneration of Acid Residues in the Manufacture of Gun-cotton.** By E. ALLARY (*Bull. Soc. Chim.*, 47, 102—103).—The acid residues, which have a mean density of about 58° Baumé, are filtered through sand to remove a small amount of nitrocellulose, and then distilled. 100 kilos. yield 10 077 kilos. of nitric acid of 50° Baumé, 6.279 kilos. of nitric acid of 10° Baumé, and 82.302 kilos. of colourless sulphuric acid of 62° Baumé, the loss amounting to 1.342 kilos.

These acid residues may also very economically replace sulphuric acid in the manufacture of nitric acid from crude commercial sodium nitrate, nitric acid of 48.45° Baumé being obtained at the first distillation. There appears to be no danger of any explosive action caused by the presence of nitrocellulose dissolved in the acids.

A. P.

**Influence of Pressure and Temperature on the Action of Potassium Chloride on Crude Methylamine Carbonate.** By J. A. MÜLLER (*Bull. Soc. Chim.*, **47**, 379—382).—The crude amines employed contained 1 per cent. of ammonia, 30 per cent. of methylamine, 50 per cent. of dimethylamine, 2 per cent. of trimethylamine, and about 17 per cent. of higher amines containing a considerable amount of amylamine. The dilute carbonic anhydride employed was obtained from a limekiln, and contained 25 per cent. of carbonic anhydride. The potassium chloride employed was Stassfurt salt, containing 97·3 per cent. of potassium chloride. 2·14 mols. of the methylamine carbonate were taken to every 2 mols. of potassium chloride. Under these conditions it was found that the conversion of the potassium chloride into hydrogen potassium carbonate took place most satisfactorily, either under ordinary pressure at a temperature of 0°, or at the ordinary temperature under a pressure of about 3 atmospheres.

A. P.

**Artificial Production of Trona or Urao.** By P. DE MONDÉSIR (*Compt. rend.*, **104**, 1505—1508).—A mixture of crystallised sodium carbonate 27 parts and sodium hydrogen carbonate 8 parts, is added gradually to a boiling solution of 28 parts of sodium chloride and 28 parts of crystallised sodium carbonate in 100 parts of water. The liquid is boiled until solution is complete, water being added to replace that lost by evaporation, and is then allowed to cool slowly, care being taken that the temperature does not fall below 20°. The carbonate,  $3\text{Na}_2\text{O}, 4\text{CO}_2, 5\text{H}_2\text{O}$ , is deposited in long, white needles, which are usually matted together. This compound is stable in saturated solutions of sodium chloride, in which it is only slightly soluble, and in presence of which it loses carbonic anhydride very slowly, even when boiled. If a mixture of the 3 : 4 carbonate and sodium chloride is treated with water, part of the carbonate dissolves unchanged, and part is decomposed into the normal carbonate and the hydrogen carbonate. The 3 : 4 carbonate can, however, be separated from the chloride by dissolving the mixture in hot water, and allowing to cool, when the unaltered carbonate separates almost immediately, and is purified by washing with cold water. With the proportions given above, the carbonate is obtained practically free from chloride.

This artificial carbonate is identical in composition, crystalline form, &c., with natural trona or urao.

C. H. B.

**Silver Suboxide.** By G. H. BAILEY (*Chem. News*, **55**, 263).—The author thinks that Pfordten's results (this vol., p. 699) fail to establish the existence of silver suboxide, as they do not include the preparation of any definite salt of the base, but merely a partial analysis of a black powder of problematic constitution.

R. R.

**Solubility of Calcium and Magnesium Chlorides in Water at 0°.** By R. ENGEL (*Bull. Soc. Chim.*, **47**, 318—320).—The results given by various authors who have examined the solubility of these salts are very discrepant, the author finds, as the result of very careful experiment, that 100 parts of water at 0° dissolve 60·3 parts of calcium chloride, the solution having a sp. gr. of 1·367. 100 parts of water

at 0° dissolve 52.2 parts of anhydrous magnesium chloride. The saturated solution has a sp. gr. of 1.3619 at 15°. A. P.

**Solubility of Lead Chloride in Solutions of Mercuric Chloride.** By J. FORMÁNEK (*Chem. Centr.*, 1887, 270—271).—Results are given to show that the solubility of lead chloride in a solution of mercuric chloride is greater than in water, although the increase in solubility seems not to be due to the formation of a double salt. V. H. V.

**Ammonium Copper Iodides.** By A. SAGLIER (*Compt. rend.*, 104, 1440—1442).—100 grams of ammonium iodide is dissolved in 10 times its weight of water, and mixed with 10 to 15 grams of copper hydroxide, which partially dissolves in the cold and is completely soluble on heating. The liquid is then boiled with a large excess of copper until it becomes colourless, concentrated, and allowed to cool slowly, when it deposits long, white needles, of the composition  $\text{Cu}_2\text{I}_2 \cdot 2\text{NH}_4\text{I} + \text{H}_2\text{O}$ . These crystals can only be preserved in the mother-liquor, and even under these conditions become brown after some time. In air they lose ammonia and ammonium iodide, and when heated, yield black cuprous iodide. They are decomposed by water with separation of cuprous iodide, and also by alcohol. When the original mother-liquor is exposed to the air it deposits black crystals of the composition  $\text{Cu}_2\text{I}_2 \cdot 2\text{NH}_4\text{I} \cdot 2\text{NH}_3 + 4\text{H}_2\text{O}$ .

If the solution of cupric oxide in ammonium iodide, obtained as above, is allowed to cool without being boiled with metallic copper, it deposits black needles of the composition  $\text{CuI}_2 \cdot 2\text{NH}_4\text{I} \cdot 2\text{NH}_3 + 2\text{H}_2\text{O}$ , which may be preserved in the mother-liquor, but alter when exposed to air. They are insoluble in water and ethyl alcohol, and dissolve with difficulty in ammonia. When the ammoniacal solution cools it deposits blue crystals of the composition  $\text{CuI}_2 \cdot 4\text{NH}_3 + \text{H}_2\text{O}$ , which are decomposed by heat, the final product being cuprous iodide.

If cupric hydroxide is dissolved in ammonium di-iodide, analogous compounds containing the di-iodide are obtained. A solution of ammonium iodide is mixed with an equivalent quantity of iodine and treated as above, the solutions being somewhat more dilute. The product consists of violet-black needles of the composition  $\text{CuI}_2 \cdot 2\text{NH}_4\text{I}_2 \cdot 2\text{NH}_3 + 6\text{H}_2\text{O}$ , which are red by transmitted light. They are more stable than the corresponding compound containing ammonium moniodide, but alter when exposed to air, and are even decomposed by water. They dissolve with difficulty in dilute ammonia.

The ammonium cupric iodides yield black cupric oxide when treated with potassium hydroxide; the cuprous iodides yield cuprous oxide.

C. H. B.

**Solubility of Copper Sulphate.** By A. ÉTARD (*Compt. rend.*, 104, 1614—1616).—The curve which represents the percentage composition of the saturated solution of a salt at different temperatures is usually a straight line. In the case of copper sulphate the direction of the line changes at three points.

Starting with the ordinary hydrate,  $\text{CuSO}_4 + 5\text{H}_2\text{O}$ , the quantity

of anhydrous copper sulphate in 100 parts of the solution between  $-2^{\circ}$  and  $+55^{\circ}$  is given by the equation  $y = 11.6 + 0.2614t$ , and between  $+55^{\circ}$  and  $105^{\circ}$  by the equation  $y = 26.5 + 0.3700t$ . Between these limits no formation of a definite hydrate can be detected, but there are perturbations in the conditions of equilibrium, and small quantities of a basic salt,  $3\text{CuSO}_4 \cdot 4\text{CuO} + 12\text{H}_2\text{O}$ , are deposited. Between  $105^{\circ}$  and  $190^{\circ}$ , however, the percentage quantity of anhydrous salt is given by the expression  $y = 45.0 - 0.0293t$ , and the solubility diminishes with a rise of temperature. These last conditions correspond with the formation of a trihydrate,  $\text{CuSO}_4 \cdot 3\text{H}_2\text{O}$ .

This hydrate is obtained by heating at  $108-110^{\circ}$  a flask containing a boiling saturated solution of copper sulphate. After about 48 hours' continuous evaporation the larger crystals were separated and preserved in sealed tubes. The crystals of the trihydrate are paler in colour than those of the pentahydrate, and break up in moist air, absorbing  $2\text{H}_2\text{O}$ . They have two optical axes, and seem to be rhombic octahedra. The same hydrate can be obtained in the amorphous condition by the careful dehydration of the pentahydrate.

C. H. B.

**Schweizer's Reagent and "Eau Celeste."** By H. BAUBIGNY (*Compt. rend.*, 104, 1616—1618).—"Eau celeste" is obtained by dissolving copper salts in ammonia, and contains salts of the type  $\text{CuSO}_4 \cdot 4\text{NH}_3 + \text{H}_2\text{O}$ . Schweizer's reagent is prepared by treating cupric hydroxide with ammonia, and contains the base  $\text{CuO} \cdot 4\text{NH}_3 + 4\text{H}_2\text{O}$ , isolated by Malaguti and Sarzeau. Both solutions deposit cupric hydroxide when largely diluted. "Eau celeste" contains salts of the base which exists in the free state in Schweizer's reagent. It follows that solutions of basic cupric salts should behave as mixtures of "eau celeste" and Schweizer's reagent, and this is found to be the case. Such solutions dissolve cellulose more readily the more basic the salt. Conversely, the addition of an ammonium salt to Schweizer's reagent partially converts it into "eau celeste," and if the former has previously been saturated with cellulose, the cellulose is precipitated as the ammonium salt is added. This change is produced by ammonium carbonate and by carbonic anhydride, and it follows, therefore, that when Schweizer's reagent is exposed to the air it will form cuprammonium carbonate, and will eventually be converted into "eau celeste."

The old method of preparing Schweizer's reagent by dissolving copper in ammonia in presence of air is defective, since it does not avoid the presence of carbonic anhydride, and hence gives a product with diminished solvent powers. Potassium sulphate and sodium chloride are not decomposed by ammonia nor by the cuprammonium base, and therefore they do not affect the properties of Schweizer's reagent. The addition of potassium or sodium hydroxide to "eau celeste" produces a liquid which is capable of dissolving cellulose.

The best method of preparing Schweizer's reagent is to precipitate a solution of copper sulphate with the calculated quantity of soda and dissolve the hydroxide in ammonia.

There can be little doubt that the Schweizer's reagent distributed

over vines as a preventative of mildew will be rapidly transformed into "eau celeste," which is the actual preservative. The more easily prepared "eau celeste" can therefore be used for this purpose instead of the Schweizer's reagent.

C. H. B.

**Stability of Corrosive Sublimate Solutions.** By V. MEYER (*Ber.*, 20, 1725—1729).—Anreger has recently stated that solutions of mercuric chloride in ordinary (not distilled) water can be rendered sufficiently permanent for antiseptic purposes by the addition of sodium chloride in weight equal to that of the mercuric chloride, the precipitation of mercuric oxychloride being thus prevented. The author's experiments fail to confirm this statement even with a large excess of sodium chloride; precipitates being still formed in solutions made with ordinary water.

A. J. G.

**Behaviour of Mercuric Chloride with Hydrogen Ammonium Carbonate.** By K. THÜMMEL (*Arch. Pharm.* [3], 25, 245—249).—Hydrogen sodium carbonate containing not more than 0.1 per cent. of hydrogen ammonium carbonate in solution, gives a white turbidity with mercuric chloride; if more is present, a white, flocculent precipitate is produced which quickly becomes yellow, and if the mercury salt is not added in excess, almost the whole of it is found in the precipitate. This precipitate was found to have approximately the composition  $3\text{HgO}, \text{HgCl}_2 + \text{NH}_2\text{HgCl}$ .

A similar precipitate obtained with pure ammonium carbonate had the formula  $\text{HgO}, \text{HgCl}_2 + 2\text{NH}_2\text{HgCl}$ . The yellow residue obtained on boiling *hydr. præc. alb* in water, and found by Kane (*Ann. Phys. Chem.*, 48, 182) to be  $\text{HgO}, \text{NH}_2\text{HgCl}$ , was found by the author to contain  $(\text{HgO}, \text{NH}_2\text{HgCl})_6 + \text{HgCl}_2$ .

J. T.

**Action of Carbonic Anhydride on Ultramarine.** By E. BÜCHNER (*Chem. Zeit.*, 11, 314).—Carbonic anhydride when passed into water containing ultramarine in suspension, causes an evolution of hydrogen sulphide. If the passage of the carbonic anhydride is continued until the evolution of hydrogen sulphide ceases, and during the passage of the gas the water is frequently changed by decantation, after subsidence of the ultramarine, a considerable amount of soda is found in solution. The author explains the reaction by supposing that ultramarine contains sodium sulphide, and that this sulphide is decomposed by carbonic anhydride, although nitroprusside of sodium fails to give any indication of the presence of an alkaline sulphide in the ultramarine. The reaction takes place also when carbonic anhydride is passed over dry ultramarine in a finely divided state. Ultramarine when acted on by carbonic anhydride whilst suspended in water, loses its fine blue tone, the product when dried being of a dull-red colour.

J. P. L.

**Manganese Sulphate.** By B. CLAASSEN (*Arch. Pharm.* [3], 25, 310).—To obtain crystals of manganese sulphate of definite composition is usually difficult; those obtained below  $6^\circ$  contain 7 mols.  $\text{H}_2\text{O}$ ,

between  $7^{\circ}$  and  $20^{\circ}$  5 mols.  $\text{H}_2\text{O}$ , and between  $20^{\circ}$  and  $30^{\circ}$  4 mols.  $\text{H}_2\text{O}$ ; frequently also the crystallisation only takes place after a long time. The author overcomes the difficulty by treating a concentrated solution of sulphate with 95 per cent. alcohol, when almost the whole of the sulphate separates out as a syrupy liquid, which after a short time begins to form crystals. If, at this point, the liquid and alcohol be repeatedly and strongly shaken, a crystalline meal results, but if allowed to remain at rest, well-formed, reddish-white, prismatic crystals are formed, identical with those obtained between  $7^{\circ}$  and  $20^{\circ}$  before-mentioned, and having the formula  $\text{MnSO}_4 + 5\text{H}_2\text{O}$ .

J. T.

**Action of Selenious Acid on Manganese Dioxide.** By P. LAUGIER (*Compt. rend.*, 104, 1508—1511).—Powdered native manganese dioxide is not readily attacked by a saturated solution of selenious acid even in sealed tubes, but precipitated hydrated manganese dioxide is readily dissolved with development of heat. The solution is brown, and seems to contain a selenite of manganese dioxide, but, like the solution of the dioxide in hydrochloric acid, it readily decomposes, manganese selenate remaining in solution, whilst an orange compound is precipitated. No oxygen is evolved. The precipitate contains manganese sesquioxide and selenious anhydride, but usually retains unaltered manganese dioxide.

An orange-yellow compound,  $\text{Mn}_2\text{O}_3 \cdot 4\text{SeO}_2$ , is obtained by heating hydrated manganese dioxide,  $\text{MnO}_2 + 4\text{H}_2\text{O}$  (1 mol.) and selenious anhydride (6 mols.) in sealed tubes with water at  $140^{\circ}$  for about eight hours. It is insoluble in water, and is not attacked by concentrated sulphuric or nitric acid in the cold. If these acids are diluted with three or four times their bulk of water, they have no action on the compound even when boiled. The compound is dissolved by selenious acid with subsequent precipitation of selenium, is attacked by cold hydrochloric acid with evolution of chlorine, and is dissolved by alkalis with formation of a selenite and manganese sesquioxide. It does not lose water at  $200^{\circ}$ , but at  $600^{\circ}$  selenious anhydride is volatilised, and a rose-coloured residue of manganous selenate is left.

If the preceding compound is heated with water in sealed tubes at  $140^{\circ}$  for about four hours, small, green prisms of the compound  $\text{Mn}_2\text{O}_3 \cdot 2\text{SeO}_2$  are obtained. This substance does not lose selenious anhydride at  $600^{\circ}$ , but in other respects it behaves like the preceding compound. It is obtained directly by heating a concentrated solution of selenious anhydride (2 mols.) with hydrated manganese dioxide (1 mol.).

If the second compound is left in contact with a solution of selenious acid for about a month, it is converted into a well-crystallised, red compound with properties similar to those of the original substance. It has the composition  $\text{Mn}_2\text{O}_3 \cdot 3\text{SeO}_2 \cdot 5\text{H}_2\text{O}$ , loses water at  $200^{\circ}$ , and selenious anhydride at  $600^{\circ}$ .

C. H. B.

**Cobaltammonium Compounds.** By S. M. JÖRGENSEN (*J. pr. Chem.* [2], 35, 417—448).—The following formulæ are assigned to the luteocobalt salts described (compare *J. pr. Chem.* [2], 23, 229, and

Abstr., 1884, 1093) :— $(\text{Co}_2, 12\text{NH}_3)6\text{NO}_3$ , the reactions of the solution, with a number of reagents are also described;  $(\text{Co}_2, 12\text{NH}_3)2\text{NO}_3, 2\text{SO}_4$ , corresponding with a chromium compound;  $(\text{Co}_2, 12\text{NH}_3)2\text{NO}_3, 2\text{PtCl}_6 + 2\text{H}_2\text{O}$ , also corresponds with a chromium salt; it is not decomposed by water;  $(\text{Co}_2, 12\text{NH}_3)\text{Cl}_6$  is anhydrous and very stable, not being changed by strong hydrochloric acid at  $100^\circ$ , whilst the corresponding chromium salt changes into the purpleochloride even in the cold;  $(\text{Co}_2, 12\text{NH}_3), 3\text{PtCl}_6 + 6\text{H}_2\text{O}$ ; this salt was first examined with correct results by Gibbs and Genth; they however claim to have obtained also  $(\text{Co}_2, 12\text{NH}_3)3\text{PtCl}_6 + 21\text{H}_2\text{O}$ , this was probably the salt  $(\text{Co}_2, 12\text{NH}_3)\text{Cl}_2, 2\text{PtCl}_6 + \text{H}_2\text{O}$ ;  $(\text{Co}_2, 12\text{NH}_3)\text{Cl}_4, \text{PtCl}_6 + 2\text{H}_2\text{O}$  is also described; these three platinum double chlorides easily undergo change, the one being converted into the other. The crystals of the second salt contain many cavities full of liquid.  $(\text{Co}_2, 12\text{NH}_3)\text{Cl}_4, 2\text{HgCl}_2$  and  $(\text{Co}_2, 12\text{NH}_3)6\text{HgCl}_2 + 2\text{H}_2\text{O}$  are described, but it is believed that the salt described by Carstanjen with  $4\text{HgCl}_2$  does not exist.  $(\text{Co}_2, 12\text{NH}_3)\text{Br}_6$ ;  $(\text{Co}_2, 12\text{NH}_3)\text{Br}_2, 2\text{SO}_4$ ;  $(\text{Co}_2, 12\text{NH}_3)\text{Br}_2, 2\text{PtBr}_6 + 2\text{H}_2\text{O}$ ;  $(\text{Co}_2, 12\text{NH}_3)\text{I}_6$  must be prepared from the hydrate;  $(\text{Co}_2, 12\text{NH}_3)3\text{SO}_4, 5\text{H}_2\text{O}$ , this salt contains  $5\text{H}_2\text{O}$ , as Gibbs and Genth showed, and not  $4\text{H}_2\text{O}$ , as described by Fremy and Genth;  $(\text{Co}_2, 12\text{NH}_3)2\text{SO}_4, 2\text{AuCl}_4$ ;  $(\text{Co}_2, 12\text{NH}_3)2\text{SO}_4, 2\text{AuBr}_4$ ;  $(\text{Co}_2, 12\text{NH}_3)2\text{PO}_4 + 8\text{H}_2\text{O}$  can be obtained more simply than originally described by Braun;  $(\text{Co}_2, 12\text{NH}_3)3\text{PO}_4\text{H} + 4\text{H}_2\text{O}$ . These salts are described in detail in the original.

The pyrophosphate has been examined by Braun, Gibbs, Vortmann, and Porumbaru; when a cold solution of luteocobalt chloride is precipitated with sodium pyrophosphate, the salt  $(\text{Co}_2, 12\text{NH}_3)2\text{P}_2\text{O}_7, \text{Na} + 23\text{H}_2\text{O}$  is formed; when washed with hot water it is converted into  $(\text{Co}_2, 12\text{NH}_3), 3\text{P}_2\text{O}_7 + 20\text{H}_2\text{O}$ ; if, however, the component salts are mixed hot, then a third salt,

is formed, but under no such conditions is an acid salt ever obtained, as has been reported by other investigators; the acid pyrophosphate is formed by treating the above with dilute acetic acid; its composition is  $(\text{Co}_2, 12\text{NH}_3)2\text{P}_2\text{O}_7\text{H}$ ; a corresponding acid, roseocobalt pyrophosphate,  $(\text{Co}_2, 10\text{NH}_3, 2\text{H}_2\text{O})2\text{P}_2\text{O}_7\text{H}$ , is also described; some further details are also given respecting the salt  $(\text{Co}_2, 12\text{NH}_3)\text{Co}_2\text{Cy}_{12}$ .

H. B.

**Chromiodates.** By A. BERG (*Compt. rend.*, 104, 1514—1517).—*Chromiodic acid*,  $\text{IO}_2\cdot\text{O}\cdot\text{CrO}_2\cdot\text{OH} + 2\text{H}_2\text{O}$ , is obtained by dissolving chromic anhydride (1 mol.) and iodic acid (1 mol.) in a small quantity of water, and evaporating over sulphuric acid. It forms small, ruby-red, deliquescent, rhombic crystals, which melt when heated, then lose water, and finally give off oxygen. Chromiodic acid oxidises alcohol, but with less energy than chromic acid.

*Potassium chromiodate*,  $\text{IO}_2\cdot\text{O}\cdot\text{CrO}_2\cdot\text{OK}$ , is obtained by concentrating a solution of potassium dichromate (1 mol.) and iodic acid (2 mols.) containing a slight excess of chromic acid, or by dissolving potassium iodate in an excess of chromic acid. It forms brilliant red, anhydrous, crystalline crusts, and sometimes isolated crystals; sp. gr. = 3.66.

In presence of a large excess of chromic acid it separates in orange-yellow plates.

The ammonium salt is obtained in a similar manner, and forms red, rhombic crystals, which are somewhat more soluble than the potassium salt; sp. gr. = 3.50. A hydrated salt containing 1 mol.  $\text{H}_2\text{O}$  also seems to exist.

The sodium salt and lithium salt are obtained in the same manner, and both crystallise with 1 mol.  $\text{H}_2\text{O}$ . The sodium salt forms red, crystalline crusts, which are very soluble in water; sp. gr. 3.21.

All these salts are decomposed by water into iodates and chromic acid, but the decomposition is limited by the liberation of the chromic acid. The hydrated salts lose their water at  $120\text{--}140^\circ$ ; at a higher temperature iodine and oxygen are given off, and a residue of dichromate is left. The solutions of these salts have an acid reaction, and when treated with alkalis or alkaline carbonates, yield a mixture of iodate and chromate. They readily give up oxygen to reducing agents, with formation of green chromic iodate together with some normal chromate and dichromate. Manganese, cobalt, and nickel form similar salts, but the corresponding salts of the alkaline earths do not appear to exist.

C. H. B.

**Structure of some Complex Inorganic Acids.** By F. KEHRMANN (*Ber.*, 20, 1811—1813).—The author discusses certain constitutional formulæ for phosphomolybdates and phosphotungstates.

**Phosphotungstic Acids.** By F. KEHRMANN (*Ber.*, 20, 1805—1811).—When a cold concentrated solution of disodium tungstate (1 mol.) is mixed with aqueous phosphoric acid (4 mols.), a clear colourless liquid is obtained, which, when heated to boiling, turns yellow. On evaporation, after about three hours' boiling, and cooling, greenish-yellow plates separate. These consist of the sodium salts of at least three different phosphotungstic acids, which can be separated by conversion into the potassium salts followed by fractional crystallisation, for the details of which the original must be consulted. The derivative of one only of these acids is described.

*$\alpha$ -Phospholuteotungstic acid*,  $\text{H}_5\text{PW}_8\text{O}_{29} + \text{Aq}$ , is obtained in solution only by decomposing its silver salt with hydrochloric acid. The solution is colourless and strongly acid, and when evaporated turns yellow from formation of an anhydro-acid. The normal potassium salt forms small, white crystals; it is obtained by the action of hydrogen potassium carbonate on the potassium salt of the anhydro-acid. The normal *silver* salt,  $\text{Ag}_5\text{PW}_8\text{O}_{29} + x\text{Aq}$ , is obtained as a pulverulent, yellowish-white precipitate. The normal ammonium salt,  $(\text{NH}_4)_5\text{PW}_8\text{O}_{29} + x\text{H}_2\text{O}$ , crystallises in sparingly soluble, lustrous, colourless tables.

*$\alpha$ -Anhydrophospholuteotungstic acid*,  $\text{H}_3\text{PW}_8\text{O}_{28} + 16\text{H}_2\text{O}$ , one of the three acids obtained as described above, is prepared by treating its potassium salt with hydrofluosilicic acid, or by evaporation of solutions of the hydrated acid. It crystallises in large, citron-yellow, six-sided, hexagonal or orthorhombic tables. It is a strong bibasic acid, yielding

readily soluble, yellow salts. The potassium salt,  $K_3PW_8O_{28} + 20$  (or 21)  $H_2O$ , barium salt, barium ammonium salt,  $BaNH_4PW_8O_{28} + xAq$ , ammonium salt,  $(NH_4)_3PW_8O_{28} + 20H_2O$ , and silver salt,  $Ag_3PW_8O_{28} + 20H_2O$ , are described. A. J. G.

**Physical Constants of Germanium and Titanium and their Compounds.** By L. F. NILSON and O. PETTERSSON (*Chem. Centr.*, 1887, 329—330).—Determinations are given of the specific and atomic heats of germanium and titanium and its oxide, and of the vapour-densities, critical temperatures, and vapour-tensions of some of the compounds of germanium.

The atomic heats of germanium and titanium between the limits of temperature  $100-0^\circ$ , vary from  $5.3-5.4$ , or about one unit less than the usual value; that of titanium increases with increase of temperature up to  $7.77$ , at the temperature of sulphur vapour, whilst that of germanium remains constant.

Vapour-density determinations of germanium tetrachloride, tetraiodide, and monosulphide are in accordance with the formulæ  $GeCl_4$ ,  $GeI_4$ , and  $GeS$ . The critical temperature of germanium chloride is  $276.9$ . V. H. V.

**Crystallised Compounds of Zirconium.** By M. WEIBULL (*Ber.*, 20, 1394—1396).—*Zirconyl chloride*,  $ZrOCl_2 + 8H_2O$ , is obtained crystallised in prismatic needles from a hydrochloric acid solution of the so-called zirconium oxychloride. The crystals belong to the tetragonal system, and give  $a:c = 1:0.31816$ . They are optically uniaxial, and show positive double refraction. *Zirconyl bromide*,  $ZrOBr_2 + 8H_2O$ , yields similar tetragonal needles. *Zirconyl sulphate*,  $Zr(SO_4)_2 + 4H_2O$ , is obtained by the slow evaporation of a solution containing free acid. The hexagonal plates belong to the rhombic system, and show  $a:b:c = 0.6326:1:1.3350$ . L. T. T.

**Gold.** By G. KRÜSS (*Annalen*, 238, 241—275; continued from this vol., p. 450).—The atomic weight of gold is found to be  $196.669$ , as the mean of 30 analyses of potassium aurobromide and of a neutral solution of auric chloride. The results obtained from the analysis of sublimed auric chloride are somewhat lower, and are rejected by the author on the grounds that the sublimed auric chloride probably contains traces of free chlorine.

The atomic weight of gold has recently been determined by Thorpe and Laurie (*Trans.*, 1887, 565), who obtain the value  $196.852$ .

W. C. W.

**Alloys of Platinum, Iron, and Copper.** By E. MAUMENÉ (*Bull. Soc. Chim.*, 47, 39—41).—On heating 31.8 grams of platinum and 31.8 grams of iron with 66.6 grams of copper in a Perrot gas furnace, some of the iron remains unfused, but the fused portion of the metals forms a homogeneous alloy containing 7.43 per cent. of iron, 19.65 per cent. of platinum, and 72.92 per cent. of copper. This alloy is very readily oxidisable, being quickly covered with a coating of iron oxide and copper carbonate when exposed to the air.

A. P.

**Crystalline Alloys of Tin and the Platinum Metals.** By H. DEBRAY (*Compt. rend.*, **104**, 1470—1472).—Platinum or an allied metal in the state of powder is fused in a porcelain crucible, with 20, 30, or even 50 times its weight of pure tin. Combination takes place with development of heat, and the alloy is allowed to cool slowly, and is then treated with dilute or concentrated hydrochloric acid, as the case may require.

The crystalline alloy of platinum and tin is only obtained by the action of very dilute hydrochloric acid on an alloy containing not more than 2 per cent. of platinum. The regulus dissolves gradually, and leaves a residue of brilliant lamellæ of the composition  $\text{PtSn}_4$ . With a stronger acid, or with a smaller proportion of tin in the regulus, the residue is variable in composition.

The alloy of tin and rhodium is obtained in small, brilliant crystals of the composition  $\text{RhSn}_3$ , by the action of slightly diluted hydrochloric acid at  $0^\circ$ , on a regulus containing 3 per cent. of rhodium. The crystals are not affected by cold, concentrated hydrochloric acid.

The iridium alloy is obtained in a similar manner from a regulus containing 6 per cent. of iridium. It forms small crystals of the composition  $\text{IrSn}_3$ , which are probably regular octahedra.

When the regulus obtained by fusing ruthenium with 10 times its weight of tin is treated with hydrochloric acid diluted with an equal volume of water, the alloy  $\text{RuSn}_3$  is left in small, hopper-shaped crystals.

Osmium forms no similar alloy.

The alloys were analysed by heating them to bright redness in a current of hydrogen chloride, when the tin volatilises, or by heating to redness the alloy mixed with twice its weight of sodium chloride in a current of dry chlorine.

C. H. B.

**Action of Acids on Alloys.** By H. DEBRAY (*Compt. rend.*, **104**, 1577—1582).—The alloys of platinum and tin are somewhat readily attacked by hydrochloric acid even in the cold, whilst the alloys of tin with the other metals of the platinum group are not so readily affected (preceding Abstract).

The residues thus obtained form black scales which resemble graphite, and contain in addition to the platinum metal a considerable proportion of tin, together with small quantities of oxygen and hydrogen. Their composition, however, is very variable. They behave like platinum-black, developing more or less heat when placed in an atmosphere of hydrogen, and causing the detonation of explosive gaseous mixtures. The development of heat is not merely a result of the condensation of the hydrogen in the pores of the substance, but is partly due to the partial reduction of the metallic substance and the consequent formation of water. Probably many substances which are called "platinum-black" are of a similar nature, and act in a similar manner.

When the metallic residues are heated in a vacuum they lose water, and afterwards deflagrate without losing oxygen, and sometimes even become incandescent. They are more readily attacked by reagents than the metals which they contain. The residues from

the rhodium, ruthenium, and iridium alloys are partly dissolved by aqua regia, but the action is never complete. The rhodium residue alters even when dried in the air.

The residues still contain oxygen after having been heated in a vacuum, but they no longer have any catalytic properties.

The alloys of zinc with the platinum metals yield similar residues, but that from the platinum alloy itself contains neither oxygen nor hydrogen, and does not deflagrate when heated. The rhodium residue deflagrates violently, and is almost completely soluble in aqua regia.

The author has previously found that the alloys of the platinum metals and lead are attacked by dilute nitric acid, and yield black, explosive products (Abstr., 1880, 706).

The alloy of rhodium with copper is completely soluble in nitric acid, and the alloys of copper with the other platinum metals dissolve in notable quantity, but leave black, explosive residues which contain the platinum metal, copper, nitrogen, and oxygen, but are very variable in composition. The iridium residue is mixed with metallic iridium in the form of a crystalline powder, which indicates that some of the iridium dissolves in the copper, and separates out on cooling.

C. H. B.

## Mineralogical Chemistry.

**Native Gold from Thibet.** By A. KALECSINSZKY (*Zeit. Kryst. Min.*, 13, 73).—Native gold from East Thibet collected during Count Béla Széchenyi's expedition to Asia, gave on analysis the following results:—

| Au.   | Ag.  | Cu.  | Fe.  | Total. | Sp. gr. |
|-------|------|------|------|--------|---------|
| 91·74 | 7·03 | 0·74 | 0·46 | 99·97  | 17·12   |

B. H. B.

**Granular Limestones of Stainz in Styria.** By E. HUSSAK (*Zeit. Kryst. Min.*, 13, 52—54).—North-west of Stainz in Styria a bed of granular limestone containing felspar occurs in gneiss. The limestone contains microcline, albite, quartz, biotite, muscovite, tourmaline, hornblende, garnet, titanite, augite, and, occasionally, zoisite, zircon, chlorite, apatite, rutile, iron pyrites, magnetic pyrites, calcite, and, very rarely, orthoclase. With the exception of the microcline, all these minerals also occur in the gneiss enclosing the limestone.

An analysis of the microcline gave the following results:—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | CaO.  | K <sub>2</sub> O. | Na <sub>2</sub> O. | Ignition. | Total. |
|--------------------|----------------------------------|----------------------------------|-------|-------------------|--------------------|-----------|--------|
| 64·55              | 19·75                            | trace                            | trace | 13·97             | 1·91               | 0·25      | 100·43 |

The sp. gr. is 2·561. From its analogy to Becke's micropertthite, the author regards the name of microcline-perthite as the most suitable for the Stainz felspar.

B. H. B.

**Manganese Apatite. Composition of Apatite.** By M. WEIBULL (*Ber.*, 20, 1525—1527).—Manganese apatite occurs in Westana, partly in reddish-brown masses, partly in crystals in pyrophyllite; the crystals are pale green, and more or less transparent; well-formed crystals are rare, sp. gr. = 3.225 at 17°. In the following series of numbers, the column A contains those obtained by analysis; B the same number less the amount of lime corresponding to that of fluorine; in C the relation of the atoms are given:—

|                                     | A.        | B.    | C.   |        |
|-------------------------------------|-----------|-------|------|--------|
| CaO .....                           | 50.12     | 44.65 | 7.97 | } 8.81 |
| MnO .....                           | 5.95      | 5.95  | 0.84 |        |
| P <sub>2</sub> O <sub>5</sub> ..... | 42.04     | 42.04 | 2.97 |        |
| F .....                             | 3.64—3.84 | 3.74  | 1.97 |        |
| Cl .....                            | trace     | trace | —    |        |
| Ca .....                            | —         | 3.91  | 0.98 |        |

The numbers point to the formula  $\text{Ca}_5(\text{Mn})\text{FO}_9(\text{PO})_3$  (comp. Völcker, *Abstr.*, 1884, 162).  
N. H. M.

**Celestine in Nautilus Aratus.** By W. STAHL (*Chem. Zeit.*, 11, 508—509).—The author has determined the composition of crystals found on the inner layer of a fossil *Nautilus aratus* from the Jura, near Rosswangen. The analysis gave—

|                   |      |       |      |
|-------------------|------|-------|------|
| SO <sub>3</sub> . | BaO. | SrO.  | CaO. |
| 43.93             | 3.65 | 49.30 | 2.80 |

corresponding to the formula  $\text{BaCa}_2\text{Sr}_{20}(\text{SO}_4)_{23}$ ; the specific gravity of the crystals was 3.91.  
J. P. L.

**Artificial Formation of Alabandine.** By H. BAUBIGNY (*Compt. rend.*, 104, 1372—1373).—1.1 gram of manganese sulphate was dissolved in 150 c.c. of water, mixed with a slight excess of ammonium acetate and a few drops of acetic acid, saturated at 0° with hydrogen sulphide, and sealed up in glass tubes. After remaining at the ordinary temperature from four or five years, distinct, dark green, octahedral crystals were formed. These were not analysed, but there can be little doubt that they are alabandine or crystallised manganous sulphate.  
C. H. B.

**Artificial Production of Crocoisite.** By L. BOURGEOIS (*Compt. rend.*, 104, 1302—1303).—When lead chromate is heated with nitric acid diluted with 5—6 vols. of water, and the clear liquid decanted or filtered, it deposits crystals of lead chromate as it cools. The best results are obtained when the liquid is heated in sealed tubes, excess of lead chromate being avoided. The crystals are brilliant, deep orange-red, monoclinic prisms, which become crimson and then deep purple when heated, but regain their original colour on cooling. In crystalline form, optical properties, and other physical and chemical properties, the crystals are identical with crocoisite; sp. gr. = 6.29.  
C. H. B.

**Långbanite, a new Swedish Mineral.** By G. FLINK (*Zeit. Kryst. Min.*, **13**, 1—8).—This mineral occurs at Långbanshyttan, in Wernmland, in association with schefferite, and appears to be extremely rare. An analysis of 0.4117 gram gave the following results:—

| SbO <sub>2</sub> . | SiO <sub>2</sub> . | Mn <sub>3</sub> O <sub>4</sub> . | Fe <sub>2</sub> O <sub>3</sub> . |
|--------------------|--------------------|----------------------------------|----------------------------------|
| 0.0603             | 0.0448             | 0.2934                           | 0.0472                           |

The other substances were present in quantities too small to be estimated. The finely-powdered mineral was soluble in warm hydrochloric acid, no chlorine being given off. It may, therefore, be assumed that the iron and manganese are present as protoxides. The analysis would then be—

| Sb <sub>2</sub> O <sub>5</sub> . | SiO <sub>2</sub> . | MnO.  | FeO.  | Total. |
|----------------------------------|--------------------|-------|-------|--------|
| 15.42                            | 10.88              | 64.00 | 10.32 | 100.62 |

The formula suggested is  $37\text{Mn}_5\text{SiO}_7 + 10\text{Fe}_3\text{Sb}_2\text{O}_8$ .

The mineral occurs only in the form of crystals. They belong to the hexagonal system; the axial ratio being  $a : c = 1 : 1.6437$ . The following planes were determined with certainty:—Base, 0P; prisms,  $\infty\text{P}$ ,  $\infty\text{P}_2$ ; protopyramids, P,  $\frac{1}{2}\text{P}$ ,  $2\text{P}$ ; deuteropyramids,  $\frac{1}{3}\text{P}_2$ ,  $\frac{2}{3}\text{P}_2$ ,  $\frac{4}{3}\text{P}_2$ ; dihexagonal pyramids,  $3\text{P}_{\frac{3}{2}}$ ,  $\frac{5}{6}\text{P}_{\frac{5}{4}}$ .

The colour of the mineral is an iron black with metallic lustre. It has a hardness of 6.5 and a sp. gr. of 4.918. B. H. B.

**Mineralogical Notes.** By A. H. CHESTER (*Amer. J. Sci.*, **33**, 284—291).—1. *Fuchsite*.—This variety of mica occurs on Aird Island, in the district of Algoma, Canada, in a coarsely crystalline dolomite. An analysis of a pure sample, carefully separated from the accompanying mica, gave the following results:—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Cr <sub>2</sub> O <sub>3</sub> . | CaO. | MgO. | K <sub>2</sub> O. | Na <sub>2</sub> O. | H <sub>2</sub> O. | Total. |
|--------------------|----------------------------------|----------------------------------|------|------|-------------------|--------------------|-------------------|--------|
| 45.49              | 31.08                            | 3.09                             | 0.51 | 3.36 | 9.76              | 0.90               | 5.85              | 100.04 |

The occurrence of chrome mica in Canada has been mentioned by Dawson; but no analysis has heretofore been published. The dolomite in which the fuchsite occurs is interesting on account of its peculiar appearance, which causes it to be readily mistaken for calcite. Analysis shows it to be a true dolomite in which part of the magnesium carbonate is replaced by iron carbonate.

2. *Pink Celestine*.—Celestine occurs at the stone quarries near Lairdsville in masses of prismatic crystals. It is interesting on account of its colour, which is usually pink, although sometimes the mineral has the ordinary blue tint. Analysis gave the following results:—

| SrO.  | BaO. | CaO. | SO <sub>3</sub> . | SiO <sub>2</sub> . | Total. |
|-------|------|------|-------------------|--------------------|--------|
| 46.71 | 7.28 | 2.01 | 43.20             | 0.28               | 99.48* |

3. *Zinkenite*.—This rare mineral has been discovered with antimony ores at the Stewart Mine, Sevier Co., Arkansas.

\* 100.38 in original.

4. *Brochantite*.—A specimen of this mineral from Chili gave on analysis the following results, after deducting 4.45 per cent. of insoluble matter:—

| CuO.  | SO <sub>3</sub> . | H <sub>2</sub> O. | Total. |
|-------|-------------------|-------------------|--------|
| 71.73 | 18.21             | 10.06             | 100.00 |

5. *Pectolite*.—A specimen of the so-called okenite from Disco Island gave on analysis—

| SiO <sub>2</sub> . | CaO.  | Al <sub>2</sub> O <sub>3</sub> . | Na <sub>2</sub> O. | K <sub>2</sub> O. | H <sub>2</sub> O. | Total. |
|--------------------|-------|----------------------------------|--------------------|-------------------|-------------------|--------|
| 52.86              | 34.33 | 0.71                             | 7.50               | 0.47              | 4.70              | 100.57 |

This is evidently pectolite, and probably resembles much that is called okenite from the same locality.

6. *Scorodite*.—This rare mineral has been found at the Horn Silver mine, at Frisco, Utah. A pure sample for analysis could not be obtained. Before the blowpipe, the mineral gives the reactions of arsenic acid, iron, and water.

7. *Bismuthite*.—A mineral from Casher's Valley, North Carolina, proved to be bismuthite. The analysis gave the following results:—

| BiO <sub>2</sub> . | CO <sub>2</sub> . | H <sub>2</sub> O. | Insoluble. | Total. | Sp. gr. |
|--------------------|-------------------|-------------------|------------|--------|---------|
| 86.36              | 7.79              | 2.02              | 3.63       | 99.80  | 7.45    |

The formula suggested is  $\text{Bi}_2\text{C}_3\text{O}_9 + 2\text{Bi}_2\text{H}_2\text{O}_4$ . Comparing this formula with that given by Weisbach for his bismutosphærite, it is found that they differ only in the hydration of the bismuth oxide. A new examination of bismutosphærite appears desirable, for it is curious that the loss in the analysis should be exactly equal to the amount of water required to make it the well-known mineral bismuthite.

8. The author also describes some hemimorphic crystals of barytes from De Kalb, St. Lawrence Co., New York, and some interesting pseudomorphs of cerargyrite after pyrargyrite occurring at the Horn Silver Mine, Frisco, Utah.

B. H. B.

**Minerals of the Serpentine-Chlorite-group.** By V. WARTHA (*Zeit. Kryst. Min.*, 13, 71—72).—The author gives analyses of two rocks he found in the Montafun Valley, Vorarlberg. The first came from Grandau (Analysis II), and resembles serpentine. The second came from Tafamunt (Analysis III), and resembles chlorite-schist. As the Grandau rock closely resembles the so-called *precious serpentine* from Borostyánkő in Eisenburg County, West Hungary, the author also gives an analysis of this (Analysis I). The analytical results were as follows:—

|      | SiO <sub>2</sub> . | FeO. | Fe <sub>2</sub> O <sub>3</sub> . | Al <sub>2</sub> O <sub>3</sub> . | MgO.  | H <sub>2</sub> O. | CaO. | Total. | Sp. gr. |
|------|--------------------|------|----------------------------------|----------------------------------|-------|-------------------|------|--------|---------|
| I.   | 30.45              | 3.70 | 2.21                             | 18.96                            | 32.20 | 12.79             | —    | 100.31 | 2.693   |
| II.  | 29.44              | 5.60 | 2.00                             | 20.98                            | 30.31 | 12.29             | —    | 100.62 | 2.722   |
| III. | 39.83              | 6.22 | 11.78                            | 4.43                             | 26.87 | 8.23              | 2.32 | 99.68  | 2.876   |

From these results, the author concludes that the Hungarian rock

and that from Grandau are identical with Kenngott's pseudophite, whilst the Tafamunt rock is serpentine-schist.

In conclusion the author gives a number of analyses of serpentines free from alumina, and compares them with the analyses of minerals of the pennine, ripidolite, and chlorite-groups. He concludes that the typical serpentine (massive serpentine from Zermatt and from Windisch Matrey) contains a certain quantity of alumina, and that, with reference to the percentage of alumina, there is always observable a transition from serpentine to pennine. Serpentine, in fact, is nothing else than a characteristic member of the chlorite-group, in which the percentage of alumina is eventually equal to nought.

**Imperfectly known Silicates.** By E. SCHLUTTIG (*Zeit. Kryst. Min.*, 13, 73—76).—*Glaucophane*.—An analysis of the glaucophane, described by A. v. Lasaulx, from the Pointe des Chats, Brittany, gave the following results:—

|     | SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | FeO. | CaO. | MgO.  | K <sub>2</sub> O. | Na <sub>2</sub> O. | Total. |
|-----|--------------------|----------------------------------|----------------------------------|------|------|-------|-------------------|--------------------|--------|
| I.  | 56.65              | 12.31                            | 3.01                             | 4.58 | 2.20 | 12.29 | 1.05              | 7.93               | 100.02 |
| II. | 57.13              | 12.68                            | 8.01                             |      | 3.34 | 11.12 | trace             | 7.39               | 99.67  |

A. v. Lasaulx' results (II) are added for purposes of comparison.

*Violan* from St. Marcel in Piemont gave on analysis the following results:—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | FeO.               | NiO + CoO. | MnO.    | CaO.  | MgO.  | K <sub>2</sub> O. |
|--------------------|----------------------------------|--------------------|------------|---------|-------|-------|-------------------|
| 52.02              | 2.60                             | 0.80               | 0.39       | 2.87    | 22.94 | 15.18 | 0.75              |
|                    |                                  | Na <sub>2</sub> O. | Total.     | Sp. gr. |       |       |                   |
|                    |                                  | 4.94               | 102.49     | 3.231   |       |       |                   |

The mineral was of a violet colour, and was associated with quartz, tremolite, and piemontite.

*Sapphirine* from Fiskensäs in Greenland gave on analysis the following results:—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | FeO. | MgO.  | Total. |
|--------------------|----------------------------------|------|-------|--------|
| 14.76              | 63.23                            | 1.65 | 19.75 | 99.39  |

This agrees with Rammelsberg's formula (MgFe)<sub>5</sub>Al<sub>10</sub>Si<sub>2</sub>O<sub>23</sub>.

*Felspar in the Corsican Diorite*.—This has hitherto been regarded as anorthite. The author concludes that it is a labradorite, composed of albite (1 mol.) and anorthite (3 mols.) His analysis gave—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | CaO.  | MgO. | K <sub>2</sub> O. | Na <sub>2</sub> O. | H <sub>2</sub> O. | Total. | Sp. gr. |
|--------------------|----------------------------------|----------------------------------|-------|------|-------------------|--------------------|-------------------|--------|---------|
| 47.38              | 29.58                            | 1.34                             | 12.26 | 1.50 | 3.15              | 2.14               | 2.33              | 99.68  | 2.70    |

B. H. B.

**Plagioclase from Tynemouth Dyke.** By J. J. H. TEALL (*Zeit. Kryst. Min.*, 13, 96).—An analysis of a specimen of plagioclase from the rock of a North-of-England dyke gave the following results:—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | CaO.  | MgO. | K <sub>2</sub> O. | Na <sub>2</sub> O. | Loss. | Total. |
|--------------------|----------------------------------|----------------------------------|-------|------|-------------------|--------------------|-------|--------|
| 47.30              | 31.50                            | 1.85                             | 14.88 | 0.93 | 0.38              | 1.22               | 1.80  | 99.86  |

The crystals are porphyritic, and glassy in texture. A section parallel to the basal plane gave  $55^{\circ} 10'$  as the angle between the extinction positions of adjacent lamellæ. The corresponding angle in anorthite lies between  $57^{\circ}$  and  $74^{\circ}$ , and in labradorite between  $10^{\circ}$  and  $14^{\circ} 30'$ .

B. H. B.

**Action of Heat on Clays.** By H. LE CHATELIER (*Compt. rend.*, 104, 1443—1446).—The author has investigated the behaviour of clays on heating with a view to determine their constitution, and if possible to devise a scheme of classification. The temperatures were measured by means of a thermoelectric couple consisting of pure platinum, and platinum containing 10 per cent. of rhodium, and were registered photographically by means of a reflecting galvanometer.

It was found that when small quantities of clay are heated the rate of increase of temperature slackens considerably at the moment of dehydration, and this point can be used as a means of distinguishing between different classes of hydrated silicates. The position of this point is independent of the conditions and notably of the rapidity of heating. The phenomenon is due to the fact that as soon as the velocity of a chemical change attains a notable value it increases very greatly for small increments of temperature. During the heating of the clays, however, there is not only a reduction in the rate of increase of temperature due to dehydration, but sudden accelerations are observed which indicate the occurrence of changes accompanied by a development of heat.

The examination of a large number of clays shows that these substances are much less complicated than was believed. They may be divided into five well-defined groups, typical members of which are halloysite from Miglos; allophane from Saint Antoine; kaolin from Red Mt., Colorado; pyrophyllite from Beresow, and montmorillonite from St. Jean de Cole respectively. The first group shows a feebly marked reduction in the rate of increase at  $150$ — $200^{\circ}$ ; a second well-marked reduction ending at  $700^{\circ}$ , followed by an acceleration at  $1000^{\circ}$ . The second shows well-marked reduction at  $150$ — $220^{\circ}$ , followed by acceleration at  $1000^{\circ}$ . The third shows a reduction at  $770^{\circ}$ , followed by a slight acceleration at about  $1000^{\circ}$ . The fourth shows a well-marked reduction ending at  $700^{\circ}$ , and a second less strongly marked reduction at  $850^{\circ}$ . The fifth shows a well-marked reduction at  $200^{\circ}$ , a second less strongly marked at  $770^{\circ}$ , and a doubtful reduction at  $950^{\circ}$ .

C. H. B.

**Constitution of Clays.** By H. LE CHATELIER (*Compt. rend.*, 104, 1517—1520).—When hydrated silica is gently heated it shows a diminution of the rate of increase of temperature between  $100^{\circ}$  and  $200^{\circ}$ . Alumina under the same conditions behaves differently according to the method by which it has been prepared. If precipitated from sodium aluminate it shows a first diminution below  $200^{\circ}$ , and a second ending at  $360^{\circ}$ ; if precipitated from aluminium salts or prepared by calcination of the nitrate at a moderate temperature it shows the same reductions followed by a sudden acceleration in the rise of temperature at  $850^{\circ}$ ; bauxite shows a diminution at  $700^{\circ}$ .

From these facts it follows that the author's experiments (preceding Abstract) cannot be taken as showing the presence of free silica in clays, and they indicate that the first two hydrates of alumina cannot exist in any of the clays examined, whilst the hydrate present in bauxite can only be present in halloysite if in any. The evolution of heat at high temperatures is due to a molecular change in the alumina, which beyond this point becomes insoluble. Free alumina does not exist in clays, but is liberated by their decomposition on dehydration.

Clays belonging to the montmorillonite-group have the composition  $4\text{SiO}_2, \text{Al}_2\text{O}_3, \text{H}_2\text{O} + \text{Aq}$ , whilst halloysites have the composition  $2\text{SiO}_2, \text{Al}_2\text{O}_3, 2\text{H}_2\text{O}$ , and in this respect are identical with kaolin. They are, however, distinguished from the latter by their behaviour during dehydration, and their solubility in acids after heating.

## Organic Chemistry.

---

**Iodoform and Bromoform.** By F. GÜNTHER (*Arch. Pharm.* [3], 25, 373—394).—Most of the methods given in text-books for the preparation of bromoform yield either none of that compound or very little. Methyl alcohol under the action of alkali and bromine gives no bromoform unless the alcohol be impure, formic acid being obtained. Ethyl alcohol under the same conditions gives acetic acid. If, however, the compound analogous to bleaching powder is prepared with bromine and milk of lime, this when heated with ethyl alcohol and then distilled gives bromoform. The best raw material is acetone. This when mixed with ten times its weight of a 20 per cent. soda solution heated at 50°, and treated with bromine in the smallest possible portions at a time, gives a yield of 81 per cent. of the theoretical amount of bromoform. The process goes quietly but lasts for some days. Caustic alkali in place of the carbonate accelerates the process, but the yield falls to 62·5 per cent. Acetaldehyde in presence of an alkali and bromine gives no bromoform.

Anhydrous aldehyde under the action of bromine gives as one product a substance having the empirical formula  $C_4H_7BrO_2$ , but whose constitution is quite uncertain; when heated with aqueous alkalis it yields bromoform and what seems to be a true resin.

**Iodoform.**—Alcohol containing 20 to 25 per cent. aldehyde is the most suitable raw material for the production of this compound. It is mixed with ten times its weight of soda solution, iodine is added, and the mixture stirred round from time to time; the iodoform gradually and quietly separates out. The process is completed in the cold. Some sodium iodide may be added with advantage, to increase the solubility of the iodine. As bye-product, sodium iodide nearly free from iodate is obtained. J. T.

**Products from the Residues of Compressed Gas.** By A. COLSON (*Compt. rend.*, 1286—1289).—The residues from compressed gas were heated at about 35°, and one part of the evolved gases was condensed in a flask by means of a freezing mixture, whilst the remainder was absorbed by bromine, the bromides being afterwards fractionated. The fraction boiling at 148° is isobutylene bromide, about 100 grams being obtained from 6 litres of gas oil. The fraction at 156—159° is smaller, and consists of diethylidene bromide, but the greater quantity of the brominated product consists of ethylvinyl bromide boiling at 167°.

The portion of the gas condensed by the freezing mixture contains a certain quantity of the three butylenes, but consists mainly of hydrocarbons richer in carbon (b. p. 11—30°), and when treated with bromine yields the erythrene bromide described by Caventou. This bromide is soluble in boiling concentrated nitric acid, and is deposited unchanged on cooling. It is very slightly attacked at 180° by a solution of lead acetate in benzene. If powdered silver nitrate is

added to the nitric acid solution, silver bromide is precipitated, but even after boiling for half an hour the decomposition of the erythrene bromide is not complete. If the acid liquid is then poured into cold water, a yellow oil of the composition  $\text{NO}_2 \cdot \text{C}_4\text{H}_5\text{Br}_2(\text{NO}_3)_2$  separates; sp. gr. 1.800.

Aniline reacts energetically with erythrene bromide, and forms the base  $\text{C}_4\text{H}_6\text{Br}_2(\text{NHPh})_2$ , which melts at  $62^\circ$ , and is soluble in ether, but almost insoluble in water. It is coloured reddish-brown by nitric acid, and dissolves in hydrochloric acid, but is precipitated unchanged when the latter is mixed with water.

Orthotoluidine also reacts with erythrene bromide.

Ethylene bromide reacts with aniline, and forms the base  $\text{C}_2\text{H}_4(\text{NHPh})_2$  described by Hofmann. With orthotoluidine it yields *ethyleneditolyldiamine*,  $\text{C}_2\text{H}_4(\text{NC}_7\text{H}_5)_2$ , which is separated from orthotoluidine by adding excess of hydrobromic acid. The hydrobromide is somewhat soluble in boiling water containing hydrobromic acid, and separates on cooling. It is partially decomposed by pure boiling water; ammonia precipitates the base from the solution. Ethyleneditolyldiamine is a white, crystalline solid which melts at  $72^\circ$ . It dissolves in 7 parts of ether and 10–12 parts of alcohol, the solubility in both cases increasing with the temperature. It also dissolves in 300 parts of boiling water. It has very little taste; its alcoholic solution reacts with methyl-orange, but not with phenolphthaleïn.

Ethylenediphenyldiamine reacts with indicators, both in alcoholic and aqueous solutions. Its hydrochloride,  $\text{C}_2\text{H}_4(\text{NPh}_2)_2\text{HCl}$ , is bitter, and only slightly soluble in water. C. H. B.

**Caprylidene: Constitution of Capraldehyde.** By A. BÉHAL (*Bull. Soc. Chim.*, **47**, 33–39).—The compound  $\text{C}_8\text{H}_{16}\text{O}$  obtained on distilling neutral sodium ricinoleate, when treated with phosphoric chloride, yields octylene chloride, and this when boiled for 72 hours with alcoholic potash in a reflux apparatus yields chlorooctylene and a little octylidene. The chlorooctylene,  $\text{C}_8\text{H}_{15}\text{Cl}$ , separated on the addition of water to the alcoholic solution, is heated with alcoholic potash in a sealed tube at  $150^\circ$  for 12 hours. Water is then again added, and the oily liquid which separates is fractioned; the portion boiling between  $130^\circ$  and  $136^\circ$  contains the *caprylidene*; this hydrocarbon,  $\text{C}_8\text{H}_{14}$ , is evidently a member of the acetylene series, as it yields characteristic precipitates with cuprous chloride and silver nitrate solutions. It may be converted into methyl hexyl ketone by adding it very gradually to well-cooled sulphuric acid which is kept constantly agitated, the liquid darkens and sulphurous anhydride is given off, the mixture is then poured on a sufficient quantity of ice to reduce the temperature considerably when an oily layer separates, the mixture is next neutralised with sodium carbonate and distilled; the distillate coming over first with the vapour of water is dried over calcium chloride and again fractioned; thus prepared *methyl hexyl ketone* has an agreeable odour somewhat like that of apples. It boils at  $171^\circ$  under 761.7 mm. pressure, sp. gr. at  $0^\circ = 0.8351$ ; it is insoluble in water, but dissolves readily in alcohol and ether, does not

reduce either an ammoniacal solution of silver nitrate nor Fehling's solution, but forms a combination with hydrogen sodium sulphite which is decomposed again by hot water; on oxidation of the ketone with chromic mixture, caproic and acetic acids are formed. From the above results the author considers that the view held by Staedeler and Pettersen (*Ann. Chem. Phys.*, **118**, 78), that the compound  $C_5H_{16}O$  obtained on distilling sodium ricinoleate is a methyl hexyl ketone is clearly shown to be erroneous, and that the compound produced is in fact capraldehyde, differing altogether in properties from the methyl hexyl ketone which may be prepared from it. A. P.

**Erythrene Bromides.** By E. GRIMAUX and C. CLOEZ (*Compt. rend.*, **104**, 1446—1448).—Whatever its origin, erythrene tetrabromide (see this vol., p. 352) melting at  $115-116^\circ$  distils easily in the vapour of water. The anhydrous compound distils completely at  $260-270^\circ$  with evolution of very little hydrogen bromide, and formation of a small, carbonaceous residue. When the distillate is treated with light petroleum, in which the tetrabromide is only very slightly soluble, and the petroleum is allowed to evaporate, it deposits bulky, transparent, tabular crystals which melt at  $37.5^\circ$ , but have the same composition as the crystals melting at  $115-116^\circ$ , and yield the same products with alcoholic potash. It may be assumed that the tetrabromide splits up into hydrogen bromide and the derivative  $CH_2 : CBr \cdot CBr : CH_2$ , which afterwards recombine, forming the compound  $CH_3 \cdot CBr_2 \cdot CBr_2 \cdot CH_3$ . This compound was obtained by Ciamician and Dennstedt from erythrene derived from pyrroline, but they regarded it as a direct product of the action of bromine, whereas its formation was really due to the fact that they purified their tetrabromide by distillation in a vacuum.

Both forms of tetrabromide when treated with alcoholic potash yield dibromerythrene, which however only exists in alcoholic or ethereal solution, and polymerises rapidly even in the dark when separated from its solvents. It combines readily with bromine to form dibromerythrene dibromide, which crystallises from ether in slender needles melting at  $67^\circ$ , and is very soluble in alcohol or ether. It combines slowly with excess of bromine, forming the tetrabromide  $C_4H_4Br_2Br_4$ , which crystallises in brilliant, nacreous plates melting at  $170^\circ$  with decomposition. It is slightly soluble in ether.

When the more volatile portion of the oil from compressed gas is treated with a limited quantity of bromine, it yields butylene bromide, together with a small quantity of erythrene dibromide which boils between  $190^\circ$  and  $200^\circ$  but has not yet been isolated. C. H. B.

**Free Thiocyanic Acid and Cyanuric Acid, and their Compounds with Ethers and Alcohols.** By P. KLASON (*J. pr. Chem.*, [2], **35**, 400—413).—The preparation of free thiocyanic acid has been described by Wöhler, Liebig, and Hermes; the present work refers to its decompositions. Hydrogen chloride has no action whatever, even at  $100^\circ$ , on potassium thiocyanate; but when passed into the fused salt, it acts rapidly, a volatile liquid consisting of carbon bisulphide and hydrocyanic acid, a yellow-red sublimate consisting

essentially of persulphocyanic acid and dithiocyanic acid, and a residue of ammonium chloride, melamine and unaltered potassium cyanate being obtained. On mercuric thiocyanate, hydrogen sulphide has but little action, but hydrogen chloride acts readily with formation of a white sublimate. A 10 per cent. aqueous solution of thiocyanic acid when distilled in a vacuum, and the vapours dehydrated by passing over calcium chloride at  $40^{\circ}$ , yields an acrid and very volatile distillate, which when taken from the freezing mixture becomes hot and solidifies. For the preparation of the aqueous acid, the methods of Vogel and Sommering, and of Hermes, are not suitable; it is most easily obtained by decomposition of barium thiocyanate with sulphuric acid. Although the aqueous acid cannot be distilled under ordinary conditions without decomposition, yet on distillation in a vacuum an acid of 10 per cent. suffers no decomposition; and an acid of even 30 per cent. may be obtained by distilling in a vacuum a mixture of potassium thiocyanate and hydrochloric acid, both in strong aqueous solution. An acid of less than 5 per cent. may be preserved; stronger acids can only be kept at low temperatures; when free from polymerisation products they give no precipitate with iodine solution; when distilled the acid comes over first. An aqueous acid shaken with ether yields almost all its acid to the ether; on distillation the ether passes over until the residue contains 30 to 36 per cent. of acid, after which the acid begins to decompose; but distilled in a vacuum it passes over unaltered, and after treatment with calcium chloride contains equal molecules of ether and thiocyanic acid; the vapour-density corresponds to a mixture of the two components, the vapour is not altered by heating at  $100^{\circ}$ , but decomposes on cooling. The free acid is therefore stable only in weak aqueous solution, or as a vapour. A compound of thiocyanic acid and methyl alcohol is obtained by passing hydrogen chloride into a solution of ammonium thiocyanate in methyl alcohol, and distilling in a vacuum; by fractional distillation a liquid of constant boiling point is obtained, consisting of two molecules of methyl alcohol to one of thiocyanic acid. An exactly similar ethyl compound is obtained in like manner, and an aqueous solution of the free acid when shaken with amyl alcohol yields a solution which after fractionation in a vacuum contains almost three molecules of the alcohol to one of the acid.

Cyanic acid is also absorbed by ether, and on distilling the temperature gradually rises, but a substance of constant composition could not be isolated. It is considered that when cyanic acid acts on alcohols, compounds are first formed similar to those yielded by thiocyanic acid, and that the urethanes are products of their decomposition.

H. B.

**Action of Polyatomic Alcohols on Solutions of Boric Acid and Hydrogen Sodium Carbonate.** By C. JEHN (*Arch. Pharm.* [3], 25, 250—251).—R. Sulzer has recently shown that solutions of boric acid and hydrogen sodium carbonate do not react on each other, but that the addition of glycerol or honey causes a reaction resulting in the evolution of carbonic anhydride. Normal carbonate gives no reaction under like conditions. Borax behaves like boric acid with

both hydrogen and normal carbonate. Also Sulzer showed that cane-sugar and milk-sugar do not induce reaction, whilst grape-sugar causes reaction. The action of honey is doubtless due to the presence of grape-sugar. Thus the reaction is induced by a triatomic alcohol, glycerol, and the aldehyde of a hexatomic alcohol, glucose. Hence it became of interest to ascertain if other polyatomic alcohols and their corresponding aldehydes possessed similar power. Mannitol caused reaction between boric acid and hydrogen sodium carbonate; but not in the case of borax and the salt. Erythrite, a tetratomic alcohol, behaved like mannitol. J. T.

**Sugar Compounds.** By W. STROMEYER (*Arch. Pharm.* [3], 25, 229—245).—Some of the saline compounds formed by the action of the sugars on certain bases have been repeatedly examined with conflicting results. The barium, calcium, and lead compounds were again examined. The author shows that the barium salt is an additive product of one molecule of cane-sugar with one molecule of barium oxide,  $C_{12}H_{22}O_{11}.BaO$ , thus confirming the view previously expressed by Peligot, Soubeiran, and Gerhardt. A similar monocalcium compound,  $C_{12}H_{22}O_{11}.CaO$ , was prepared by Peligot's method, in which freshly ignited calcium oxide is added to an excess of sugar in solution, and the salt is precipitated by the addition of alcohol. A tricalcium compound was prepared as indicated by Peligot, namely, by boiling the aqueous solution of the monocalcium compound. This was found to have the formula  $C_{12}H_{22}O_{11}.3CaO$ , thus agreeing with the views of Peligot, Daniell, and E. v. Lippmann. The lead compound on the contrary appears to be a substitution-product approaching in composition to  $C_{12}H_{18}Pb_2O_{11}$ , as maintained by Peligot, Soubeiran, and Mulder. This may arise from the facility with which basic compounds of organic lead salts are formed. An attempt to obtain an aluminium compound was unsuccessful. Chromium oxide was also found to be only slightly soluble in sugar solution. J. T.

**Formation of Galactose and Lævulose from Raffinose.** By J. HAEDICKE and B. TOLLENS (*Annalen*, 218, 308—318).—When raffinose is boiled for some hours with dilute sulphuric acid, it is converted into galactose and lævulose. On treating with sodium amalgam the mother-liquor from which the galactose has been deposited, a mixture of dulcitol and mannitol is obtained. W. C. W.

**Galactose from Carragheen Moss.** By J. HAEDICKE, R. W. BAUER, and B. TOLLENS (*Annalen*, 238, 302—307).—Carragheen moss, the dried algæ *Chondrus crispus*, yields on extraction with water containing 0.6 per cent.  $SO_3$ , and on further purification with alcohol, a small quantity of a crystalline compound which resembles galactose in its composition, action on polarised light, and its behaviour with nitric acid. On oxidation with nitric acid, the dry moss yields about 21.6 to 22.2 per cent. of mucic acid; almost the same yield is obtained from raffinose. W. C. W.

**Saccharification of Starch by Nitric Acid.** By A. SEYBERLICH and H. TRAMPEDACH (*Chem. Centr.*, 1887, 346—347).—The saccharification of starch by nitric acid has not as yet proved successful, as the product retains a considerable quantity of the syrup, and with it the soluble metallic salts which impart a saline taste to the sugar. The process adopted by the authors, by means of which the syrup is removed from the crystals, is as follows:—Dry starch is stirred with twice its weight of water to form an emulsion, and one two-hundredth of its weight of nitric acid added. The boiling process is conducted in a wooden vessel provided with reflux condensers; the syrup is neutralised with chalk, sodium carbonate added to slight alkaline reaction, and then evaporated to crystallisation in a vacuum. From this alkaline solution the sugar separates in small, individual crystals which do not retain the syrup. When crystals are no longer obtainable from the syrup, sulphuric acid is added in sufficient quantity to convert the calcium nitrate into sulphate, and after separation of the latter the liquid can be used in a succeeding operation.

V. H. V.

**Nitrocellulose.** By F. NETTLEFOLD (*Chem. News*, 55, 306).—The nature of the fibre influences the degree of nitration in nitrocellulose preparations. Thus whilst cotton attains 13·94 per cent. nitrogen, or very nearly the theoretical proportion in trinitrocellulose, pine flour and wood pulp reach only 11·2. But in these last instances, and in others mentioned in the paper, the product is divisible by solvents into different fractions with proportions of nitrogen that indicate the existence of nitro-compounds more complicated than di- and tri-nitrocellulose.

R. R.

**Amines in Suint.** By A. BUISINE (*Compt. rend.*, 104, 1292—1293).—A fresh aqueous extract of suint contains very little ammonia, but after standing for some time the proportion of this alkali increases considerably. It results from the decomposition of urea, exists in the form of carbonate, and is completely expelled by boiling. In addition to ammonia, the vapour given off when the solution is boiled contains monomethylamine and trimethylamine, the proportion between the three alkalis being ammonia 95, monomethylamine 4, trimethylamine 1.

C. H. B.

**Trimethyl- $\alpha$ -amidobutyrobetaine.** By E. DUVILLIER (*Compt. rend.*, 104, 1520—1522).—This compound is obtained by the action of ethyl bromobutyrate (1 mol.) on an alcoholic solution of trimethylamine (1·5 mol.). When the liquids are mixed, a precipitate is at once formed, but no heat is developed. The liquid is heated in closed tubes at 100° for about 12 hours, treated with barium hydroxide, distilled, the barium precipitated exactly with sulphuric acid, and the filtrate treated with silver oxide and concentrated. A syrupy alkaline liquid is obtained, which eventually becomes solid, and when this is treated with alcohol and the soluble product recrystallised from alcohol, *trimethyl- $\alpha$ -amidobutyrobetaine*,  $\text{CH}_2\text{Me}\cdot\text{CH}\langle\begin{smallmatrix} \text{CO} \\ \text{NMe}_3 \end{smallmatrix}\rangle\text{O} + \text{H}_2\text{O}$ , is obtained in bulky, transparent crystals, which become anhydrous at 120°. It is extremely soluble in water, very soluble in

alcohol, but insoluble in ether; it has a neutral reaction and a bitter taste.

The mother-liquor contains tetramethylammonium hydrate, together with the betaine, and by addition of platinic chloride and systematic crystallisation the two compounds can be separated. *Trimethyl- $\alpha$ -amidobutyrobetaine platinochloride* forms elongated, pointed, orange-yellow prisms, which are almost insoluble in alcohol; they contain 1 mol.  $\text{H}_2\text{O}$ , but become anhydrous at  $100^\circ$ . The *hydrochloride* is obtained from the platinochloride, but will not crystallise. If its solution is mixed with auric chloride, a precipitate seems to form, but this is really an emulsion of the aurochloride, which after some time separates as a yellow oil; this dissolves readily on heating, but is reprecipitated as an oil when the liquid cools. After some time it solidifies and forms lamellar crystals.

Attempts to obtain the corresponding ethyl-derivative were unsuccessful. A small quantity of triethyl- $\alpha$ -amidopropiobetaine was, however, obtained by the action of ethyl- $\alpha$ -amidopropionate on triethylamine.

C. H. B.

**Action of Ammonia on Chlorethanes: Direct Union of Ammonia with Non-saturated Compounds.** By R. ENGEL (*Compt. rend.*, 104, 1621—1624).—Vinyl chloride, obtained by treating ethylene chloride with alcoholic potash, was washed with alcohol, and passed into alcoholic ammonia until no more was dissolved. At the ordinary temperature there is no action, even after several months. Vinyl bromide likewise has no action on alcoholic ammonia at the ordinary temperature. At  $100^\circ$  there is also practically no action, but at  $150$ — $160^\circ$ , in presence of concentrated alcohol, a complex reaction takes place, the principal product being ethylenediamine. This result shows that certain non-saturated compounds are capable of combining directly with ammonia, a reaction which furnishes a new method of preparing amines. The author has obtained several acid amines by the action of ammonia on non-saturated acids.

In all cases when ammonia acts on ethylene chloriodide in aqueous or alcoholic solution, only ethylene bases are formed, both halogens being removed simultaneously. These results agree with Simpson's observations. Friedel and Silva have likewise shown that when ethylene chloriodide is treated with silver the products are ethylene and ethylene chloride.

Ammonia acts more readily on chlorethylene chloride in either alcoholic or aqueous ammonia even at the ordinary temperature. The product is always  $\text{C}_2\text{H}_2\text{Cl}_2$ , boiling at  $37^\circ$ , and hence the action of ammonia under these conditions is similar to that of potash. The theoretical yield is obtained.

C. H. B.

**Red Dye from Chloral Hydrate.** By J. Z. LERCH (*Chem. Centr.*, 1887, 299).—Walz, Ogston, and others have noticed the formation of red colouring matter of the composition  $\text{C}_{18}\text{H}_{24}\text{S}_{13}\text{N}_4\text{O}_6$  when ammonium sulphide is added to chloral hydrate. If hydrogen sulphide is passed into an ammoniacal solution of chloral hydrate a larger amount of the dye is produced. On prolonged passage of the

gas the red passes into a yellow coloration simultaneously with the disappearance of the alkaline reaction. A good result is obtained with sodium thioantimonate, the liquid becoming turbid with separation of sulphur and antimony pentasulphide. This reaction can be used for the detection of chloral hydrate. After acidification, the red colouring matter can be taken up by petroleum, chloroform, and carbon bisulphide to form yellow solutions, turning red on addition of alkali. From the solution in petroleum, the compound is obtained in fine crystals of a green, metallic lustre. Salts of mercury, lead, and silver form red compounds with solutions of the crystals, which decompose slowly after a time, but more rapidly on heating, with separation of metallic sulphides. V. H. V.

**Condensation of Normal Butyraldehyde.** By G. A. RAUPEN-  
STRAUCH (*Monatsh. Chem.*, 8, 108—119).— *$\alpha$ -Ethyl- $\beta$ -propylacrylic aldehyde*,  $\text{CH}_2\text{Me}\cdot\text{CH}_2\cdot\text{CH}:\text{CET}\cdot\text{CHO}$ , is prepared by adding 35 grams of 10 per cent. aqueous soda to a mixture of 35 grams of normal butyraldehyde and 600 c.c. of water. The whole is shaken and heated for two hours at  $40^\circ$ . After 24 hours it is made neutral or slightly acid by dilute sulphuric acid, and steam-distilled in an atmosphere of carbonic anhydride. The oily product is dried and distilled in a current of carbonic anhydride. It is a colourless oil boiling at  $172.4$ — $173.4^\circ$  (corr.); it is almost insoluble in water, insoluble in hydrogen sodium sulphite. It reduces ammoniacal silver solution, and reacts with phenylhydrazine. When treated with bromine the compound  $\text{C}_8\text{H}_{14}\text{Br}_2\text{O}$  is formed. When oxidised with potassium dichromate and sulphuric acid, an acid,  $\text{C}_8\text{H}_{16}\text{O}_2$ , is obtained.

*Ethylbutylacetaldehyde*,  $\text{C}_4\text{H}_9\cdot\text{CHET}\cdot\text{CHO}$ , is obtained by reducing the above aldehyde with iron filings and 60 per cent. acetic acid; the product is distilled, and the fraction boiling below  $179^\circ$  treated with sodium hydrogen sulphite, and the crystalline double compound washed with ether and decomposed by sodium carbonate. It is then steam-distilled. It is an oily substance, boiling at  $160$ — $162^\circ$  (uncorr.). It reduces ammoniacal silver solution, and does not form an additive compound with bromine. The portion of the product which boils above  $179^\circ$  appears to consist of an unsaturated alcohol,  $\text{C}_7\text{H}_{13}\cdot\text{CH}_2\cdot\text{OH}$ , and the corresponding saturated octyl aldehyde. N. H. M.

**Glyceraldehyde.** By E. GRIMAUX (*Compt. rend.*, 104, 1276—1278).—Anhydrous glycerol oxidises somewhat rapidly in contact with comparatively inactive platinum-black, and if the platinum is very active it is necessary to dilute the liquid with about 2 vols. of water in order to moderate the energy of the reaction. The liquid acquires considerable reducing power and becomes acid, the acidity increasing as the reducing power diminishes if the action of the platinum is prolonged, owing to the conversion of the aldehyde into the acid. The product is extracted with water and the solution concentrated in a vacuum. It reduces Fehling's solution, gives a mirror with ammonio-silver nitrate, and becomes yellow when boiled with alkalis, lime, or baryta. If the concentrated solution is mixed with sodium hydrogen sulphite, heat is developed, and on addition of alcohol

a gummy mass is precipitated which seems to be a combination of the sulphite and glyceraldehyde. With phenylhydrazine hydrochloride and sodium acetate the solution yields coloured precipitates, some of which dissolve in potash, whilst the others are insoluble and have not yet been obtained pure. The hydrazine-derivative soluble in alkalis is recrystallised from benzene and afterwards from dilute alcohol. It then has a constant melting point.

The products of the oxidation of glycerol by platinum-black ferment in contact with beer yeast, and yield carbonic anhydride and ethyl alcohol. Fermentation is slow owing to the presence of a large quantity of unaltered glycerol, and is never complete.

The formation of hydrazine-derivatives soluble in alkalis, and the small quantity of carbonic anhydride evolved, compared with the reducing power of the product, indicate the formation of an aldehydic acid. Other oxidising agents, such as chromic acid, chlorine, bromine, or sunlight convert glycerol into substances having great reducing power.

Erythrol in contact with platinum-black is oxidised more slowly than glycerol, but seems to yield products which have a strong reducing power, and are fermented by yeast.

The author refers to a paper by Fisher and Tafel (this vol., p. 651) on azones derived from the products of oxidation of glycerol and erythrol.

C. H. B.

**Alkyl Hypochlorites from Isonitroso-compounds.** By R. MÖHLAU and C. HOFFMANN (*Ber.*, **20**, 1504—1507).—When an aqueous solution of hydroxylamine is treated with hypochlorous acid (equal mols.), a reaction takes place with formation of nitrogen, chlorine, and water.

*Acetoxime hypochlorite*,  $\text{NOCl} : \text{CMe}_2$ , is obtained by adding a solution of hypochlorous acid (prepared by saturating a cold 10 per cent. solution of soda) to a saturated aqueous solution of acetoxime kept cold with ice. An excess of hypochlorous acid must be used, and the whole well shaken until the blue colour at first produced disappears. The ether is then separated, washed with water, and dried with calcium chloride. It is a mobile liquid of an agreeable odour, sparingly soluble in water, readily in alcohol and ether. When cooled by means of ether and carbonic anhydride, it solidifies to colourless prisms. It distils with steam. When suddenly heated it explodes, but when carefully heated, boils at  $134^\circ$  (uncorr.) with partial decomposition.

*Acetaldoxime hypochlorite*,  $\text{NOCl} : \text{CHMe}$ , is prepared in a manner similar to the above compound. It is a colourless liquid having a powerful odour; it decomposes very readily, giving off hydrogen chloride, and could not be analysed. It explodes when heated.

N. H. M.

**Capraldoxime and Methylhexylacetoxime.** By A. BÉHAL (*Bull. Soc. Chim.*, **47**, 163—165).—The aldoxime and acetoxime were prepared from the capraldehyde and methyl hexyl ketone respectively, which were shown to be distinct compounds in a preceding memoir (this vol., p. 788). The compounds obtained are very similar to one another in appearance, being oleaginous liquids which do not yield

crystals when cooled with ice and salt; they have an aromatic odour and are lighter than water in which they are insoluble; they dissolve readily, however, in alcohol and ether. The aldoxime boils at  $121^{\circ}$  to  $123^{\circ}$ , and the acetoxime at from  $116^{\circ}$  to  $117^{\circ}$ . A. P.

**Synthetic Acetic Acid and its Derivatives.** By L. HENRY (*Compt. rend.*, **104**, 1278—1281).—Synthetic acetic acid from acetonitrile has never been examined and compared with acetic acid produced in the ordinary way.

Acetonitrile was prepared by the action of methyl iodide on potassium cyanide, and was converted into acetic acid by mixing with 2.5 parts of hydrochloric acid of 40 per cent. in a well-cooled flask. When the reaction ceases the liquid is heated on a water-bath for several hours, the acid distilled off, converted into the anhydrous sodium salt, and decomposed by dry hydrogen chloride.

The acid thus obtained was carefully compared with acetic acid produced by fermentation and by the destructive distillation of wood. It was converted into monochloroacetic acid, ethyl acetate, and acetamide, and a portion of the monochloro-derivative was converted into malonic acid by Kolbe and Muller's method.

Synthetic acetic acid and its derivatives are identical in every respect with the corresponding compounds prepared in the ordinary way, and hence they may be used in the preparation of the  $\beta$ ,  $\gamma$ , and  $\delta$  monosubstitution-derivatives of methane (this vol., p. 711).

C. H. B.

**Cyanacetic Acid.** By L. HENRY (*Compt. rend.*, **104**, 1618—1621).—The hydrogen in the  $\text{CH}_2$ -group in malonitrile can be replaced by metals, notably by silver, and the hydrogen in hydrocyanic acid is distinctly basic. It was therefore to be expected that the hydrogen in the  $\text{CH}_2$ -group in cyanacetic acid, united as it is with a cyanogen-group and a carboxyl-group, would likewise be basic. Experiment confirms this conclusion.

A solution of ethyl cyanacetate in ether is rapidly and energetically decomposed by sodium, with evolution of hydrogen and separation of a white, pulverulent substance insoluble in ether. This product, *ethyl cyanosodacetate*, is a very light, very hygroscopic, and easily fusible solid, which reacts readily with haloïd ethers, forming liquids which have a more agreeable odour than that of cyanacetic acid, and are insoluble in, and heavier than, water. The following compounds were obtained in this way:—*Ethyl methylcyanacetate*, which boils at  $194^{\circ}$ , vapour-density 4.34; *ethyl ethylcyanacetate*, which boils at  $204$ — $205^{\circ}$ ; and *ethyl allylcyanacetate*, which boils at  $215$ — $220^{\circ}$ .

Ethyl cyanacetate is rapidly decomposed by aqueous ammonia, and if the solution is allowed to evaporate spontaneously, crystals of cyanacetamide separate. The alkyl-derivatives just described are only very slowly attacked by ammonia. *Cyanacetamide*,  $\text{CN}\cdot\text{CH}_2\cdot\text{CONH}_2$ , crystallises from alcohol in small needles, which melt at  $118^{\circ}$ ; *ethylcyanacetamide*,  $\text{CN}\cdot\text{CHEt}\cdot\text{CONH}_2$ , forms small, nacreous plates which melt at  $113^{\circ}$ .

Ethyl cyanosodacetate readily reacts with carbonic chloride, yielding a crystalline product,  $\text{CN}\cdot\text{CH}(\text{COOEt})_2$ .

The alkyl-derivatives are very readily obtained by Conrad and Limpach's method, that is, by the action of the corresponding alkyl-iodides on the product of the action of an alcoholic solution of sodium ethoxide on ethyl cyanacetate.

The hydrogen of the  $\text{CH}_2$ -group is very readily replaced by chlorine and bromine. The chlorine-derivative,  $\text{CN}\cdot\text{CHCl}\cdot\text{COOEt}$ , is a colourless liquid which has a pungent odour like that of chloropicrin, and boils at about  $190^\circ$ ; vapour-density 5.11.

Pure cyanacetic acid is readily obtained in well-defined, white crystals which melt at  $65$ — $66^\circ$ , and not at  $55^\circ$  as stated by Van t'Hoff. C. H. B.

**Ethyl Cyanacetate.** By A. HALLER (*Compt. rend.*, **104**, 1626—1627).—When a solution of ethyl cyanacetate in its own volume of absolute alcohol is treated with the theoretical quantity of sodium ethoxide, it yields a crystalline magma of ethyl cyanosodacetate,  $\text{CN}\cdot\text{CHNa}\cdot\text{COOEt}$ , which is dried on porous plates and then over sulphuric acid in a vacuum. This compound forms white crystals almost insoluble in alcohol, but soluble in water, by which it is decomposed. When exposed to air it absorbs water and carbonic anhydride.

If the alcohol is present in sufficient quantity to keep the sodium-derivative in solution, the corresponding derivatives of the other metals can be obtained by double decomposition, but have not yet been analysed. The silver-derivative is yellow, but rapidly becomes brown when exposed to light, and black when boiled with water; the copper-derivative is greenish-blue, and becomes grey when heated with water; the zinc-derivative is white.

When an alcoholic solution of ethyl cyanosodacetate is treated with ethyl iodide, it yields a product which boils at  $210$ — $215^\circ$ ; with an ethereal solution of acetic chloride it yields ethyl cyanacetoacetate, identical with the product obtained by the author and Held by the action of cyanogen chloride on ethyl acetosodacetate. C. H. B.

**$\alpha$ -Methylamidovaleric Acid.** By A. MENOZZI and C. BELLONI (*Gazzetta*, **17**, 116—119).—*Methylamidovaleric acid*,

a homologue of sarcosine, is formed by warming a mixture of butaldehyde and hydrocyanic acid in molecular proportion, then adding the required quantity of methylamine; the nitrile thus obtained is then saponified. The acid crystallises in long, glistening needles very soluble in water; it sublimes slightly at  $110^\circ$ , more completely at  $160^\circ$ . The salts are very soluble in water and alcohol. The *nitrate* and *sulphate* crystallise in needles, the *sulphate* in prisms; the *copper* salt,  $\text{Cu}(\text{C}_6\text{H}_{13}\text{NO}_2)_2\cdot 2\text{H}_2\text{O}$ , in violet-blue prisms. V. H. V.

**Substituted Crotonic Acids.** By W. AUTENRIETH (*Ber.*, **20**, 1531—1533).—Escales and Baumann (*Abstr.*, 1886, 879) obtained a thiophenylcrotonic acid melting at  $176$ — $177^\circ$  from ethyl  $\beta$ -dithiophenylbutyrate. The same acid can be obtained from chlorcrotonic

acid, melting at  $59^{\circ}$ , by the action of sodium phenylmercaptide. The chlorocrotonic acid melting at  $94^{\circ}$  yields an isomeric thiophenylcrotonic acid which melts at  $158^{\circ}$  with evolution of carbonic anhydride. It is much more soluble in alcohol than the isomeride of higher melting point, and the barium salt crystallises with 1 mol.  $\text{H}_2\text{O}$ . The two thioethylcrotonic acids corresponding to the thiophenylcrotonic acids melt at  $91\text{--}92^{\circ}$  (from chlorocrotonic acid melting at  $59^{\circ}$ ) and  $113\text{--}115^{\circ}$  respectively.

N. H. M.

**Croton Oil.** By KOBERT (*Chem. Zeit.*, **11**, 416).—Senier found that English pressed croton oil dissolved or was miscible with alcohol in any proportion not exceeding the volume of the oil employed, but that if an excess of alcohol was used, some of the oil was rendered insoluble. By this means he separated croton oil into two distinct parts possessing different physiological properties, the part soluble in alcohol possessing the well-known vesicating but no purgative property, whilst the insoluble portion was found to possess the purgative but not the vesicating property (Abstr., 1884, 909, 947).

This separation by means of alcohol, the present author contends, is incorrect. The chief element in the solubility is the age of the oil, and there are, moreover, some kinds of croton oil soluble in every proportion of alcohol.

He further states that the purgative and vesicating properties of croton oil are due solely to the presence of crotonolic acid which exists free and combined as a glyceride in all croton oils. A process is given for the preparation of the pure acid from croton oil.

J. P. L.

**Acids from Drying Oils.** By K. HAZURA and A. FRIEDRICH (*Monatsh. Chem.*, **8**, 156—164; compare this vol., p. 359).—When the acids from poppy and nut oils (30 grams) are saponified with 36 c.c. of a solution of potassium hydroxide (sp. gr. = 1.27), the product dissolved in 3 litres of water, and oxidised with a solution of potassium permanganate (30 grams) in water (3 litres), they both yield 4 to 5 grams of sativic acid,  $\text{C}_{18}\text{H}_{32}\text{O}_2(\text{OH})_4$ , melting at  $161\text{--}162^{\circ}$ . When the two acids are treated with bromine they yield the same bromo-derivatives as does the acid from hemp oil: a compound melting at  $175^{\circ}$ , and the compound  $\text{C}_{18}\text{H}_{32}\text{Br}_4\text{O}_2$  melting at  $112\text{--}115^{\circ}$ . Sativic acid is also formed when linoleic acid is oxidised in dilute solution; when a more concentrated solution is oxidised, sativic acid and *linusic acid*,  $\text{C}_{18}\text{H}_{36}\text{O}_6$ , are formed. The latter crystallises from water in microscopic needles melting at  $203^{\circ}$ ; it is a monobasic acid. The *acetyl-derivative*,  $\text{C}_{18}\text{H}_{30}\text{O}_2(\text{OAc})_6$ , is a thick, yellow oil. When linoleic acid in concentrated alkaline solution is oxidised with finely-powdered potassium permanganate, azelaic acid,  $\text{C}_9\text{H}_{16}\text{O}_4$ , is formed. Bromine acts on linoleic acid with formation of a compound,  $\text{C}_{18}\text{H}_{30}\text{Br}_5\text{O}_2$ , identical with the tetrabromide of the dibromo-acid from hemp oil.

The authors think it probable that linoleic acid contains an unsaturated acid of the series  $\text{C}_n\text{H}_{2n-6}\text{O}_2$ , which yields linusic acid when oxidised. The presence of such an acid would also account for the fact that linoleic acid dries more readily than the others.

N. H. M.

**Acid from Hemp-seed Oil.** By K. HAZURA (*Monatsh. Chem.*, **8**, 147—155).—The *tetrabromide* of the acid from hemp-seed oil,  $C_{18}H_{32}Br_4O_2$ , is formed together with the *tetrabromide of the dibromo-acid*,  $C_{18}H_{30}Br_6O_2$ , when 50 grams of the acid dissolved in glacial acetic acid is treated with 21 grams of bromine. It crystallises in white, lustrous plates which melt at  $114-115^\circ$ , and dissolve readily in glacial acetic acid, chloroform, benzene, ether, and alcohol; it is insoluble in water. The *salts*, with the exception of the alkali salts, are insoluble in water and in ether. The compound  $C_{18}H_{30}Br_6O_2$  is white, melts at  $177^\circ$ , is very sparingly soluble in alcohol, glacial acetic acid, benzene, &c., insoluble in water. When the acid  $C_{18}H_{32}Br_4O_2$  is reduced with tin and hydrochloric acid, the bromine is eliminated but not replaced by hydrogen. These results point to the formula  $C_{18}H_{32}O_2$  for the acid from hemp oil. Sativic acid is shown to be *tetrahydroxystearic acid*,  $C_{18}H_{32}O_2(OH)_4$ . *Tetracetylsativic acid*,  $C_{18}H_{32}O_2(OAc)_4$ , prepared by boiling sativic acid with acetic anhydride, forms a light-yellow oil insoluble in water, soluble in alcohol, ether, light petroleum, &c.

N. H. M.

**Ethyl Cyanacetoacetate.** By A. HALLER and A. HELD (*Compt. rend.*, **104**, 1627—1629).—The ethyl cyanacetoacetate obtained by James (*Trans.*, 1887, 287) by the action of potassium cyanide on ethyl chloracetoacetate is identical with the compound obtained by the authors (*Abstr.*, 1882, 1280) by the action of cyanogen chloride on ethyl acetosodacetate. The formation of this compound from ethyl chloracetoacetate shows that the latter has the constitution

and not  $CH_2Cl \cdot CO \cdot CH_2 \cdot COOEt$ , as supposed by James.

A much higher yield can be obtained by James's method than is stated in his paper.

C. H. B.

**Preparation of Levulinic Acid.** By P. RISCHBIETH (*Ber.*, **20**, 1773—1775).—The following method is recommended as avoiding the use of the large quantities of ether required in the usual process. 3 kilos. of powdered potato-starch are added to 3 litres of hydrochloric acid of sp. gr. 1.1, contained in a pan on the water-bath, the mixture being constantly stirred until all is dissolved to a thin syrup. This is then transferred to two capacious flasks provided with reflux tubes, and heated for 20 hours in a vigorously boiling water-bath. The magma obtained is pressed in order to separate humous substances, and the liquid is again heated for some hours on the water-bath in a flask connected to a water-pump, when water, hydrochloric acid, and formic acid distil. The residual syrup (consisting mainly of levulinic acid) is then transferred to a capacious fractioning flask, and heated in an oil-bath under reduced pressure, when nearly pure levulinic acid passes over at  $135-150^\circ$  under 60 mm. pressure. The distillate solidifies completely, either spontaneously or when a fragment of crystallised levulinic acid is added. The acid is further purified, with but slight loss, by redistillation in a vacuum. The yields is 13 to 14 per cent. of the starch employed.

A. J. G.

**Salts of Lævulinic Acid.** By J. BLOCK and B. TOLLENS (*Annalen*, **238**, 301—302).—*Barium lævulinate*,  $(C_5H_7O_3)_2Ba + 2H_2O$ , is slowly deposited from concentrated solutions in needle-shaped crystals, freely soluble in water. *Strontium lævulinate*,  $(C_5H_7O_3)_2Sr + 2H_2O$ , crystallises in prisms. It is also freely soluble in water. W. C. W.

**Propylxanthic Acid.** By A. SCALA (*Gazzetta*, **17**, 78—82).—*Potassium propyl xanthate*,  $SK \cdot CS \cdot OPr$ , crystallises in yellow, silky needles, very soluble in water, sparingly soluble in alcohol and ether. Its *copper* salt is an orange-yellow, the *silver* salt a pale yellow, the *lead* and *mercury* salts white precipitates. On adding hydrochloric acid to a solution of the potassium salt, the free acid separates as a pale yellow, insoluble oil, rapidly decomposing into its constituents. *Propyldioxythiocarbonate*,  $OPr \cdot CS \cdot S_2 \cdot CS \cdot OPr$ , prepared from iodine and potassium propyl xanthate, is a pale yellow oil of peculiar odour. With alcoholic ammonia it yields a crystalline precipitate, probably the amide of the acid. *Methyl propyl xanthate*,  $SMe \cdot CS \cdot OPr$ , is a pale yellow oil of a nauseous, garlic-like odour, boiling at  $202-203.5^\circ$ ; the *ethyl* salt, of similar appearance and odour even more disagreeable, boils at  $215.6-217.6^\circ$ . Determinations of the vapour-densities of these compounds are given. V. H. V.

**Potassium Manganic Oxalate.** By F. KEHRMANN (*Ber.*, **20**, 1594—1596).—*Potassium manganic oxalate*,  $K_6Mn_2(C_2O_4)_6 + 6H_2O$ , is always obtained as an intermediate product when solutions of potassium permanganate are reduced with oxalic acid in the cold, but in the presence of an excess of oxalic acid the reduction goes further, and the method is unsuitable for the isolation of the compound. It can, however, be separated if the calculated quantities of finely powdered hydrogen potassium oxalate and oxalic acid are gradually added to a mixture of manganic hydroxide and snow or finely powdered ice, and the deep purple-red solution, after rapid filtration, is mixed with alcohol until crystallisation commences, and then allowed to remain for 1 to 2 hours in a mixture of ice and salt. It crystallises in almost black, monoclinic prisms, transmitting light of a red colour at the edges, and is isomorphous with the corresponding iron salt; the two compounds show the same habitus, and when mixed in suitable proportions give mixed crystals on the addition of alcohol to the saturated aqueous solution. The salt is tolerably stable at the ordinary temperature and in the absence of light, but sunlight and heat decompose it with the evolution of carbonic anhydride. In water just slightly warm the salt dissolves at first without alteration, but soon decomposes with the evolution of much carbonic anhydride. The *barium* salt is obtained in dark red, sparingly soluble scales on the addition of barium chloride to a cold solution of the potassium salt. W. P. W.

**Addition of Ethyl Malonate to Compounds containing Doubly-linked Carbon-atoms.** By L. CLAISEN (*J. pr. Chem.* [2], **35**, 413—415).—A. Michael has described as a new reaction the addition of ethyl malonate or ethyl acetoacetate to substances with

doubly-linked carbon-atoms (this vol., p. 672). It is pointed out that the action of the aldehydes on ethyl malonate and ethyl acetoacetate, described by Komnenos and Claisen, Perkin, Junr., and by Hantzsch, is exactly similar, the first product of the action being a non-saturated compound, which then again enters into reaction exactly as described by Michael (compare Abstr., 1884, 422, 443, 444, 445). H. B.

**$\alpha$ -Amidoisosuccinic Acid.** By G. KOERNER and A. MENOZZI (*Gazzetta*, 17, 104—109).— $\alpha$ -Amidoisosuccinic or  $\alpha$ -isoaspartic acid,  $\text{NH}_2 \cdot \text{CMe}(\text{COOH})_2$ , is formed on warming a mixture of pyruvic and hydrocyanic acids under pressure; the product is treated with alcoholic ammonia, the nitrite formed is best saponified by barium hydrate, and the barium salt decomposed by sulphuric acid. The free acid crystallises in transparent prisms, readily decomposed, when heated at  $100^\circ$ , into  $\alpha$ -alanine and carbonic anhydride. In conformity with the hypothesis of Van t'Hoff, the acid is optically inactive. The salts of the alkali and alkaline earth metals crystallise in needles, soluble in cold, more so in hot water; the copper salt forms sparingly soluble, blue needles, and the silver salt a white, flocculent precipitate. The hydrochloride, sulphate, and nitrate crystallise in transparent prisms.

V. H. V.

**Butyl Sebacate.** By G. GEHRING (*Compt. rend.*, 104, 1289—1290). Butyl sebacate is obtained by the action of hydrogen chloride on a mixture of normal butyl alcohol and sebacic acid heated at  $150^\circ$ . It is a colourless liquid, with an agreeable, aromatic odour and a burning taste. It is insoluble in water; is miscible with alcohol in all proportions, and somewhat less miscible with ether; sp. gr. at  $0^\circ = 0.9417$ ; at  $15^\circ = 0.9329$ . It boils at  $344\text{--}345^\circ$  without decomposition. Small quantities on a glass rod burn with a flame with a deep blue centre, but the liquid cannot be ignited on the surface by a Bunsen burner.

Butyl sebacate is decomposed by sulphuric acid in the cold, with evolution of sulphurous anhydride. With ammonia it yields white microscopic needles of sebamide,  $\text{C}_8\text{H}_{10}(\text{CONH}_2)_2$ , and when treated with chlorine in sunlight a solid is formed, which is probably  $\text{C}_{10}\text{H}_{16}\text{O}_4(\text{C}_4\text{Cl}_9)_2$ .

C. H. B.

**Perchloramyl Perchlorosebacate and Perchlorobutyl Perchlorosebacate.** By G. GEHRING (*Compt. rend.*, 104, 1624—1625).—When dry chlorine is passed into a flask containing isoamyl sebacate exposed to sunlight, the chlorine is somewhat rapidly absorbed with considerable development of heat. When the energy of the reaction diminishes the flask is gradually heated, the temperature being eventually raised to  $230^\circ$ . The substance becomes solid, but continues to absorb chlorine, and again becomes liquid. After about four days, long, white needles separate, and these are removed from time to time and dried over lime and sulphuric acid in a vacuum. They are purified by sublimation and washing with water and alcohol. The compound thus obtained is *perchloramyl perchlorosebacate*,  $(\text{C}_5\text{Cl}_{11})_2\text{C}_{10}\text{Cl}_{16}\text{O}_4$ . It forms long, semitransparent, rhombic prisms, which melt at  $179^\circ$ , sublime readily, and when exposed to moist air become yellow,

resinous, and acid, and eventually volatilise. It has an aromatic smell, but no taste, is of a waxy consistency and cannot be powdered. It is heavier than water, and is volatile in water vapour. It will not dissolve in water, but is slightly soluble in alcohol and very soluble in ether, chloroform, benzene, light petroleum, and terebenthene.

*Perchlorobutyl perchlorosebacate*,  $(C_4Cl_9)_2C_{10}Cl_{16}O_4$ , is obtained in a similar manner, but the action is still more rapid. It forms snow-white, hexagonal prisms, which melt at  $172^\circ$  and boil at  $200^\circ$ . Its other properties resemble those of the preceding compound, but after washing with much water it becomes hard and brittle.

C. H. B.

**Reciprocal Transformation of the Optically Active Asparagines.** By A. PIUTTI (*Gazzetta*, 17, 126—128).—The inactive aspartic acid, when converted into the ethereal salt, and then heated with alcoholic ammonia, yields a crystalline mixture of the optically active asparagines. The transformation is somewhat similar to that effected by Jungfleisch in the case of tartaric acid. The monethyl aspartate is best obtained by decomposing the copper salt with hydrogen sulphide; it crystallises in micaceous laminae, melting at  $200^\circ$  with decomposition.

V. H. V.

**Alkyl-compounds of Bismuth.** By A. MARQUARDT (*Ber.*, 20, 1516—1523. Compare Michaelis and Michaelis and Polis, this vol., p. 368).—These compounds are prepared by adding an ethereal solution of bismuth bromide (2 mols.) to a solution of zinc alkyl in ether. The ether is afterwards distilled off in a current of carbonic anhydride, and the residue treated with aqueous soda in an atmosphere of hydrogen when the bismuth alkyl separates.

*Trimethylbismuthine*,  $BiMe_3$ , is a clear, mobile, strongly refractive liquid, having a very disagreeable, irritating odour, sp. gr. = 2.30 at  $18^\circ$ . It fumes in air but does not inflame. It boils at  $110^\circ$ , dissolves readily in ether, alcohol, glacial acetic acid, and light petroleum; it is insoluble in water. When heated in air it explodes violently. It distils readily with steam, but decomposes when long in contact with water. Strong hydrochloric acid decomposes it with formation of bismuth chloride and methane.

*Dimethylbismuthine chloride*,  $BiMe_2Cl$ , separates in flakes when chlorine is passed through a solution of trimethylbismuthine in light petroleum, kept cold by means of ice and salt, and is purified by washing with a mixture of alcohol and much ether. It melts at  $116^\circ$  and dissolves readily in alcohol; it is insoluble in ether.

*Dimethylbismuthine bromide*,  $BiMe_2Br$ , forms a white powder, readily soluble in alcohol, insoluble in ether. It inflames when warmed.

*Methylbismuthine dichloride*,  $BiMeCl_2$ , is obtained by the action of trimethylbismuthine on bismuth chloride dissolved in glacial acetic acid. It separates in yellowish-white plates, melts at  $242^\circ$ , and dissolves sparingly in alcohol and glacial acetic acid, and is insoluble in ether.

*Methylbismuthine dibromide*,  $BiMeBr_2$ , forms a yellow powder melting at  $214^\circ$ ; it is insoluble in ether, sparingly soluble in alcohol, benzene, &c. The *diiodide*,  $BiMeI_2$ , is prepared by heating methyl

iodide and trimethylbismuthine at  $200^{\circ}$ , and forms lustrous, brick-red crystals, rather readily soluble in alcohol. It becomes black when exposed to light, and melts at  $225^{\circ}$  with decomposition.

*Diethylbismuthine bromide*,  $\text{BiEt}_2\text{Br}$ , is a powder; it inflames in air. The chloride,  $\text{BiEtCl}_2$  (Dünhaupt, *Annalen*, **92**, 371), and the bromide,  $\text{BiEtBr}_2$ , were prepared in like manner to the methyl-compounds. The iodide,  $\text{BiEtI}_2$ , forms lustrous, bright-red crystals.

*Methylbismuthine oxide*,  $\text{BiMeO}$ , is obtained by treating with ammonia the zinc-bromide of bismuth methyl bromide dissolved in alcohol. It inflames when warmed, dissolves readily in aqueous soda, and is insoluble in water.

*Dimethylbismuthine hydroxide*,  $\text{BiMe}_2\cdot\text{OH}$ , is formed when bismuth methyl bromide is treated with water. It is inflammable. Water decomposes it slowly. When heated with methyl iodide at  $100^{\circ}$ , bismuth monomethyl iodide is formed.

N. H. M.

**Furfuran-derivatives.** By G. NUTH (*Ber.*, **20**, 1332—1338).—Hantzsch described (*Abstr.*, 1886, 707) the formation of complex furfuran-derivatives by the action of sodium phenoxides on ethyl chloroacetoacetate, and of sulphuric acid on the resulting compound. The author has employed substituted phenols in analogous reactions.

*Ethyl paranitromethylcumarilate*,  $\text{NO}_2\cdot\text{C}_6\text{H}_3\langle\text{O}\text{---}\text{CMe}\rangle\text{C}\cdot\text{COOEt}$ , formed from paranitrophenol and ethyl chloroacetoacetate, crystallises in white needles, is soluble in ether and the usual solvents, and melts at  $74^{\circ}$ . The free acid forms yellow needles, moderately soluble in boiling water, ether, and alcohol; it melts at  $178^{\circ}$ . Its salts are sparingly soluble; the lead, mercury, cobalt, copper, and silver salts were prepared. The above reaction only took place when the constituents were heated together in an anhydrous condition. Metanitrophenol appears to act in a similar way, but the yield was very small. The ortho-compound gave very unsatisfactory results. Methyl salicylate yielded no furfuran-derivative.

Quinol yielded *ethyl parabenzodimethyldifurfurandicarboxylate*,  $\text{C}_6\text{H}_2\langle\text{O}\text{---}\text{CMe}\rangle\text{C}\cdot\text{COOEt}_2$ . This substance crystallises in greenish, glistening scales, very sparingly soluble in the usual solvents, insoluble in cold alkalis; it melts at  $150^{\circ}$ . The free acid forms a yellowish-green, amorphous mass containing 1 mol.  $\text{H}_2\text{O}$ , which it loses at  $110^{\circ}$ . The alkaline salts are soluble, the remainder insoluble. When distilled with lime, the potash salt yields *parabenzodimethyldifurfuran*,  $\text{C}_6\text{H}_2\langle\text{O}\text{---}\text{CMe}\rangle\text{CH}_2$ . This crystallises in large, glistening tables, having a bluish fluorescence. It is soluble in alcohol, ether, &c., and melts at  $108^{\circ}$ .

Quinol yields only the above difurfuran-derivative. When the monosodium-compound of quinol is used instead of the di-compound the result is a diminished yield, but no monofurfuran-derivative is formed.

Catechol likewise yields only *ethyl orthobenzodimethyldifurfurandicarboxylate*. This crystallises in short, white prisms and melts at

155°. The free *acid* resembles that of the para-compound, but contains no combined water.

The para-compounds when warmed with strong sulphuric acid give the intense blue coloration characteristic of most furfuran-derivatives, but the ortho-compounds give a green coloration which, on stronger heating, changes to steel-blue.

The difurfuran obtained by Hantzsch from resorcinol (this vol., p. 262) melts at 27° and not at 17° as originally given. L. T. T.

**Normal Propylthiophen-derivatives: Glyoxylic Acids of the Thiophen Series.** By H. RUFFI (*Ber.*, 20, 1740—1750).—It was thought that it might be possible to oxidise propylthiophen into an acid of the formula  $C_4SH_3 \cdot CO \cdot CO \cdot COOH$ , but notwithstanding many variations in the method of working,  $\alpha$ -thiophenic acid was always obtained.

*Bromopropylthiophen*,  $C_4SH_2BrPr^a$ , prepared by shaking propylthiophen with bromine-water (equimolecular proportions), is a colourless oil of aromatic odour and boils at 189°. The *dibromo*-compound,  $C_4SHBr_2Pr^a$ , is prepared in a similar manner; it is a clear yellow oil of agreeable odour and boils at 248°. A tribromo-derivative seemed also to be formed in small quantity at the same time, but attempts to prepare it by treating dibromopropylthiophen with pure bromine led to the formation of tetrabromothiophen. *Iodopropylthiophen*,  $C_4SH_2IPr^a$ , was also prepared; it is a yellow oil of agreeable odour which volatilises with steam, but cannot be distilled alone. *Dinitropropylthiophen*,  $C_4SH(NO_2)_2Pr^a$ , is prepared by drawing the vapours of propylthiophen through fuming nitric acid; it is a yellow oil and can be distilled with steam.

*Propylthiophenic acid*,  $C_4SH_2Pr^a \cdot COOH$ , is obtained as its ethyl salt by heating a mixture of iodopropylthiophen (20 grams), ethyl chlorocarbonate (10 grams), and 1 per cent. sodium amalgam (500 grams), and distilling the product with steam, when the ethyl salt passes over as an oil. The free acid crystallises in slender needles or lamellæ and melts at 57° (uncorr.).

*Acetopropylthiënone*,  $C_4H_2SPr^a \cdot COMe$ , is prepared by heating propylthiophen dissolved in light petroleum with acetic chloride and aluminium chloride. It is a yellow oil of fruity odour and boils at 255° (uncorr.). The *phenylhydrazide* is crystalline and melts at 60°. The *oxime*,  $C_4SH_2Pr^a \cdot CMe : NOH$ , crystallises in slender needles and melts at 55°.

*Propylthiënylglyoxylic acid*,  $C_4SH_2Pr^a \cdot CO \cdot COOH$ , is obtained by oxidising acetopropylthiënone with an alkaline solution of potassium permanganate at the ordinary temperature, as an oil which gradually crystallises.

$\alpha$ -*Methylthiënylglyoxylic acid*,  $C_4SH_2Me \cdot CO \cdot COOH$  [= 2 : 5], is prepared by acetylisng  $\alpha$ -thiotolen (obtained from levulinic acid) and oxidising the ketone so obtained. It melts at 80°. The calcium and barium salts were prepared.

$\alpha$ -*Methylthiënylglyoxylic acid*, [= 3 : 5 ?], is prepared in like manner from  $\beta$ -thiotolen (from pyrotartaric acid). It crystallises in long needles, melts at 142° and sublimes, even at the ordinary tempera-

ture. When heated with hydroxylamine and aqueous potash it yields a nitroso-acid,  $C_4SH_2Me \cdot C(NO_2) \cdot COOH$ , which crystallises in colourless needles and melts at  $104^\circ$ . The phenylhydrazide melts at  $141^\circ$ . The acid does not react with bromine.

$\alpha$ - $\alpha$ -Dimethylthiënylglyoxylic acid,  $C_4SHMe_2 \cdot CO \cdot COOH$  [= 2 : 5 : 3], is formed, together with an acid melting at  $106^\circ$ , by oxidising acetothioxylen (Messenger, Abstr., 1885, 1205). It is obtained as an oil which gradually solidifies.

From these results it follows that the acetylated thiophens when oxidised first yield glyoxylic acid, and this, whether or no the carbon-atom to which the acetyl-group is attached is in direct union with the sulphur-atom.

A. J. G.

**Bye-products of the Manufacture of Thiophen.** By V. MEYER and K. NEURE (*Ber.*, 20, 1756).—The material worked on was an oil boiling above  $220^\circ$  obtained in the manufacture of thiophen by distilling succinic acid with phosphorous sulphide. When exposed to cold, the greater part crystallised; the crystals proved to be thio-succinic anhydride. Small quantities of succinic anhydride were also obtained. The liquid portion when distilled with steam, gave a distillate heavier than water, most of which was soluble in alkalis. The insoluble portion was too small for proper investigation; it probably contained the still unknown thiënnyl sulphide. The substance soluble in alkali proved to be thiënnyl mercaptan, and as a considerable amount was obtained further investigation of its derivatives was made.

The *acetate*,  $C_4SH_3 \cdot SAc$ , is a colourless oil boiling at  $230$ — $232^\circ$ . *Thiënnyl disulphide*,  $S_2(C_4SH_3)_2$ , obtained by the spontaneous evaporation in contact with air of a solution of the mercaptan in concentrated alcoholic ammonia, crystallises in yellow, lustrous needles and melts at  $55$ — $56^\circ$ . The *silver salt*,  $C_4SH_3 \cdot SAg$ , is obtained as a yellow precipitate on adding silver nitrate to a neutralised solution of the mercaptan. *Methyl thiënnyl thioether*,  $C_4SH_3 \cdot SMe$ , is obtained by the action of sodium hydroxide and methyl iodide on the mercaptan; it is a colourless oil and boils at  $186^\circ$ .

If thiënnyl mercaptan is mixed with powdered diazobenzenesulphonic acid and a little water added, the liquid boils with vigorous evolution of gas, and an oil soluble in ether is formed. This reaction, which differs very essentially from that of phenyl mercaptan, could not be further studied for want of material.

A. J. G.

**Formation of Croconic Acid from Benzene-derivatives.** By R. NIETZKI (*Ber.*, 20, 1617—1620).—When aqueous potash or soda is added to a solution of an alkaline salt of rhodizonic acid, the intense reddish-yellow colour changes to a pale-yellow and is not restored on neutralisation with an acid, whilst the resulting solution on acidification with acetic acid and treatment with barium chloride remains clear, and only begins to deposit the yellow barium croconate after remaining for one day. The intermediate compound thus evidently formed during the conversion of rhodizonic into croconic acid is obtained as a flocculent, orange-yellow barium salt on addition of ammonia to the acetic acid solution after treatment with barium

chloride, and the yield is equally good whether the operation is conducted in air or hydrogen. The new barium salt is identical with the barium salt of croconic acid hydride (Abstr., 1886, 449), but on analysis gives figures which agree better with the formula  $C_5H_2O_5Ba + 2H_2O$  than that previously assigned to the compound. Croconic acid hydride,  $C_5H_4O_5$ , most probably has the formula

and adopting the suggestion thrown out by Zincke (*Ber.*, **20**, 1267, footnote), the author considers that rhodizonic acid first yields a labile hydroxy-acid,  $\begin{array}{c} <CO \cdot C(OH) > \\ <CO \cdot C(OH) > \end{array} C(OH) \cdot COOH$ , which at once breaks up into carbonic anhydride and croconic acid hydride.

W. P. W.

**The Halogen Carriers in the Natural Groups of the Elements.** By C. WILLGERODT (*J. pr. Chem.* [2], **35**, 391—400).—Benzene was treated with chlorine in the dark and in presence of the various substances examined, the alteration in weight noticed, and the product then subjected to fractional distillation. Yttrium and yttrium chloride are without action, lanthanum has a slight action; titanium none, germanium and germanium chloride none; zirconium is very active, and is thus the first active element in the carbon-group; cerium and cerium chloride are inactive, thorium and thorium chloride are almost inactive. Vanadium oxychloride,  $VOCl_2$ , acts slightly; niobium and niobium chloride are active, didymium chloride is inactive, but tantalum and tantalum chloride are active. Of the elements of the oxygen-group, molybdenum and tellurium have already been shown to be very active; chromic chloride is inactive, and it therefore appears unlikely that sulphur is a chlorine carrier as has been stated previously by the author, and he now shows that the monochloride is quite inactive; uranium and uranium tetrachloride are active, the latter especially so. In the fluorine-group the only known chlorine carrier is iodine.

H. B.

**The Halogen-benzene Haloids:  $\alpha$ -Trichlorobenzenehexachloride.** By C. WILLGERODT (*J. pr. Chem.* [2], **35**, 415—416).—Reference is made to previous work and to further experiments on paradichlorobenzenehexachloride.  $\alpha$ -Trichlorobenzenehexachloride,  $C_6H_3Cl_3 \cdot Cl_6$  [ $Cl_3 = 1:2:4$ ], is crystalline, melts at  $95-96^\circ$ , and when heated with alcoholic potash yields pure hexachlorobenzene. H. B.

**Action of Acetylene on Benzene in presence of Aluminium Chloride.** By R. VARET and G. VIENNE (*Compt. rend.*, **104**, 1375—1377).—A mixture of benzene (200 grams) and aluminium chloride (50 grams) was treated with a current of acetylene for five hours per day during six days. At the beginning of each treatment, the liquid was gently heated, but afterwards the heat developed by the reaction itself was sufficient. The product was washed with water and alkalis, and then fractionated. It consisted of 80 parts of cinnamene, boiling at  $143-145^\circ$ , 15 parts of diphenylethane boiling at  $265-270^\circ$ , and 5 parts of dibenzyl boiling at  $280-286^\circ$ .

No naphthalene hydride,  $C_{10}H_{10}$ , nor hydrocarbon,  $C_{12}H_{12}$ , was formed.  
C. H. B.

**Influence of Light on the Action of Halogens on Aromatic Compounds.** By J. SCHRAMM (*Monatsh. Chem.*, 8, 101—106).—Chlorine acts quickly on ethylbenzene in sunlight, with rise of temperature and formation of chlorethylbenzene; if sunlight is cut off by clouds or if the chlorine is passed in too quickly, substitution takes place in the benzene nucleus. The constitution of the product was determined by the method employed by Radziszewski for determining the constitution of  $\alpha$ -bromethylbenzene. No other product is formed.

The action of chlorine on boiling ethylbenzene is much slower than in sunlight. The product contains the same chlorethylbenzene as that formed when the reaction takes place in sunlight (compare Abstr., 1886, 451).  
N. H. M.

**Phenol.** By E. MYLIUS (*Arch. Pharm.* [3], 25, 308).—Various reasons have been assigned for the red colour of phenol; the author attributes it to the action of the alkali obtained from the glass containing vessel. He has previously pointed out the great difference in the solubility of various glasses, and the resulting precipitates induced in morphine and antimony solutions, &c. This is quite sufficient to account for the coloration (that is, the oxidation of phenol). Of course this is not sufficient to account for the colour where the phenol is red under all circumstances, but only when one and the same sample becomes red in one flask and not in another.

J. T.

**Action of Sulphur Dichloride on Phenol.** By G. TASSINARI (*Gazzetta*, 17, 83—87 and 90—94).—A violent reaction takes place on mixing sulphur dichloride and phenol; if this be moderated by lowering the temperature, a yellow solid gradually separates, which can be purified by solution in alkali and reprecipitation by carbonic anhydride. The compound, *hydroxyphenyl sulphide*,  $S(C_6H_4\cdot OH)_2$ , crystallises in leaflets, melting at  $150^\circ$ , sparingly soluble in cold, more readily in hot water. The reaction leading to its formation is as follows:— $2C_6H_5\cdot OH + SCl_2 = S(C_6H_4\cdot OH)_2 + 2HCl$ ; it is, however, probable that the phenolic hydrogen is at first displaced by the sulphur, and subsequently by an intramolecular change; the sulphur-atom displaces hydrogen in the phenyl-group. The metallic derivatives are unstable, but the acetyl-derivative,  $(C_6H_4\cdot OAc)_2S$ , is a sparingly soluble, crystalline substance, melting at  $92$ — $94^\circ$ , partially decomposed on boiling with water, readily by alkalis.

In like manner parabromophenol yields a corresponding bromo-derivative,  $S(C_6H_3Br\cdot OH)_2$ , melting at  $175$ — $176^\circ$ , converted by hydrogenation with zinc-dust into a hydroxyphenyl sulphide, crystallising in micaceous scales, isomeric with the compound above described. It melts at  $128$ — $129^\circ$ , is very soluble in caustic potash, and gives a blue coloration with ferric chloride.

The homologues of phenol yield similar derivatives; in the paper are described *paramethylhydroxyphenyl sulphide*, melting at  $117$ —

118°, the corresponding ortho-derivative, melting at 123—124°, *paramethylpropylhydroxyphenyl sulphide*, melting at 152—153°, and *hydroxynaphthoyl sulphide*, melting at 214—215°, probably identical with a compound obtained by Merz and Weith directly from  $\beta$ -naphthol. V. H. V.

**Derivatives of Orthobenzoquinone.** By T. ZINCKE (*Ber.*, 20, 1776—1777).—Notwithstanding numerous attempts, orthobenzoquinone has never been prepared; the author, however, has now succeeded in obtaining its tetrabromo- and tetrachloro-derivatives by oxidising the corresponding catechol compounds.

*Tetrabromorthoquinone*,  $C_6Br_4O_2$ , is best obtained by dissolving tetrabromocatechol in hot glacial acetic acid, allowing to cool somewhat, and adding excess of nitric acid (sp. gr. 1.4) previously diluted with glacial acetic acid. The liquid turns deep red; it is allowed to remain for a few minutes, and the quinone then precipitated by the careful addition of water. The oxidation may also be effected with chlorine or bromine, but the result is far less certain than with nitric acid; finally the substance can be obtained directly from catechol by adding bromine to a hot solution of catechol in glacial acetic acid. It crystallises in thick, dark garnet-red prisms and tables, or, by quick cooling, in dark red, transparent plates of metallic lustre, melts at 150—151°, and is readily soluble in ether, alcohol, benzene, and glacial acetic acid, sparingly soluble in light petroleum. It is characterised by its oxidising powers; thus it oxidises quinol to quinone or quinhydrone, and dimethylaniline and methyldiphenylamine to blue colouring matters, being at the same time itself reduced to tetrabromocatechol. With aniline it yields a compound crystallising in bluish-black plates or thick needles, and melting at 172—173°; this compound would seem, however, to contain several aniline residues, and may, therefore, probably be a derivative of ordinary quinone.

The substance described by Stenhouse as erythrobromocatechol is considered by the author to be impure tetrabromorthoquinone.

A quinhydrone-like substance is obtained by mixing equal parts of tetrabromorthoquinone and tetrabromocatechol dissolved in ether or benzene, and separates on evaporation in black, lustrous needles, which melt with change of colour at about 110°.

*Tetrachlororthoquinone*,  $C_6Cl_4O_2$ , is prepared by the action of nitric acid on tetrachlorocatechol or directly by the action of chlorine on catechol. It is more difficult to prepare than the bromo-compound, which it resembles in appearance and reactions; it is, however, more soluble in glacial acetic acid, and melts at 131—132°.

*Tetrachlorocatechol* is obtained by passing chlorine into a hot concentrated solution of catechol in glacial acetic acid; it crystallises in colourless needles or thick plates, and melts at 174°. Tetrabromocatechol melts at 192—193°, not 187° as stated by Stenhouse.

A. J. G.

**Dinitroso-orcinol and Dinitrosoresorcinol.** By H. GOLDSCHMIDT and J. STRAUSS (*Ber.*, 20, 1607—1611).—The behaviour of dinitroso-orcinol towards hydroxylamine should afford evidence as to whether it is a nitroso- or an isonitroso-derivative, since it is to be

supposed that in the latter case it would readily exchange the two atoms of oxygen present in the ketonic condition for two isonitroso-groups. 2 grams of the compound were heated at  $100^{\circ}$  with 15 grams of alcohol and 2 grams of solid hydroxylamine hydrochloride; after some time complete solution took place, and on further heating *toluidiquinoyltetroxime*,  $C_6HMe(NO)_4$ , separated as a yellow compound, indistinguishable in appearance from dinitroso-orcinol, and very sparingly soluble in all ordinary solvents. When this is heated with acetic anhydride, and the resulting solution poured into aqueous soda, the *anhydride*,  $O\langle\overset{N}{\parallel}\rangle C_6HMe\langle\overset{N}{\parallel}\rangle O$ , is obtained as an oil which crystallises from benzene in flat, white needles melting at  $47^{\circ}$ . Toluidiquinoyltetroxime, dissolved in aqueous potash, and treated with a hot solution of potassium ferricyanide, yields the oxidation-product,  $\langle\overset{NO}{\parallel}\rangle C_6HMe\langle\overset{NO}{\parallel}\rangle$  (comp. Koreff, Abstr., 1886, 363; Ilinski, *ibid.*, 472); this crystallises from benzene in pale yellow, thin, transparent needles, melts at  $103^{\circ}$ , and when moist becomes coloured red on exposure to the air.

Dinitrosoresorcinol, when similarly treated with hydroxylamine hydrochloride, yielded a compound richer in nitrogen; it could not, however, be obtained pure, but when heated with acetic anhydride was converted into the *anhydride* of diquinoyltetroxime,  $C_6H_2N_4O_2$ . This crystallises in white needles, melts at  $61^{\circ}$ , and is soluble in benzene and ether.

Dinitrosoresorcinol may therefore be regarded as diquinoyldioxime,  $C_6H_2O_2(NO)_2$  [ $NOH : O = 1 : 2$  and  $5 : 4$ ], and dinitrosoresorcinol as toluidiquinoyldioxime,  $C_6HMeO_2(NO)_2$  [ $NOH : O : Me = 1 : 2 : 3 : 4 : 5$ ].  
W. P. W.

**Action of Acetaldehyde on Polyvalent Phenols.** By H. CAUSSE (*J. Pharm.* [5], 15, 554—556).—The publication of a memoir by Claus and Trainer on the action of acetaldehyde on some monatomic phenols has led the author to publish a *résumé* of his researches on the aromatic acetals. In the action of acetaldehyde on some polyvalent phenols, the products obtained differ completely according to the method of preparation. Taking pyrogallol for example, 10 parts dissolved in 100 parts of water was mixed with 2 grams of sulphuric acid and heated at  $60^{\circ}$ , dilute aldehyde was then dropped in. The liquid became brown but nothing definite separated out. On removing from the water-bath, the temperature dropped, the liquid became troubled, the temperature rose, and the vessel became filled with a brown spongy mass. In this same liquid, maintained at  $60^{\circ}$ , if sulphuric acid is added in 5 c.c. portions up to one-tenth, and better, a solution made up of sulphuric acid 1 part, sodium sulphate 1 part, water 9 parts, the reaction is quite different, instead of a resinous body, beautiful crystals are obtained. These facts apply to catechol as well as to resorcinol, and the products obtained are clearly crystalline. The nature of the product depends moreover on the temperature. To 10 parts of hydrogen potassium sulphate dissolved in 100 parts of water is added 10 grams of resorcinol and 15 c.c. of pure aldehyde of

one-fifth. The flask is stoppered and heated at  $20^{\circ}$ . Crystals soon form and rapidly increase in volume. The liquid filtered from the colourless crystals and heated at  $60^{\circ}$  gives large, yellow crystals. The colourless crystals have a composition approaching to acetal sesquihydrate. The slight deviation in composition is due to the facility with which the hydrate parts with water of crystallisation. Exposed to the air it gradually becomes yellow; the same transformation is more readily effected by the action of anhydrous solvents. Thus anhydrous ether dissolves the colourless crystals, and deposits voluminous, anhydrous, yellow crystals which the author has described as resorcinol-acetal. The latter can exist in two forms—the one hydrated and colourless, the other yellow and anhydrous. J. T.

**Formation of Haloid Substitution-derivatives of Amido-compounds by the Reduction of Nitro-derivatives of Hydrocarbons.** By E. KOCK (*Ber.*, 20, 1567—1569).—Some time ago the author observed that the reduction of metanitrotoluene with zinc-dust and hydrochloric acid results not only in the formation of metatoluidine but also of a solid compound which on examination is found to be identical with the chlorotoluidine (m. p. =  $83^{\circ}$ ) described by Goldschmidt and Hönig (this vol., p. 363). An examination of the action of various reducing agents on other nitro-derivatives, under conditions as similar as possible with respect to temperature and concentration of the acid, has led to the results summarised in the table (p. 811).

The yield of the chlorinated amine is considerable; for example, from 70 grams of nitrobenzene, 29 grams of aniline and 17.5 grams of pure parachloraniline were obtained. The temperature during the reduction is found to exercise an essential influence on the yield of the chlorinated derivative.

The following derivatives of the chlorotoluidine (m. p. =  $83^{\circ}$ ) are described:—The *sulphate*,  $(C_6H_3MeCl \cdot NH_2)_2 \cdot H_2SO_4$ , sparingly soluble in water; *diorthochlorometatolylcarbamide*,  $CO(NH \cdot C_6H_3MeCl)_2$ , crystallising in small scales melting at  $271^{\circ}$ ; and the *thiocarbamide*,  $CS(NH \cdot C_6H_3MeCl)_2$ , crystallising in small, silky needles melting at  $177^{\circ}$ .

W. P. W.

**Metanitroparachloraniline.** By A. CLAUS and A. STIEBEL (*Ber.*, 20, 1379—1382).—When orthoparadinitrochlorobenzene is dissolved in alcohol, concentrated hydrochloric acid added, and then just sufficient stannous chloride to reduce one nitro-group, the principal product is metanitro-ortho-chloraniline, which separates on the addition of water. If the mother-liquor is neutralised with ammonia a small quantity of *metanitroparachloraniline* is precipitated. This compound is also formed by nitrating parachloraniline dissolved in a large excess of strong sulphuric acid. It is soluble in alcohol, ether, chloroform, and boiling water; crystallises in long needles, and melts at  $102.5$ — $103^{\circ}$  (uncorr.). It is more basic than the above orthochloro-derivatives, but its salts are decomposed by water. The *platinochloride* forms red crystals which decompose at  $270^{\circ}$ . The *acetyl-derivative* forms yellow needles melting at  $99$ — $100^{\circ}$ . The con-

W. C. W.

**Dibenzylaniline and its Derivatives.** By C. MATZUDAIRA (*Ber.*, 20, 1611—1617).—*Dibenzylaniline*,  $\text{PhN}(\text{C}_7\text{H}_7)_2$ , is prepared by heating a mixture of benzyl chloride (15 parts), aniline (5·4 parts), and sodium hydroxide (3 parts) at 100° for about three weeks until a sample ceases to give the green colour of nitrosodibenzylamine when treated with hydrochloric acid and sodium nitrite. It crystallises in colourless needles, melts at 67°, and is readily soluble in ether and benzene, sparingly soluble in cold alcohol and acetic acid, and insoluble in water. It is a feeble base, and its salts are decomposed by water; the *hydrochloride*,  $\text{NPh}(\text{C}_7\text{H}_7)_2\text{HCl} + \text{H}_2\text{O}$ , forms lustrous, prismatic crystals; the *platinochloride*,  $[\text{NPh}(\text{C}_7\text{H}_7)_2]_2\text{H}_2\text{PtCl}_6$ , crystallises in thin, orange-yellow scales, and the *picrate* crystallises in long, yellow needles, melting at 131—132° with decomposition. *Nitrodibenzylaniline*,  $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{N}(\text{C}_7\text{H}_7)_2$  [ $\text{NO}_2 : \text{N} = 1 : 4$ ], is formed when dibenzylaniline in acetic acid solution is nitrated in the cold with the theoretical quantity of fuming nitric acid. It crystallises in yellow needles, melts at 130°, and is soluble in ether and benzene, sparingly soluble in hot alcohol. Nitrodibenzylaniline is destitute of basic properties, and is unaltered when boiled with hydrochloric acid or aqueous soda. On reduction with tin and hydrochloric acid it yields *amidodibenzylaniline*, which crystallises in colourless, lustrous needles, melts at 89—90°, and is soluble in ether and hot alcohol. The base becomes coloured brown on exposure to air, and yields with feeble oxidising agents, such as ferric chloride, an intense red colour, which gradually changes, particularly on heating, to a dark yellow; but if sulphuric acid is present, ferric chloride forms with the base a blue precipitate insoluble in water. When heated with hydrochloric acid it decomposes into benzyl chloride and 1 : 4 diamidobenzene. Amidodibenzylaniline combines with benzaldehyde in the cold, forming a molecular compound,  $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{N}(\text{C}_7\text{H}_7)_2\text{CHPhO}$ ; this is a yellow microcrystalline substance melting at 130°, and is decomposed by dilute acids into its constituents. *Nitrosodibenzylaniline*,  $\text{NO}\cdot\text{C}_6\text{H}_4\cdot\text{N}(\text{C}_7\text{H}_7)_2$  [ $\text{NO} : \text{N} = 1 : 4$ ], is obtained when a well-cooled mixture of dibenzylaniline, hydrochloric acid and alcohol is treated with amyl nitrite. It crystallises in thin plates which appear steel-blue by reflected and green by

transmitted light, melts at 91—92°, is soluble in alcohol, ether, and carbon bisulphide, and on reduction with tin and hydrochloric acid yields the above amidodibenzylaniline.  
W. P. W.

**Benzyl-derivatives of Hydroxylamine.** By F. WALDER (*Ber.*, 20, 1751—1755; compare *Abstr.*, 1886, 796; this vol., p. 246).—The base,  $N_2(C_7H_7)_4O$ , previously described, when heated with hydrochloric acid for some hours at 220°, yields much benzaldehyde together with resinous substances and a little benzylamine.

*Dibenzylethylamine*,  $NEt(C_7H_7)_2$ , is obtained by the action of ethyl iodide and sodium ethoxide on dibenzylhydroxylamine. It is a pale-yellow liquid, boils about 300°, is readily soluble in alcohol, ether, and acids, and shows strongly marked basic characters. The platinochloride forms thin plates. In this reaction a crystalline base,  $C_{13}H_{21}N$ , of unknown constitution is also formed. It forms slender, interlaced needles, melts at 83—84°, and explodes when quickly heated. From these results it follows that the reaction with ethyl iodide is quite different to that with methyl iodide.

By the action of propyl iodide and sodium propoxide on dibenzylhydroxylamine, propyl ether, benzylamine and benzyl benzoate are formed. With ethyl iodide and sodium ethoxide it yields ethyl cetyl ether, benzyl ether, and benzylamine.

*Dibenzylhydroxylamine mercurochloride*,  $N(C_7H_7)_2 \cdot OH, HgCl_3$ , forms white, crystalline plates; the *picrate* crystallises in lustrous, yellow plates, and melts at 151° (corr.).

Dibenzylhydroxylamine gives, after a time, a sulphur-yellow coloration with a colourless solution of ferric chloride (compare Landwehr, this vol., p. 124).  
A. J. G.

**Intermediate Products in the Formation of Indole from Dichlorether and Aromatic Amines.** By J. BERLINERBLAU and H. POLIKIEV (*Monatsh. Chem.*, 8, 187—191).—*Monochlorethylideneanilide*,  $CH_2Cl \cdot CH : NPh$ , is prepared by dissolving dichlorether in an equal volume of water, adding water, and boiling for 15 to 30 minutes. As soon as it is cold an aqueous solution of aniline is added. After some hours, the product is washed with a little water containing hydrochloric acid, and then with water alone until free from chlorine. It is an amorphous substance, insoluble in water, readily soluble in alcohol, less in ether; it melts at 86—87°. When dried until of constant weight it forms a reddish-brown powder melting at 135—136°. When treated with potassium nitrite and dilute hydrochloric acid in the cold, a yellowish-brown, amorphous compound is obtained which gives a green and then a greenish-blue solution when treated with phenol and sulphuric acid. The colour changes to red when the solution is diluted with water, but returns to green on addition of alkali.

*Anilidoethylideneanilide*,  $NPh : CH \cdot CH_2 \cdot NPh$ , is obtained by heating monochlorethylideneanilide (4 grams) with aniline (5 grams) in a small flask on a sand-bath. It dissolves rather readily in alcohol and ether, and melts at 103—105°.

*Monochlorethylideneparatoluide*,  $CH_2Cl \cdot CH : N \cdot C_6H_4Me$ , is prepared

by dissolving 22 grams of dichlorether in 20 c.c. of water, adding 180 c.c. of water, and boiling for 20 to 30 minutes. 33 grams of paratoluidine dissolved in a little alcohol and suspended in 1 litre of water is added. As soon as the whole becomes turbid it is filtered as quickly as possible and left for four to five hours. It resembles monochlorethyleneanilide, and melts at  $58^{\circ}$ . N. H. M.

**Action of Chloracetic Chloride on Orthamidophenol.** By O. ASCHAN (*Ber.*, **20**, 1523—1524).—*Chloracetamidophenol*,  $\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{NH}\cdot\text{CO}\cdot\text{CH}_2\text{Cl}$ , is obtained by the action of chloracetic chloride on orthamidophenol dissolved in benzene. It crystallises in large plates of a silvery lustre, and melts at  $136^{\circ}$ . It dissolves readily in aqueous alkali; when the solution is boiled a compound melting at  $169^{\circ}$  is obtained probably of the formula  $\text{C}_6\text{H}_4\langle\begin{smallmatrix} \text{NH}\cdot\text{CO} \\ \text{O}\cdot\text{CH}_2 \end{smallmatrix}\rangle$ . When chloracetamidophenol is heated at  $170^{\circ}$  it is converted with effervescence into an oil. This contains chlorine, and has a powerful odour.

By fusing anhydrous oxalic acid with orthamidophenol at  $140$ — $150^{\circ}$  a compound melting at  $272^{\circ}$  is formed. N. H. M.

**Action of Cinnamic Acid on Diphenylamine in Presence of Zinc Chloride.** By A. BERNTHSEN (*Ber.*, **20**, 1552—1554).—When a mixture of cinnamic acid (100 grams), diphenylamine (100 grams), and zinc chloride (250 grams), is heated for  $1\frac{1}{2}$  to 2 days at  $240$ — $250^{\circ}$ , phenylacridine and a compound melting at  $127$ — $128^{\circ}$  are obtained.

*Cinnamyl diphenylamine*,  $\text{CHPh}:\text{CH}\cdot\text{CO}\cdot\text{NPh}_2$ , is prepared by heating diphenylamine (2 mols.) with crude cinnamyl chloride. It crystallises from alcohol in yellowish needles melting at  $152$ — $153^{\circ}$ .

N. H. M.

**Action of Cœnanthaldehyde and Heptyl Chloride on Dimethylaniline in the Presence of Zinc Chloride.** By V. AUGER (*Bull. Soc. Chim.*, **47**, 42—51).—A base of the constitution  $\text{C}_6\text{H}_{13}\cdot\text{CH}(\text{C}_6\text{H}_4\cdot\text{NMe}_2)_2$  is formed by treating dimethylaniline and zinc chloride with cœnanthaldehyde. It crystallises from alcohol in long needles, is but slightly soluble in cold alcohol, insoluble in water, melts at  $59.5^{\circ}$ , and boils at  $275^{\circ}$  under 15 mm. pressure. The platinochloride is but sparingly soluble in water and insoluble in alcohol and ether. Attempts to obtain a carbinol from the base by oxidation were unsuccessful, as it was invariably decomposed, cœnanthaldehyde and cœnanthylic acid being formed.

On treating a mixture of equal parts of dimethylaniline and zinc chloride with chloroheptane, two compounds are formed: the first is a leuco-base having the composition  $\text{C}_{23}\text{H}_{32}\text{N}_2$ , it melts at  $72.5^{\circ}$  and boils without decomposition at  $278^{\circ}$  under 15 mm. pressure; the platinochloride cannot be prepared in aqueous solutions, as platinum chloride acts as an oxidising agent, and a blue precipitate of the platinochloride of the oxidised base is formed; prepared from an alcoholic solution, however, it forms pale-yellow, sparingly soluble crystals. On heating the base with methyl iodide in a sealed tube at  $100^{\circ}$ , the salt  $\text{C}_{23}\text{H}_{32}\text{N}_2\cdot 2\text{MeI}$  is obtained; it forms long, silky needles,

has a very bitter taste, and is decomposed by heat into the base and methyl iodide. On oxidising the leuco-base with ferric chloride, a blue hydrochloride of the base  $C_{23}H_{30}N_2$ , is formed; it crystallises in microscopic tables which have a bronze lustre, and is readily soluble in water, forming an indigo-blue coloured solution, but cannot be crystallised from this solvent as it spontaneously decomposes after a short time; the *iodide*,  $C_{23}H_{30}N_2 \cdot HI$ , however, which may be precipitated by the addition of potassium iodide to the aqueous solution of the chloride, is more stable, and may be crystallised from hot dilute alcohol, forming small prisms having a green lustre.

On reducing the base,  $C_{23}H_{30}N_2$ , with zinc in an acid solution, the leuco-base is again formed. The dehydrated base seems to form colourless acid salts, as on adding excess of acid to the blue solutions of the normal salts, the colour disappears but returns again on dilution or neutralisation. The blue solutions dye cotton and silk a brilliant blue, which is not, however, permanent. On adding even dilute solutions of potash or soda to the blue solutions, they become colourless, a red powder is precipitated, and a strong odour of ammoniacal bases is perceptible.

The second compound formed by the action of chloroheptane on dimethylaniline in the presence of zinc chloride is *dimethamidophenyl heptyl ketone*,  $C_6H_{13} \cdot CO \cdot C_6H_4NMe_2$ ; when crystallised from alcohol it forms long, colourless needles; it melts at  $48.5^\circ$ , and boils at  $190^\circ$  under 20 mm. pressure. The corresponding acetoxime,  $C_{15}H_{23} : NOH$ , was prepared; it crystallises in brilliant, colourless plates, and melts at  $99^\circ$ . By acting on the ketone with cold concentrated acid, the mononitro-derivative,  $C_6H_{13} \cdot CO \cdot C_6H_3(NO_2) \cdot NMe_2$ , is obtained; it crystallises in yellow, silky needles and melts at  $65^\circ$ .

As both of the above compounds have such high molecular weights, the author confirmed their formula by preparing that first described synthetically from diphenylheptane by the following process. The diphenylheptane was nitrated and dinitrophenylheptane,

obtained in the form of a heavy pale-yellow oil, and by reducing this with tin and hydrochloric acid, diamidodiphenylheptane,

was obtained; this base is a heavy oil which becomes coloured when exposed to the air; its nitrate crystallises in small and brilliant tablets. By heating the free base with excess of methyl alcohol and methyl iodide in a sealed tube at  $100^\circ$  for three hours, the tetramethyl compound is obtained and agrees in every respect with the compound obtained by the action of cœnanthaldehyde on dimethylaniline in the presence of zinc chloride.

In the course of this research the following compounds were also prepared:—

*Nitroheptylbenzene*,  $C_7H_{15} \cdot C_6H_4 \cdot NO_2$ , prepared by the nitration of heptylbenzene at the ordinary temperature; it is a heavy straw-coloured oil, boiling at  $178^\circ$  under 10 mm. pressure.

*Amidoheptylbenzene*,  $C_7H_{15} \cdot C_6H_4 \cdot NH_2$ , obtained by the reduction of the last compound, is a heavy oil boiling at  $175^\circ$  under 10 mm. pressure; its stannochloride crystallises in needles.

*Hexyl phenyl ketone*,  $C_6H_{13} \cdot CO \cdot Ph$ , obtained by the action of aluminium chloride on a mixture of chloroheptane and benzene, crystallises in large, colourless plates, has a faint aromatic odour, melts at  $17^\circ$ , and boils at about  $267^\circ$  under 740 mm. pressure; the corresponding acetoxime crystallises in slender needles and melts at  $55^\circ$ .

A. P.

**Tetramethyldiamidothiobenzophenone.** By O. BAITHER (*Ber.*, 20, 1731—1739).—This substance,  $CS(C_6H_4 \cdot NMe_2)_2$ , or possibly,

$NMe_2 \begin{array}{c} \diagup C_6H_4 \diagdown \\ \diagdown S \diagup \end{array} C \cdot C_6H_4 \cdot NMe_2$ , as its intense colour scarcely agrees with

its being a simple ketone, is prepared commercially but has not yet been described. It crystallises in fine ruby-red plates with blue lustre and melts at  $202^\circ$ . It is soluble in benzene, carbon bisulphide (1.15 in 100), acetic acid, chloroform (4.58 in 100), less in ether (0.27 in 100), and still less in alcohol (0.072 in 100), insoluble in water and light petroleum. It can be volatilised in small quantity, but the vapour-density could not be determined. Salts could not be prepared, as hydrochloric acid converts it into tetramethyldiamidobenzophenone, and platinum chloride gives a precipitate which does not contain sulphur. With hydroxylamine it yields the oxime of tetramethyldiamidobenzophenone described by Münchmeyer (*Abstr.*,

1886, 877). The *methiodide*, probably  $NMe_2 \begin{array}{c} \diagup C_6H_4 \diagdown \\ \diagdown S \diagup \end{array} C \cdot C_6H_4 \cdot NMe_3I$ ,

forms cantharidine-green plates of coppery lustre, decomposes at  $108^\circ$ , dissolves in water with deep bluish-green colour and red fluorescence, in alcohol with green colour, and is very little soluble in ether. It dyes silk green. Aqueous soda only decomposes it to a slight extent at summer temperature, giving the free base, a yellowish-white substance, soluble in ether.

No definite bromo-derivatives were obtained from the thioketone. When distilled with zinc-dust it yields dimethylaniline and tetramethyldiamidodiphenylmethane.

When treated in carbon bisulphide solution with thiocarbonyl chloride,  $CSCl_2$ , it is converted into a very unstable colouring matter, probably  $NMe_2Cl \begin{array}{c} \diagup C_6H_4 \diagdown \\ \diagdown S \diagup \end{array} C(CSCL) \cdot C_6H_4 \cdot NMe_2$ . This forms a black powder, which dissolves in water to a deep blue solution, but the colour soon disappears. If the reaction is conducted in chloroform solution and the liquid allowed to remain for some time, the colour gradually disappears, and thick, white, crystalline crusts of a decomposition product,  $CCl_2(C_6H_4 \cdot NMe_2)_2 + CHCl_3$ , separate, which is decomposed by water.

A. J. G.

**Action of Monatomic Aldehydes of the Fatty Series on Metaparatoluylenediamine.** By O. HINSBERG (*Ber.*, 20, 1585—1591).—Crystallographic examination of benzylbenzenyldiamidotoluene

(monobenzylanhydrobenzoyldiamidotoluene, Abstr., 1886, 943) establishes its identity with Ladenburg's tolubenzaldehydine (Abstr., 1878, 571).

Ethylethenyldiamidotoluene is obtained, together with small quantities of ethenyldiamidotoluene, when metaparatoluylenediamine (1 mol.), dissolved in acetic acid, is treated in the cold with acetaldehyde (2 mols.); the solution is allowed to remain for an hour, heated to remove any excess of aldehyde, precipitated with ammonia, and the base extracted with ether. After evaporation of the ether, the base is saturated with strong hydriodic acid, and from the resulting solution the hydriodide separates after some time. The base is identical with that obtained by Hübner (Abstr., 1882, 505) by ethylating ethenyldiamidotoluene.

*Isobutenyldiamidotoluene*,  $C_7H_6 < \begin{smallmatrix} N \\ NH \end{smallmatrix} > C \cdot CHMe_2$ , is the chief product obtained when a cold solution of metaparatoluylenediamine in dilute acetic acid is treated with an aqueous or alcoholic solution of isobutyl alcohol until the whole of the diamine has entered into combination; after filtration from the insoluble compound formed at the same time, the solution is precipitated with ammonia and the base purified by the repeated recrystallisation of its tartrate. It crystallises in colourless needles, melts at  $157-158^\circ$ , is readily soluble in alcohol and ether, sparingly soluble in water, and has an intensely bitter taste. Its salts generally are very soluble in water with the exception of the platinumchloride and the ferrocyanide; the *tartrate*,  $C_{11}H_{14}N_2 \cdot C_4H_6O_6 + 2H_2O$ , crystallises in white needles, melts at  $98^\circ$ , and is also sparingly soluble in water.

The insoluble compound obtained in the foregoing reaction consists of *isobutylisobutenyldiamidotoluene*,  $C_7H_6 < \begin{smallmatrix} N \\ N(C_4H_7) \end{smallmatrix} > CPr$ ; it is formed in relatively small quantity, and has not been obtained pure. Its *hydrochloride*,  $C_{15}H_{22}N_2 \cdot HCl$ , forms large, colourless crystals.

Propaldehyde and cœnanthaldehyde also yield very stable compounds with orthodiamines. The formation of these anhydro-compounds is not materially influenced by the presence or absence of solvents, and it is immaterial whether the aldehyde is added to the diamine or *vice versa*.

W. P. W.

**Diazo-compounds.** By P. GRIESS (*Ber.*, 20, 1528—1531).—*Paratriazobenzenesulphonic acid phenylhydrazine*,

is readily obtained by mixing an aqueous solution of phenylhydrazine with paradiazobenzenesulphonic acid, and leaving the whole for some hours. The mother-liquor is poured off, the crystals pressed between filter-paper and crystallised from hot water. It forms long, narrow, yellowish-white, lustrous plates, rather readily soluble in hot water and in hot alcohol, insoluble in ether and chloroform. When heated it detonates. Alkalis decompose it into phenylhydrazine and paratriazobenzenesulphonic acid.

*Paratriazobenzenesulphonic acid*,  $\llbracket \text{N} \rrbracket \text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{SO}_3\text{H}$ , is prepared from the barium salt, and forms white, deliquescent needles, very soluble in alcohol. The *barium salt*, with 2 mols.  $\text{H}_2\text{O}$ , is obtained from the phenylhydrazine-compound by boiling with barium carbonate. It crystallises in almost white, hexagonal plates.

*Triazonaphthalenesulphonic acid*,  $\text{N}_3 \cdot \text{C}_{10}\text{H}_6 \cdot \text{SO}_3\text{H}$ , is obtained from its phenylhydrazine-compound in a manner similar to triazobenzenesulphonic acid, and crystallises in white needles, very soluble in alcohol and in water. The *barium salt* forms white plates of a silvery lustre, very sparingly soluble. The *phenylhydrazine compound* resembles the corresponding triazobenzene-derivative in its chemical and physical behaviour.

N. H. M.

**Constitution of Diazoamido-compounds.** By R. MELDOLA (*Phil. Mag.* [5], 32, 513—529).—Only one diazoamido-compound of the constitution  $\text{X} \cdot \text{N}_2 \cdot \text{NH} \cdot \text{Y}$  is known, whichever radicle has been first diazotised, whilst three ethyl-derivatives are known: (1) prepared by diazotising  $\text{X} \cdot \text{NH}_2$  and combining with  $\text{Y} \cdot \text{NHEt}$ ; (2) by diazotising  $\text{Y} \cdot \text{NH}_2$  and combining with  $\text{X} \cdot \text{NHEt}$ ; and (3) by directly replacing the H in the compound  $\text{X} \cdot \text{N}_3 \cdot \text{H} \cdot \text{Y}$  by ethyl. These facts cannot be reconciled with the usual formula of Kekulé. The conditions to be fulfilled by any formula are: (1) that it should be symmetrical so as to represent the identity of the mixed diazoamido-compounds; (2) that it should be capable of representing more than two isomeric alkyl-derivatives of mixed compounds. Griess' formula,  $\text{C}_6\text{H}_4 : \text{NH} : \text{NH} : \text{NH} : \text{C}_6\text{H}_4$ , is objected to, since it represents diazoamido-benzene as a phenylene-derivative, and contains three replaceable hydrogens, whilst the dinitrodiazoamido-compounds point to only one being present, and it does not represent the easy resolution of diazoamido-compounds by acids. Victor Meyer's abandoned formula,  $\text{NH} \llbracket \text{NX} \rrbracket \text{NY}$ , fails to represent the N of the NH as being directly attached to either of the radicles. The formulæ  $\llbracket \text{N} \rrbracket \text{NHXY}$  and  $\text{N} : \text{N} : \text{NHXY}$ , due to the author, are also discarded, as they do not represent the decomposition by acids or the existence of isomeric alkyl-derivatives. Finally the formula  $\text{NH} \llbracket \text{X} \cdot \text{N} \rrbracket \text{Y} \cdot \text{N}$ , in which the phenyl of the radicles X and Y is regarded as triatomic, is considered best to represent the reactions of the mixed diazoamido-compounds, the phenyl having the constitution  $= \text{C} \begin{smallmatrix} \text{CH} : \text{CH} \\ \text{CH} : \text{CH} \end{smallmatrix} > \text{CH}$ —in accordance with Fittig's theory of the constitution of quinone. The third ethyl-derivative of the mixed diazoamido-compounds can now be considered to be formed by the replacement of the nitrogen-attached hydrogen of the above formula, whilst, owing to the symmetry of the formula, the same mixed diazoamido-compound will be formed irrespective of the order of combination. Again, by supposing the  $\text{N} : \text{N}$  to be eliminated with the radicles X and Y in turn, the production of two diazo- and two diamido-compounds by means of hydrochloric acid is explained. On

the other hand, this formula does not satisfactorily represent the normal compounds. In representing the compound obtained from diazotised paranitraniline or para-ethylnitraniline as

the ethyl-derivatives from diazotised paranitraniline and meta-ethylaniline and from diazotised metanitraniline and para-ethylaniline should have a similar constitution, but the formula being symmetrical the compounds would be identical, whereas they are undoubtedly isomeric. Although Kekulé's formula accurately represents the reactions of the normal compounds, their stability is at variance with such a chain formula, no other instance of which is known amongst nitrogen compounds, the author therefore prefers the formula  $\text{N} \llbracket \text{X} \rrbracket \text{NHX}$ , the compound splitting when decomposed, so as to leave the  $\text{N} : \text{N}$  in combination with the lower  $\text{X}$ , and thus giving only two products. The para-position is chosen for the free bonds in the radicle  $\text{C}_6\text{H}_5'''$ , in accordance with the conversion of diazoamidobenzene into amidazobenzene, in which the substituents hold the para-position.

H. K. T.

**Diazoamido-compounds.** By B. FISCHER and H. WIMMER (*Ber.*, 20, 1581—1583).—A comparison of the methods proposed by Fischer (Abstr., 1834, 1014), and by Staedel and Bauer (Abstr., 1886, 943), for the preparation of diazoamidobenzene shows that they are equally satisfactory in this particular, but that the former is to be preferred when mixed diazoamido-compounds are required. The melting point of the diazoamidobenzene prepared by either method is  $98^\circ$ , and the product obtained by Fischer's method is free from amidoazobenzene. Diazoamidoparatoluene can also be readily prepared from paratoluidine under the same conditions.

*Diazoamido-orthotoluene* is formed when orthotoluidine (2 mols.) is dissolved in hydrochloric acid (3 mols.) and water (3 mols.), the solution cooled to  $-5^\circ$ , and treated with a solution of sodium nitrite (1 mol.), sodium acetate being added as required to remove the hydrochloric acid set free. The temperature is maintained at  $-5^\circ$  for six hours; the crystals of diazoamido-orthotoluene are then separated, drained on a tile, dissolved in cooled alcohol, and thrown out of solution in the crystalline form by addition of ice. It is an orange-yellow, crystalline powder, melts at about  $50^\circ$ , and decomposes even during the spontaneous evaporation of its solutions in various media, such as alcohol, ether, &c.

*Diazoamidoxylylene*, prepared from xylydine by a similar method, separated as an oil, and could not be obtained in a crystalline state.

W. P. W.

**Hydroxyazo-compounds.** By B. FISCHER and H. WIMMER (*Ber.*, 20, 1577—1581).—The authors, working on similar lines to Heumann and Economides (this vol., pp. 480, 684), have independently obtained hydroxyazo-compounds by the addition of a diazoamido-derivative (1 mol.) to a phenol (1 mol.) in the fused state. In this way orthotolueneazoresorcinol is formed from diazoamido-orthotoluene and

resorcinol, and a *xyleneazoresorcinol*,  $C_8H_9 \cdot N_2 \cdot C_6H_3(OH)_2$ , from diazo-amidoxylylene and resorcinol; the latter compound crystallises from alcohol in fiery-red needles, and melts at  $205-206^\circ$ ; it is identical with the azo-compound prepared by the action of diazoxylylene chloride on resorcinol.

Under similar conditions diazoamidobenzene, diazoamido-ortho-toluene, and diazoamidoparatoluene when added to fused  $\beta$ -naphthol yield benzeneazo- $\beta$ -naphthol, orthotolueneazo- $\beta$ -naphthol, and paratolueneazo- $\beta$ -naphthol respectively (this vol., p. 55). W. P. W.

**Unsymmetrical Benzoylphenylhydrazine.** By A. MICHAELIS and F. SCHMIDT (*Ber.*, **20**, 1713—1718).—The doubt expressed in the author's first communication (this vol., p. 365) as to the constitution of this compound has now been removed, as it has been found that it unites readily with benzaldehyde and with acetone, with elimination of water; it must therefore contain a nitrogen-atom in union with two hydrogen-atoms, that is, have the formula  $NPhBz \cdot NH_2$ . The author suggests that phenylhydrazine-derivatives, where substitution occurs in the  $NH$ -group, shall be termed  $\alpha$ -compounds, the term  $\beta$ -compounds being applied to the symmetrical derivatives in which substitution has occurred in the  $NH_2$ -group. The statement (*loc. cit.*) as to the difference in behaviour of the authors' dibenzoylphenylhydrazine with that described by Fischer was due to a misprint in Fischer's paper; the substances are identical.

The following salts of  $\alpha$ -benzoylphenylhydrazine are described: the *hydrobromide* melts at  $191^\circ$ ; the *sulphate* crystallises in groups of slender needles and melts at  $191^\circ$ . The *nitrate* forms long, lustrous plates and melts at  $145^\circ$ ; the *picrate* melts at  $122^\circ$ .

When treated with nitrous acid in strongly acid solution,  $\alpha$ -benzoylphenylhydrazine is converted into benzoylaniline and nitrous oxide, in neutral solution, on the other hand, it yields diazobenzenimide and benzoic acid.

$\alpha$ -Benzoyl- $\beta$ -acetylphenylhydrazine,  $NPhBz \cdot NHAc$ , obtained by the action of acetic anhydride on the base, crystallises in long needles and melts at  $152-153^\circ$ ; it is also obtained by the action of benzoic chloride on  $\beta$ -acetylphenylhydrazine.

*Benzoylphenylsemicarbazide*,  $NPhBz \cdot NH \cdot CO \cdot NH_2$ , is obtained by the action of potassium cyanide on a feebly acid solution of a salt of the base. It forms crystalline crusts, melts at  $202-203^\circ$ , and is sparingly soluble in benzene, readily in alcohol. *Diphenylbenzoylthiosemicarbazide*,  $NPhBz \cdot NH \cdot CS \cdot NHPh$ , is prepared by the action of phenylthiocarbimide on the base. It is crystalline, melts at  $310^\circ$ , and is sparingly soluble in ether, benzene, chloroform, and hot alcohol.

*Benzylidenebenzoylphenylhydrazide*,  $NPhBz \cdot N : CHPh$ , is prepared by gently heating a mixture of benzaldehyde and benzoylphenylhydrazine; it crystallises in very thin needles of silky lustre, melts at  $122^\circ$ , is nearly insoluble in water, readily in alcohol, and only reduces Fehling's solution after long boiling.

*Acetonebenzoylphenylhydrazide*,  $NPhBz \cdot N : CMe_3$ , separates after a time from a hot solution of benzoylphenylhydrazine in acetone, after dilution with water. It forms lustrous prisms, melts at  $115.5^\circ$ , and

is very soluble in acetone and alcohol, more sparingly in ether, scarcely soluble in water. *Acetophenone benzoylphenylhydrazide*,  $\text{NPhBz}\cdot\text{N}:\text{CMePh}$ , is obtained after a long time from a mixed alcoholic solution of its constituents; it crystallises in colourless needles, melts at  $124^\circ$ , and is readily soluble in alcohol, insoluble in water.

*Acetylbenzylidenephénylhydrazine*,  $\text{NPhAc}\cdot\text{N}:\text{CHPh}$ , is mentioned but not described. A. J. G.

**Manufacture of Methyl-violet.** By O. MÜHLHÄUSER (*Dingl. polyt. J.*, **264**, 37—45).—For the production of this dye 20 kilos. of methylaniline and 8 kilos. of phenol are heated at  $55^\circ$  with 175 kilos. of rock salt and 10 kilos. of copper sulphate. The operation is conducted in cast-iron cylinders provided with agitators. The oxidation-product is then washed with water and treated with milk of lime when the salt and phenol are dissolved, whilst the methyl-violet, copper hydroxide, and calcium sulphate are precipitated. The mixture is filtered and washed, and the precipitate saturated with hydrogen sulphide. The copper is thereby converted into the sulphide, and the dye separated from it by means of hydrochloric acid. The violet solution is then treated with a filtered solution of salt, which precipitates the colouring matter as a green tarry mass. This is purified by solution in hot water and reprecipitation with salt solution. The purified product is washed with water, dried and ground. It is then made up into the different brands (violet 3 B, 4 B, and 5 B) by the addition of benzyl-violet. The methyl-violet obtained by this method consists of a mixture of tetra- and penta-methylparosaniline.

D. B.

**Induline and Azophenine.** By O. N. WITT (*Ber.*, **20**, 1538—1541).—Azophenine (Thomas and Witt, *Trans.*, 1883, 117) is best prepared by heating amidoazobenzene (2 parts), aniline hydrochloride (1 part), and aniline (4 parts) for 24 hours at  $80$ — $90^\circ$ ; it is washed with alcohol and crystallised from alcohol. When the heating is continued for 12 to 20 hours at  $125$ — $130^\circ$ , the product consists of induline,  $\text{C}_{18}\text{H}_{15}\text{N}_3$ , together with the higher induline,  $\text{C}_{30}\text{H}_{23}\text{N}_5$  and its phenyl-derivative,  $\text{C}_{36}\text{H}_{27}\text{N}_5$ . Azophenine is also formed by the action of free nitrosodimethylaniline and nitrosodiethylaniline on aniline. If the aniline is replaced by toluidine, azoparatoluidine (Nölting and Witt, *Abstr.*, 1884, 742) is obtained.

When azophenine is heated at  $360^\circ$ , it is decomposed into aniline, fluorindine, and a violet dye. When reduced with tin and hydrochloric acid, it yields aniline and a sparingly soluble hydrochloride of an unstable base. It is concluded that azophenine is an azo-dye, formed by the dehydrogenation of aniline, and that it contains on the one side of one or several azo-groups, the radicle phenyl, on the other side, an unknown radicle.

When induline is distilled with lime, the greater part is carbonised and a distillate is obtained containing carbazole, together with aniline, benzene, and diphenylamine; induline is therefore a diphenylamine-derivative. N. H. M.

**Roshydrazine and a New Class of Dyes.** By J. H. ZIEGLER (*Ber.*, **20**, 1557—1558).—When 5 grams of rosaniline dissolved in 30 c.c. of strong hydrochloric acid and 70 c.c. of water is treated with 3.5 grams of sodium nitrite, and the whole then added to a solution of 12 grams of tin in 30 c.c. of hydrochloric acid, the hydrazine salt separates in green crystals, readily soluble in water, almost insoluble in strong hydrochloric acid. The yield is 13 grams. The shade of the salt of the new hydrazine, which is called *roshydrazine*, is somewhat more blue than that of magenta. The solution reduces Fehling's solution in the cold. It readily forms condensation-products with ketones and aldehydes. Formic acid yields a red compound, acetone, aldehyde, pyruvic acid, and benzophenone, red to blue-violet compounds, benzaldehyde and ethyl acetoacetate, blue dyes. The dyes dissolve readily in alcohol, sparingly or not at all in water.

N. H. M.

**Aniline Sebate and Diphenyl-sebacamide.** By G. GEHRING (*Compt. rend.*, **104**, 1451—1452).—When aniline (2 mols.) is mixed with sebacic acid (1 mol.), dissolved in alcohol, complete combination takes place without separation of water, and with formation of aniline sebate,  $(C_6H_7N)_2C_{10}H_{18}O_4$ , which is obtained by evaporation in a vacuum, and is purified by recrystallisation from hot water. It then forms thin, colourless, highly lustrous, rhomboidal lamellæ, which are only slightly soluble in cold, but more soluble in hot water, very soluble in cold alcohol, and somewhat soluble in boiling ether or chloroform. Aniline sebate melts at  $134^\circ$ , and sublimes without decomposition. It dissolves in concentrated sulphuric acid, and the solution gives the colour reactions for aniline with oxidising agents.

Aniline sebate does not lose water and form an anilide even at  $250^\circ$ . If, however, equal parts of aniline and sebacic acid are heated together, the temperature being gradually raised to  $215^\circ$ , diphenylsebacamide,  $(PhNH)_2C_{10}H_{16}O_2$ , is obtained, and is purified by recrystallisation from alcohol. It forms colourless, odourless, tasteless, rhombic scales, which melt at  $198^\circ$  and distil without decomposition above  $360^\circ$ . It is insoluble in water and light petroleum, and only very slightly soluble in boiling ether, but dissolves in alcohol, chloroform, and benzene. Phenyl sebacamide is not attacked by alcoholic potash, but when fused with potash it yields aniline. It dissolves in concentrated nitric and sulphuric acids, but is precipitated unchanged on addition of water. When heated with concentrated nitric acid in sealed tubes, it yields a nitro-derivative which crystallises in needles.

C. H. B.

**Action of Thiocarbonyl Chloride on Secondary Amines.** By O. BILLETER (*Ber.*, **20**, 1629—1632).—*Ethylphenylthiocarbamine chloride*,  $CSCl \cdot NPhEt$ , is obtained when ethylaniline (1 mol.) is shaken with thiocarbonyl chloride (1 mol.) dissolved in chloroform. It crystallises in long prisms, melts at  $56.5$ — $57^\circ$ , and is extremely soluble in chloroform, readily soluble in light petroleum and ether. Alcohol at first dissolves the compound without change, but decomposes it slowly in the cold or quickly on heating into ethylaniline hydrochloride, an oil containing sulphur, ethyl chloride, and *ethylphenylthiocarbamine oxide*,  $(CS \cdot NPhEt)_2O$ . This crystallises in com-

pact, citron-yellow needles or prisms, melts at  $143-143.5^{\circ}$ , and is soluble in ether and light petroleum, readily soluble in boiling alcohol; 100 parts of alcohol dissolve 0.7 part of the oxide at  $15^{\circ}$ .

*Methylphenylthiocarbamine chloride*,  $\text{CSCl}\cdot\text{NPhMe}$ , prepared similarly to the ethyl-compound, forms pale-yellow crystals, melts at  $34.5-35^{\circ}$ , and is soluble in light petroleum; if heated with alcohol it yields *methylphenylthiocarbamine oxide*,  $(\text{CS}\cdot\text{NPhMe})_2\text{O}$ , in sulphur-yellow crystals, melting at  $116.5^{\circ}$ .

When either ethyl- or methyl-phenylthiocarbamine chloride (1 mol.) is heated with ethyl- or methyl-aniline (2 mols.) at  $100^{\circ}$ , a considerable rise of temperature occurs and tetra-substituted thiocarbamides are obtained; these are soluble in light petroleum and alcohol, but insoluble in alkalis. *Diethyldiphenylthiocarbamide*,  $\text{CS}(\text{NPhEt})_2$ , crystallises from light petroleum in white tables, from alcohol in long needles or prisms, and melts at  $75.5^{\circ}$ ; the *dimethyl*-derivative forms monoclinic crystals and melts at  $72.5^{\circ}$ , and the *methylethyl*-derivative crystallises in forms resembling those of the methyl-derivative, and melts at  $49.5^{\circ}$ .

W. P. W.

**Orthamidophenyl Mercaptan.** By A. W. HOFMANN (*Ber.*, **20**, 1788—1797).—The action of carbon bisulphide on orthamidophenyl mercaptan or the corresponding disulphide gives, not as was expected, a thiocarbamide, but a mercaptan of the formula  $\text{C}_6\text{H}_4\langle\begin{smallmatrix} \text{N} \\ \text{S} \end{smallmatrix}\rangle\text{C}\cdot\text{SH}$ .

This crystallises in lustrous, colourless needles, melts at  $179^{\circ}$ , has an intensely bitter taste, and is insoluble in water, soluble in alcohol, ether, and acetic acid. Proof of its constitution is given by its formation by the action of chlorophenylthiocarbimide on sodium hydrosulphide, and by its decomposition into orthamidophenyl mercaptan, carbonic anhydride, and hydrogen sulphide when fused with potash. The corresponding *disulphide*,  $\text{S}_2(\text{C}_7\text{H}_5\text{NS})_2$ , is obtained by adding potassium dichromate to an acetic acid solution of the compound. It forms silvery plates, melts at  $180^{\circ}$ , and is converted into a black, amorphous substance when further oxidised. The *methyl ether*,  $\text{C}_7\text{H}_5\text{NS}\cdot\text{SMe}$ , crystallises in short, colourless prisms and melts at  $52^{\circ}$ ; it forms unstable salts, the platinochloride,

crystallises in lustrous plates.

*Thioanisidine*,  $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{SMe}$ , is prepared by the action of methyl iodide on orthamidophenyl mercaptan, and subsequent hydrolysis of the resulting hydriodide. It is a colourless liquid, distils with some decomposition at  $234^{\circ}$ , and yields well-defined salts, which can be recrystallised from water. The hydrochloride forms colourless needles.

*Dithioanisylthiocarbamide*,  $\text{CS}(\text{NH}\cdot\text{C}_6\text{H}_4\cdot\text{SMe})_2$ , is prepared by digesting thioanisidine with carbon bisulphide for some hours in a reflux apparatus; it crystallises in small, colourless prisms, and melts at  $162^{\circ}$ ; when further heated it yields *thioanisylthiocarbimide*,

and thioanisidine. The former is a light-yellow oil of burning taste, which boils about  $270^{\circ}$ , but could not be obtained pure. With alcoholic ammonia it yields *thioanisylthiocarbamide*,

a substance crystallising in prisms and melting at  $168^{\circ}$ .

*Anisylthiocarbimide*,  $\text{NCS} \cdot \text{C}_6\text{H}_4 \cdot \text{OMe}$ , is obtained by distilling dianisyl thiocarbamide; it boils at  $264$ – $266^{\circ}$ , and when treated with alcoholic ammonia is converted into *anisylthiocarbamide*,

which crystallises in colourless needles melting at  $152^{\circ}$ .

When a mixture of amidophenyl mercaptan and phenylthiocarbimide is heated, the substance previously described by the author (Abstr., 1880, 388) as anilidophenylthiocarbimide is obtained, he now regards it as having the constitution  $\text{C}_6\text{H}_4 < \begin{smallmatrix} \text{N} \\ \text{S} \end{smallmatrix} > \text{C} \cdot \text{NHPh}$ .

When an ethereal solution of amidophenyl mercaptan is mixed with ethyl chlorocarbonate, a colourless oil is obtained, which from its mode of formation and properties would seem to have the composition  $\text{SH} \cdot \text{C}_6\text{H}_4 \cdot \text{NH} \cdot \text{COOEt}$ . When distilled it yields alcohol and Hofmann's hydroxyphenylthiocarbimide.

A. J. G.

**Xylyl Phosphorous Compounds: Toluphosphinic Acids.** By J. WELLER (*Ber.*, 20, 1718–1725. Compare Michaelis and Paneck, Abstr., 1882, 958).—*Mercury dixylyl*,  $\text{Hg}(\text{C}_6\text{H}_3\text{Me}_2)_2$  [ $\text{Hg} : \text{Me}_2 = 4 : 1 : 3$ ], is obtained by heating bromometaxylylene with 2 per cent. sodium amalgam at  $140$ – $150^{\circ}$  for 12 hours. It crystallises in slender, felted needles, melts at  $169$ – $170^{\circ}$ , and is sparingly soluble in ether, alcohol, and cold benzene, readily soluble in hot benzene. Hydrochloric acid on boiling readily decomposes it into mercuric chloride and metaxylylene.

1.3.4 *Xylylphosphochloride*,  $\text{C}_6\text{H}_3\text{Me}_2 \cdot \text{PCl}_2$ , is obtained by the action of phosphorous chloride on 1:3:4 mercury dixylyl at  $230$ – $240^{\circ}$ . It is a colourless, highly refractive liquid, which fumes slightly in the air and boils at  $256$ – $258^{\circ}$ . Water decomposes it with formation of xylylphosphinous acid. Chlorine unites vigorously with it, forming the viscous, yellow tetrachloride which is decomposed by water first into the oxychloride, then into xylylphosphinic acid melting at  $194^{\circ}$ .

By the action of phosphorous chloride on metaxylylene in presence of aluminium chloride, a mixture of the preceding  $\alpha$ -compound with smaller quantities of an isomeride,  $\beta$ -xylylphosphochloride [ $\text{Me}_2 : \text{PCl}_2 = 1 : 3 : 5 ?$ ] is obtained. This mixture forms a colourless liquid boiling constantly at  $256^{\circ}$ , and of sp. gr. 1.24 at  $18^{\circ}$ . It absorbs chlorine to form a mixture of the tetrachlorides, which is obtained as a viscid mass having crystals interspersed through it. As the  $\alpha$ -tetrachloride is liquid, the crystals must be those of the  $\beta$ -compound. When treated with sulphurous anhydride the tetrachlorides are converted into the oxychlorides which distil at  $280$ – $300^{\circ}$ , but cannot be separated by distillation. The oxychlorides are therefore decom-

posed by long boiling with water into the corresponding metaxylylphosphinic acids, which can then be separated by crystallisation.

*α-Metaxylylphosphinic acid*,  $C_6H_3Me_2PO(OH)_2$  [1 : 3 : 4], forms long, white needles, melts at  $194^\circ$ , and is very readily soluble in alcohol, more sparingly in ether. 100 parts of water dissolve 1.5 parts of the acid at  $20^\circ$  and 6.9 parts at  $100^\circ$ . When heated with alkalis it is decomposed into metaxylene and phosphoric acid. Bromine acts on it in aqueous solution with formation of phosphoric acid and a mixture of brominated metaxylenes. The barium, cadmium, nickel, and silver salts are described. The metaxylylphosphinic acid (m. p.  $186-187^\circ$ ) obtained by Michaelis and Paneck (*loc. cit.*), was probably a mixture of this acid with some of the acid of lower melting point. When treated with nitric acid it yields two isomeric *nitro-acids*,  $NO_2 \cdot C_6H_2Me_2PO_3H_2$ , of which one, the less soluble in water, crystallises in needles and melts at  $182^\circ$ , whilst the other melts at  $100^\circ$ .

*β-Metaxylylphosphinic acid*,  $C_6H_3Me_2PO(OH)_2$  [1 : 3 : 5?], crystallises in thin plates, melts at  $161^\circ$ , and is soluble in alcohol and ether. 100 parts of water dissolve 1.8 parts of the acid at  $15^\circ$  and 117.3 parts at  $100^\circ$ . Its behaviour with alkalis and bromine resembles that of the *α*-acid, except that in the latter case a sparingly soluble bromoxylylphosphinic acid is also invariably formed. The salts of this acid resemble those of the *α*-acid but are somewhat more soluble. Nitric acid partly oxidises it to *β*-toluylphosphinic acid, partly converts it into a nitro-acid,  $NO_2 \cdot C_6H_3Me \cdot PO_3H_2$ .

*α-Toluylphosphinic acid*,  $COOH \cdot C_6H_3Me \cdot PO(OH)_2$ , is prepared by oxidising *α*-metaxylylphosphinic acid in dilute alkaline solution with the calculated amount of potassium permanganate. It crystallises in colourless prisms, melts at  $262^\circ$ , and is readily soluble in alcohol and hot water, sparingly soluble in ether. It is a strong tribasic acid, but its salts are difficult to prepare in a pure state, as there is a tendency to form mixtures of normal and acid salts. When strongly heated it is converted with partial carbonisation into metatoluic and metaphosphoric acids. The *chloride*,  $COCl \cdot C_6H_3Me \cdot POCl_2$ , is a thick liquid which distils at about  $310^\circ$ .

*β-Toluylphosphinic acid* melts at  $220^\circ$ , but otherwise resembles the *α*-acid from which, however, it is distinguished by not giving a crystalline precipitate when mixed with copper sulphate solution.

A. J. G.

**Condensation of Aldehydes with Phenols.** By A. MICHAEL (*Ber.*, 20, 1572—1573).—A reply to Claisen (*Ber.*, 19, 3316, footnote).

**Oxidation of Ketones with Potassium Ferricyanide.** By K. BUCHKA and P. H. IRISH (*Ber.*, 20, 1762—1767).—Claus' rule, that only those aromatic methyl ketones can be oxidised to *α*-ketonic acids which contain a side-group in the ortho-position to the methyl-group (*Abstr.*, 1886, 462), although seemingly true for oxidations with potassium permanganate, is decidedly not correct if potassium ferricyanide is employed as the oxidising agent.

When paratolyl methyl ketone is oxidised with potassium ferri-

cyanide in alkaline solution in the cold, it yields paratoluic acid and *paratolylglyoxylic acid*. The latter,  $C_6H_4Me \cdot CO \cdot COOH$  [= 1 : 4], is crystalline, melts at 95—97° (uncorr.), and is not volatile. The barium salt (+ 8 mols.  $H_2O$ ) and the potassium salt were prepared. It gives a crystalline compound with phenylhydrazine, melting at 144°, and when heated with concentrated sulphuric acid and benzene containing thiophen yields a red dye, in this resembling phenylglyoxylic acid. The acid when further oxidised yields terephthalic acid.

*Orthoxylglyoxylic acid*,  $C_6H_3Me_2 \cdot CO \cdot COOH$  [ $Me_2 : CO \cdot COOH = 4 : 3 : 1$ ], is prepared in like manner from methyl orthoxylene ketone; it melts at 92° (uncorr.), and yields a barium salt crystallising in slender needles.

*Methyl metatolyl ketone*, prepared by distilling calcium metatoluate and acetate, boils at 218—220°, and by oxidation with potassium ferricyanide is converted into an acid not volatile with steam; this is still under investigation.

A. J. G.

**Cyanacetophenone.** By A. HALLER (*Compt. rend.*, **104**, 1448—1451).—Cyanacetophenone seems to have an acid function, and dissolves readily in alkalis, but the compounds formed are very unstable. The silver-derivative,  $COPh \cdot CHAg \cdot CN$ , is obtained by adding silver nitrate to a dilute alcoholic solution of cyanacetophenone neutralised with soda or ammonia. It is insoluble in water and alcohol, and is decomposed when exposed to light.

When cyanacetophenone is boiled with concentrated potash it yields ammonia, potassium benzoate, and potassium acetate. A saturated solution in absolute alcohol when cooled at 0°, and treated with hydrogen chloride, deposits white needles of the composition  $C_{11}H_{14}O_2NCl$ , insoluble in water and ether. This compound in all probability has the constitution  $COPh \cdot CH_2 \cdot C(OEt) : NH, HCl$ , and is the hydrochloride of ethyl benzoylacetoneitrile. With ammonia it yields ammonium chloride and ethyl benzoylacetoneitrile, and with potassium nitrate it yields a corresponding nitroso-derivative, which crystallises in needles melting at 117°. When the hydrochloride is heated with dilute alcohol it yields ammonium chloride and ethyl benzoylacetate.

The action of hydrochloric acid in excess on cyanacetophenone in presence of alcohol, yields ethyl benzoate and ammonium chloride.

Ethyl cyanacetate, when treated with metallic sodium, yields the derivative  $CN \cdot CHNa \cdot COOEt$ , and this in contact with iodo-derivatives and acid chlorides, yields compounds of the type  $CN \cdot CHR \cdot COOEt$ .

C. H. B.

**Isonitroso-compounds.** By E. BECKMANN (*Ber.*, **20**, 1507—1510; compare Abstr., 1885, 618).—The intramolecular change which takes place when diphenylketoxime is treated with phosphorous pentachloride, is also produced by strong sulphuric acid at 100°. When the product of the reaction is poured into water, the precipitate treated with sodium carbonate and recrystallised from alcohol, pure benzonitrile is obtained. When the latter is heated for some time with sulphuric acid, benzoic acid and aniline are formed.

Methylphenylketoxime yields acetanilide when heated with sulphuric acid.

Benzaldoxime (2.5 parts) when poured into a mixture of 10 parts of sulphuric acid and 1 part of water, is converted into benzamide, and not into formonitrile, as was expected.

In a similar manner the dioxime of benzil is converted by sulphuric acid into a crystalline compound melting at 110°. N. H. M.

**Aromatic Ethylenediketones and Alkylated Benzoyl- $\beta$ -propionic Acids.** By A. CLAUS and others (*Ber.*, 20, 1374—1378).—The authors have obtained the above compounds by the action of succinic chloride on aromatic hydrocarbons in the presence of aluminium chloride. When 1 mol. of the hydrocarbon is used, the chief product obtained is a benzoylpropionic acid, whilst with 2 mols. of hydrocarbon it is a diketone.

1. By CLAUS and WERNER.—*Diphenyl ethylene diketone*,

prepared from benzene, crystallises in colourless needles, insoluble in water, soluble in alcohol, ether, and benzene, and melting at 140°. Benzoyl- $\beta$ -propionic acid melts at 116°, and has already been obtained by Burker (*Abstr.*, 1881, 273). *Dimetaxylyl ethylene diketone*,  $\text{C}_2\text{H}_4(\text{CO}\cdot\text{C}_6\text{H}_3\text{Me}_2)_2$  [CO : Me : Me = 1 : 2 : 4], prepared from metaxylene, forms colourless needles, soluble in alcohol, ether, and chloroform, and melting at 129°. With phenylhydrazine, it yields a *dihydrazide*, crystallising in orange needles melting at 189°. The *diisonitroso-derivative*,  $\text{C}_{20}\text{H}_{22}(\text{NOH})_2$ , is white, and melts at 140°. When oxidised with dilute nitric acid, the diketone yields metaxylic (orthoparadimethylbenzoic) acid, thus proving the constitution to be as above. *Orthoparadimethylbenzoyl- $\beta$ -propionic acid*,

is almost insoluble in water, soluble in organic solvents. It crystallises in colourless needles melting at 108°. Several of the salts are described.

II. By CLAUS and SCHLARB.—*Paraditolyl ethylene diketone*,

crystallises in colourless needles melting at 159°. Nitric acid oxidises it to paratoluic acid. *Paratoluyyl- $\beta$ -propionic acid*,

crystallises from water in minute needles melting at 127°. *Dipseudocumyl ethylene diketone*,  $\text{C}_2\text{H}_4(\text{CO}\cdot\text{C}_6\text{H}_2\text{Me}_3)_2$ , forms crystals melting at 120°, and yielding, with nitric acid, 2 : 4 : 5 trimethylbenzoic acid. 2 : 4 : 5 *Trimethylbenzoyl- $\beta$ -propionic (pseudocumyl- $\gamma$ -ketonic) acid*,  $\text{C}_6\text{H}_2\text{Me}_3\cdot\text{CO}\cdot\text{C}_2\text{H}_4\cdot\text{COOH}$ , forms colourless crystals melting at 105°.

III. By CLAUS and MURTFELD.—*Diparaxylyl ethylene diketone*,  $\text{C}_2\text{H}_4(\text{CO}\cdot\text{C}_6\text{H}_3\text{Me}_2)_2$ , forms needles melting at 123°. *Paraxylyl- $\gamma$ -ketonic acid*,  $\text{C}_6\text{H}_3\text{Me}_2\cdot\text{CO}\cdot\text{C}_2\text{H}_4\cdot\text{COOH}$ , forms colourless needles melt-

ing at 84°. The corresponding derivatives of cymene are thick oils, the ketone boiling at 320°.

All the above temperatures are uncorrected.

L. T. T.

**Chlorobenzoic Acids.** By A. CLAUS and A. W. BÜCHER (*Ber.*, **20**, 1621—1627).— $\beta$ -Dichlorobenzoic acid (m. p. = 156°), obtained together with the  $\alpha$ -acid [ $\text{COOH} : \text{Cl} : \text{Cl} = 1 : 3 : 4$ ], when benzoic acid is treated with chlorine (this *Journ.*, 1877, ii, 782), has been supposed to be identical with the dichlorobenzoic acid (m. p. = 153°), [ $\text{COOH} : \text{Cl} : \text{Cl} = 1 : 2 : 5$ ], prepared by Lellman and Klotz (*Abstr.*, 1886, 452). This view, however, is untenable, since direct comparison of the two acids shows them to be isomerides. The barium salt of Lellmann's acid crystallises in lustrous needles with  $3\frac{1}{2}$  mols. of  $\text{H}_2\text{O}$ , that of the  $\beta$ -acid in aggregates with 3 mols. of  $\text{H}_2\text{O}$ , and Lellman's acid when heated at 220° with dilute sulphuric acid (3 vols. acid to 2 vols. water), is converted into 1 : 4 dichlorobenzene and carbonic anhydride, whilst the  $\beta$ -acid is not attacked even by concentrated sulphuric acid at 300°. On distillation with lime, the  $\beta$ -acid yields a dichlorobenzene which, when nitrated, is found to be identical with nitro-orthodichlorobenzene, hence the constitution of the acid must be [ $\text{COOH} : \text{Cl} : \text{Cl} = 1 : 2 : 3$ ]. The best yield of the acid is obtained when benzoic acid ( $1\frac{1}{2}$  parts) is dissolved in water (60 parts) and concentrated hydrochloric acid (10 parts), and the warm solution treated with a concentrated aqueous solution of potassium chlorate (4 parts) in small portions at a time, so that the operation takes from 30 to 40 hours for its completion. Although orthochlorobenzoic acid is present among the products of the direct chlorination of benzoic acid, yet the quantity is variable and sometimes extremely small, and this fact is considered to lend support to the conjecture that the dichlorobenzoic acid obtained by Beilstein by the chlorination of orthochlorobenzoic acid is not the  $\beta$ -acid, but has the constitution [ $\text{COOH} : \text{Cl} : \text{Cl} = 1 : 2 : 5$ ].

The  $\alpha$ - and  $\beta$ -acids are scarcely attacked by nitric acid, and not at all when in acetic acid solution, but when heated with a mixture of nitric and sulphuric acids they yield the nitrochlorobenzoic acids [ $\text{COOH} : \text{Cl} : \text{NO}_2 = 1 : 3 : 4$ ] (m. p. = 137°) and [ $\text{COOH} : \text{Cl} : \text{NO}_2 = 1 : 3 : 2$ ] (m. p. = 136°). Both acids can also be nitrated if they are dissolved in ordinary nitric acid and treated with sulphuric acid (1 part to 3—4 parts of nitric acid). The *dichloronitrobenzoic acid* from the  $\alpha$ -acid forms colourless needles, melts at 160°, and is soluble in water; that from the  $\beta$ -acid crystallises in scales, melts at 214—215°, and is sparingly soluble in boiling water. The *barium* salt of the latter,  $(\text{C}_7\text{H}_2\text{Cl}_2\text{O}_2\text{NO}_2)_2\text{Ba} + 4\text{H}_2\text{O}$ , crystallises in lens-shaped aggregates of small needles.

The  $\alpha$ -acid, when further chlorinated by heating with manganese dioxide and hydrochloric acid for  $2\frac{1}{2}$  days at 180°, yields a trichlorobenzoic acid, which is most probably identical with the acid [ $\text{COOH} : \text{Cl} : \text{Cl} : \text{Cl} = 1 : 3 : 4 : 5$ ] (m. p. = 203°). This acid can readily be obtained from trichlorobenzotrichloride (formed together with the dichloro-derivative when benzotrichloride is chlorinated in the presence of iodine) by hydrolysis with aqueous soda. As the two

compounds could not be separated, a mixture of  $\alpha$ -dichlorobenzoic acid and trichlorobenzoic acid (m. p. =  $203^{\circ}$ ) was obtained, and the acids separated by fractional crystallisation of their barium salts. The trichlorobenzoic acid formed from the  $\beta$ -acid by heating with manganese dioxide and hydrochloric acid has not yet been obtained pure, and is difficult to prepare, inasmuch as the action tends to result in the production of higher chlorinated acids. Both the  $\alpha$ - and  $\beta$ -acid yield the same tetrachlorobenzoic acid [1 : 2 : 3 : 4 : 5], melting at  $165^{\circ}$ , which is separated from the accompanying pentachlorobenzoic acid, melting at  $199$ – $200^{\circ}$ , by fractional crystallisation from water, in which it is the less soluble. The *barium* salts of these acids,  $(C_7HCl_4O_2)_2Ba + 3\frac{1}{2}H_2O$  and  $(C_7Cl_5O_2)_2Ba + 4H_2O$ , crystallise in beautiful, stellate groups of needles. W. P. W.

**Phenylacetic Acid and Desoxybenzoins.** By R. ANSCHÜTZ and W. BERNS (*Ber.*, 20, 1389–1393).—Contrary to the experience of Hotter and others, the authors found no difficulty in obtaining phenylacetic chloride free from phosphoric compounds. The pure chloride boils at  $102.5^{\circ}$  under 17 mm. pressure. With oxalic acid it readily yields the anhydride if the chloride is kept in excess. The anhydride melts at  $72.5^{\circ}$ , and is easily converted into the acid by moisture.

By the action of alcoholic potash on desoxybenzoin the authors obtained a compound probably identical with that obtained by Limpricht and Schwanert, and named by them diethylcarbobenzoic acid,  $C_{18}H_{18}O_2$ . The authors, however, ascribe the formula  $C_{16}H_{16}C_2$  to this compound, which boils at  $238$ – $240^{\circ}$  under 11 mm. pressure. They are investigating this substance further. L. T. T.

**Glaser's Monobromocinnamic Acids.** By R. ANSCHÜTZ and C. C. SELDEN (*Ber.*, 20, 1382–1388).—The authors have prepared and compared several of the derivatives of the  $\alpha$ - and  $\beta$ -acids. The ethereal salts of the  $\beta$ -acid were prepared from the silver salt since hydrochloric or sulphuric acid converts the  $\beta$ - into  $\alpha$ -acid. The  $\alpha$ -methyl salt boils at  $158.5$ – $159.5^{\circ}$  under 14 mm. pressure, at  $286.5$ – $288.5^{\circ}$  under ordinary pressure; the  $\beta$ -methyl salt at  $145$ – $147^{\circ}$  under 11 mm.; the  $\alpha$ -ethyl salt at  $186.5$ – $188.5^{\circ}$  under 29.5 mm.; the  $\beta$ -ethyl salt at  $151$ – $153^{\circ}$  under 10.5 mm. Both  $\beta$ -salts are converted into the  $\alpha$ -compounds by distillation under ordinary pressure.  $\alpha$ -Bromocinnamic chloride is formed by the action of phosphoric chloride on either the  $\alpha$ - or  $\beta$ -acid, or any of their salts. It is a clear, slightly yellow liquid, which boils at  $152.4^{\circ}$  under 12 mm. pressure. All attempts to prepare a second ( $\beta$ ) chloride were unavailing. With ammonia the chloride yields  $\alpha$ -bromocinnamide, which crystallises from water in scales melting at  $118.5$ – $119^{\circ}$ . The anilide forms needles or hexagonal plates melting at  $80^{\circ}$ .

The authors consider the relations of the two acids to one another to be the same as those between maleic and fumaric acids.

L. T. T.

**Metamethylcinnamic Acid.** By E. BORNEMANN (*Ber.*, 20, 1382).—Referring to Müller's paper (this vol., p. 734) the author

points out that he obtained the above acid three years ago (Abstr., 1884, 1163).

**Isomerism in the Cinnamic Acid Series.** By W. ROSER and E. HASELOFF (*Ber.*, 20, 1576—1577).—A preliminary communication in which the authors announce that the action of bromine on phenylpropionic acid results in the formation of two isomeric dibromocinnamic acids, which melt at 100° and 139° respectively. The second acid is the more stable of the two, and, like cinnamic acid itself and  $\alpha$ -monobromocinnamic acid (m. p. = 131°), is not converted into an indonaphthene-derivative by the action of concentrated sulphuric acid, differing in this respect from the first acid (m. p. = 100°) and from monobromocinnamic acid (m. p. = 120°).

W. P. W.

**Polycoumarins.** By A. HANTZSCH and H. ZÜRCHER (*Ber.*, 20, 1328—1332).—Pechmann and Duisberg have shown (Abstr., 1884, 66) that when equimolecular proportions of a polyhydric phenol and of ethyl acetoacetate are acted on by a dehydrating agent, methylated hydroxycoumarins are formed. The authors find that if excess of ethyl acetoacetate is employed, small quantities of polycoumarins are formed, as well as the hydroxycoumarins. The reactions are analogous to the formation of polyfurfuran-derivatives described by Lang (this vol., p. 262).

*Dimethyldicoumarin*,  $C_6H_2\left(\begin{smallmatrix} CMe:CH \\ O \text{---} CO \end{smallmatrix} \right)_2$ , is formed when a mixture of resorcinol (1 mol.) and ethyl acetoacetate (2 mols. or more) is dissolved in concentrated sulphuric acid, left for some time and then poured into cold water. It is a white, crystalline powder, only very sparingly soluble in alcohol, almost insoluble in boiling water, ether, chloroform, and benzene. It dissolves slowly in ammonia, quickly in the fixed alkalis to a yellow, non-fluorescent liquid. Acids precipitate from this solution *dimethyldicoumaric acid*,

This acid is a white powder easily soluble in alcohol. In dry air it is slowly, at 140°, rapidly reconverted into the lactone or coumarin. It forms a greenish-blue *copper salt*.

*Trimethyltricoumarin*,  $C_6\left(\begin{smallmatrix} CMe:CH \\ O \text{---} CO \end{smallmatrix} \right)_3$ , is formed in a similar way from a mixture of phloroglucol (1 mol.) and ethyl acetoacetate (3 mols.). It is a grey, amorphous powder almost insoluble in the ordinary solvents even on boiling. It dissolves in alkalis, and acids precipitate from this solution *trimethyltricoumaric acid*,

This acid resembles the tricoumarin in appearance, and is reconverted into it when heated at 140°. The *sodium salt* forms a granular white powder.

L. T. T.

**Tetrachlororthobenzoylbenzoic Acid.** By G. KIRCHER (*Annalen*, 238, 338—349).—*Tetrachlorobenzoylbenzoic acid*,  $\text{COPh}\cdot\text{C}_6\text{Cl}_4\cdot\text{COOH}$ , is prepared by the action of aluminium chloride on tetrachlorophthalic anhydride suspended in benzene. The crude product is poured into water, and the solid mass extracted with boiling water, and afterwards dissolved in aqueous soda. The sodium salt is purified by recrystallisation; on the addition of hydrochloric acid to the solution the free acid is precipitated. It crystallises in needles, and dissolves freely in alcohol, ethyl acetate, and in hot benzene. The acid melts at about  $200^\circ$ . The *sodium salt*,  $\text{C}_{14}\text{Cl}_4\text{H}_5\text{O}_3\text{Na} + 4\text{H}_2\text{O}$ , crystallises in glistening plates. 100 parts of water dissolve 1.7 parts by weight of salt at  $20^\circ$ .  $\text{C}_{14}\text{Cl}_4\text{H}_5\text{O}_3\text{K} + 1\frac{1}{2}\text{H}_2\text{O}$  is somewhat more soluble in water than the sodium salt. The *copper salts*,  $(\text{C}_{14}\text{Cl}_4\text{H}_5\text{O}_3)_2\text{Cu} + 2\text{H}_2\text{O}$  and  $(\text{C}_{14}\text{Cl}_4\text{H}_5\text{O}_3)_2\text{Cu} + \text{CuO}$ , are crystalline compounds insoluble in water. The *methyl salt* crystallises in needles, and melts at  $92^\circ$ . The *ethyl salt* melts at  $90^\circ$ .

At  $150^\circ$  phosphoric chloride converts tetrachlorobenzoylbenzoic acid into the *chloride*  $\text{C}_6\text{H}_5\cdot\text{CO}\cdot\text{C}_6\text{Cl}_4\text{COCl}$ . This substance crystallises in needles, and melts at  $183^\circ$ . By the action of phosphorus and hydriodic acid on tetrachlorobenzoylbenzoic acid at  $180^\circ$ , *tetrachlororthobenzoylbenzoic acid*,  $\text{C}_6\text{H}_5\text{CH}_2\cdot\text{C}_6\text{Cl}_4\cdot\text{COOH}$ , is produced. It melts at  $156$ — $157^\circ$ , and dissolves freely in alcohol, benzene, and ether. The *sodium salt*,  $\text{C}_{14}\text{Cl}_4\text{H}_7\text{O}_2\text{Na} + 4\text{H}_2\text{O}$ , forms needle-shaped crystals soluble in water. The crystalline silver salt is sparingly soluble.

*Tetrachloranthraquinone*,  $\text{C}_6\text{Cl}_4\langle\text{CO}\rangle\text{C}_6\text{H}_4$ , is formed by dissolving tetrachlorobenzoylbenzoic acid in warm, concentrated sulphuric acid. The solution is poured into shallow basins, and exposed to the atmosphere for several hours. Tetrachloranthraquinone and the sulphonic acid separate out, and are collected on asbestos. On fusion with sodium hydroxide, tetrachloranthraquinone yields phthalic acid, but on oxidation with nitric acid it yields tetrachlorophthalic acid.

*Tetrachloranthracene* is formed by heating tetrachlorobenzoylbenzoic acid (1 gram) with amorphous phosphorus ( $\frac{1}{2}$  gram) and hydriodic acid boiling at  $127^\circ$  ( $4\frac{1}{2}$  c.c.) at  $220^\circ$  for five hours. The product melts at  $148$ — $149^\circ$ , and dissolves freely in chloroform, benzene, and carbon bisulphide. It is converted into tetrachloranthraquinone (m. p.  $191^\circ$ ) by oxidation with chromic acid. By the action of zinc-dust and dilute ammonia, tetrachloranthracene is converted into *dichloranthracene*. This substance melts at  $255^\circ$ , and is freely soluble in acetic acid, ethyl acetate, and in hot alcohol. When oxidised it yields dichloranthraquinone. This substance forms yellow needles melting at  $261^\circ$ ; on fusion with sodium hydroxide, alizarine is produced.

*Tetrachloranthraquinonedisulphonic acid*,  $\text{C}_{14}\text{Cl}_4\text{O}_2\text{H}_2(\text{SO}_3\text{H})_2$ , is freely soluble in alcohol and in water. It forms crystalline barium and calcium salts.

W. C. W.

**$\beta$ -Dichlorophthalic Acid.** By A. LE ROYER (*Annalen*, 238, 350—361).—The  $\beta$ -dichlorophthalic acid used in the manufacture of

certain descriptions of eosin melts at  $118^{\circ}$ , and is freely dissolved by alcohol, ether, chloroform, light petroleum, and hot water. The anhydride melts at  $151^{\circ}$ . It is soluble in benzene, toluene, and carbon bisulphide. The *ammonium salt*,  $C_6Cl_2H_2(COONH_4)_2$ , is obtained in white plates by the addition of alcohol and ether to the aqueous solution. The silver salt is crystalline.  $C_8H_2Cl_2O_4Ca + 4H_2O$  is sparingly soluble in water, and the barium salt,  $C_8H_2Cl_2O_4Ba + 2H_2O$ , is still less soluble. *Ethyl dichlorophthalate*,  $C_8H_2Cl_2O_4Et_2$ , melts at  $60^{\circ}$ , and forms monoclinic plates; it is soluble in alcohol and ether. The hydrogen salt,  $COOH \cdot C_6H_2Cl_2 \cdot COOEt$ , melts between  $75^{\circ}$  and  $85^{\circ}$ . It dissolves in ammonia, forming the compound  $COOEt \cdot C_6H_2Cl_2 \cdot COONH_4$ , which is soluble in water and alcohol.

*Dichlorophthalyl chloride*,  $C_6H_2Cl_2 < \begin{smallmatrix} CO \\ CCl_2 \end{smallmatrix} > O$ , melts at  $50^{\circ}$ . The *tetrachloride*,  $C_6H_2Cl_2 < \begin{smallmatrix} CCl_2 \\ CCl_2 \end{smallmatrix} > O$ , melts at  $117^{\circ}$ . *Dichlorophthalide*,  $C_6H_2Cl_2 < \begin{smallmatrix} CH_2 \\ CO \end{smallmatrix} > O$ , melts at  $122^{\circ}$ , and *dichloro-phthalimide*,  $C_8H_3Cl_2O_2N$ , melts at  $191^{\circ}$ .

*Orthobenzoyldichlorobenzoic acid*,  $C_6H_5 \cdot CO \cdot C_6H_2Cl_2 \cdot COOH$ , prepared by the action of aluminium chloride on a solution of dichlorophthalic anhydride in benzene, melts at  $159^{\circ}$ . It is soluble in alcohol, benzene, and ether. *Toluyldichlorobenzoic acid*,  $C_6H_4Me \cdot CO \cdot C_6H_2Cl_2 \cdot COOH$ , melts at  $156^{\circ}$ . *Dichlorofluorescein* contains 1 mol.  $H_2O$  more than ordinary fluorescein. It dissolves in alkalis, forming a red solution. *Dichloreosin* forms crystalline potassium and sodium salts, such as  $C_{20}H_4O_5Cl_2K_2$ .

*Tetraiododichlorofluorescein*,  $C_{20}H_5Cl_2I_4O_6$ , is prepared by adding iodine to a solution of dichlorofluorescein in alkali. It is a reddish-yellow powder. The potassium and sodium salts form the "Rose Bengale" of commerce.

Calcium  $\beta$ -dichlorophthalate yields orthodichlorobenzene on dry distillation.

W. C. W.

**Tetrachlorophthalic Acid.** By C. GRAEBE (*Annalen*, 238, 318—338).—*Tetrachlorophthalic acid* melts at  $250^{\circ}$ , and its anhydride melts at  $252^{\circ}$  (corr.). 100 parts of water at  $14^{\circ}$  dissolve 0.57 part by weight of tetrachlorophthalic acid and 0.54 of phthalic acid; at  $99^{\circ}$ , 3.03 parts of tetrachlorophthalic acid and 18.0 of phthalic acid. Tetrachlorophthalic acid is deposited from aqueous solutions in leaves or plates. It is also freely soluble in alcohol and ether. Tetrachlorophthalic acid is slowly attacked by oxidising agents. Hydriodic acid and phosphorus reduce tetrachlorophthalic acid to *tetrachloroxylylene oxide*,  $C_6Cl_4 : (CH_2)_2 : O$ . A solution of tetrachlorophthalic anhydride in glacial acetic acid is reduced to tetrachlorophthalide by zinc-dust. The following salts of tetrachlorophthalic acid have not been previously described.  $C_6Cl_4(COOK)_2$  is obtained in anhydrous crystals by adding alcoholic potash to an alcoholic solution of the acid.  $C_8Cl_4O_4Ba + 2\frac{1}{2}H_2O$  is a crystalline powder insoluble in water.

$C_6Cl_4O_4Cu + 2H_2O$  is obtained as a crystalline precipitate insoluble in water, by adding copper sulphate to a solution of the ammonium salt. The zinc salt is more soluble in cold than in hot water. It crystallises in needles. The *ethylic salt*,  $C_6Cl_4(COOEt)_2$ , melts at  $60.5^\circ$ , and the *methyl salt*,  $C_6Cl_4(COOMe)_2$ , crystallises in prisms which melt at  $92^\circ$ . The acid *ethyl salt*,  $COOH \cdot C_6Cl_4 \cdot COOEt$ , melts at  $94-95^\circ$ .

*Tetrachlorophthalic chloride*,  $C_6Cl_4 < \begin{smallmatrix} CCl_2 \\ CO \end{smallmatrix} > O$ , crystallises in large prisms. It melts at  $118^\circ$ , and boils at  $336^\circ$ . The *tetrachloride*,  $C_6Cl_4 < \begin{smallmatrix} CCl_2 \\ CCl_2 \end{smallmatrix} > O$ , prepared by the action of phosphoric chloride on tetrachlorophthalic anhydride in sealed tubes at  $200^\circ$ , crystallises in rhombohedra. It melts at  $140^\circ$ , and is soluble in ether. *Tetrachlorophthalide* melts at  $208.5^\circ$ . It is soluble in acetic acid and in hot toluene. *Tetrachloroxylylene oxide* melts at  $218^\circ$ . It is deposited from solution in hot benzene or toluene in long needles. When ammonia is passed into the molten anhydride, *tetrachlorophthalimide*,  $C_6Cl_4O_2NH$  is formed. It melts at about  $360^\circ$ . *Tetrachlorofluorescein* dissolves in a solution of sodium hydroxide. On the addition of an acid, a compound is precipitated which contains one molecule of water more than tetrachlorofluorescein. It is *tetrachlorororthofluorescein*. If ammonia is substituted for sodium hydroxide this compound is not formed.

*Tetrachlorororthofluorescein*,  $C_{20}Cl_4H_{10}O_6$ , is insoluble in water, but soluble in ether. The dilute alkaline solution is distinguished from that of fluorescein by its red tint. *Tetrachlorofluorescein* is insoluble in ether. The *diacetate* dissolves freely in chloroform. *Tetrachlorogallein*,  $C_{20}H_6Cl_4O_7 + 2H_2O$ , is formed by the action of pyrogallol on tetrachlorophthalic anhydride at  $190^\circ$ . It is a violet-coloured crystalline powder, and yields a colourless acetic derivative,  $C_{20}H_4Cl_4O_7Ac_4$ .

W. C. W.

**Action of Cyanamide on Benzenesulphonic Acids.** By J. VILLE (*Compt. rend.*, **104**, 1281—1284).—Amidobenzenesulphonic acid (sulphanilic acid) (10 parts) is heated at  $100^\circ$  in closed tubes for two or three days with water (200 parts), cyanamide (about 3 parts), and 20 to 25 drops of ammonia. The hot, filtered liquid deposits prismatic lamellæ which, when recrystallised, form brilliant needles of the composition  $C_7H_5N_3SO_3$ . This compound is attacked by sodium hypobromite with evolution of nitrogen, and is decomposed by boiling aqueous solutions of alkalis, with liberation of amidobenzenesulphonic acid, ammonia, and carbonic anhydride. It is therefore a creatine,  $\alpha$ -amidophenylsulphocyanine,  $SO_3H \cdot C_6H_4 \cdot NH \cdot C(NH) \cdot NH_2$ . It is neutral, has no odour and no taste, is much less soluble in cold water than sulphanilic acid, is only very slightly soluble in boiling water, and is insoluble in ether. It dissolves to a considerable extent, however, in boiling water.  $\alpha$ -Amidophenylsulphocyanine is decomposed by heat with formation of a yellowish-white sublimate. It dissolves in sulphuric and hydrochloric acids without change, and yields no dehydration-product corresponding with creatinine. In this respect it resembles taurocyanine.

With sodium hypobromite it yields a purple-red liquid, and nitrogen is evolved. With nitric acid it forms a colourless solution; with excess of sodium hypochlorite containing a drop of phenol, it gives a fugitive carmine-red coloration. All these reactions serve to distinguish it from sulphanilic acid.

C. H. B.

**Chlornitro-derivatives of the Aromatic Series.** By R. HIRSCH (*Ber.*, 20, 1569—1571).—When amidophenolsulphonic acid suspended in water is treated with bleaching-powder solution a portion goes into solution and the liquid becomes coloured a dull violet, but as soon as sufficient bleaching-powder has been added to bring about the solution of the whole of the acid, a sudden change to a very faint yellow colour occurs. The substance so produced could not, however, be isolated, and treatment of the solution with hydrogen sulphide or zinc-dust failed to effect its reduction to amidophenolsulphonic acid.

Different results are obtained when hydrochloric acid is present, and instead of a violet-coloured intermediate compound being formed quinonechlorimidesulphonic acid is obtained as the chief product of the reaction. This acid also could not be isolated from its golden-yellow solution, but was recognised by various qualitative tests, such as the production of amidophenolsulphonic acid and sulphur by the action of hydrogen sulphide, and of a deep indigo-blue solution on the addition of phenol,  $\alpha$ - and  $\beta$ -naphthol, resorcinol, and other phenols, also of dimethylaniline, &c. The blue colour with phenol is ascribed to the formation of a sulphonic acid of indophenol.

The production of chlornitro-derivatives by the action of bleaching-powder on the aromatic amines appears to be a general one, inasmuch as acetanilide chloride (this vol., p. 44), paramidodimethylaniline chloride, and also the chlorides of sulphanilic acid, naphthionic acid, and metamidobenzoic acid have been obtained and recognised by colour reactions.

W. P. W.

**Sulphimido-compounds.** By P. T. CLEVE (*Ber.*, 20, 1534—1538).—*Orthosulphimidobenzene*,  $C_6H_4<\begin{smallmatrix} NH \\ SO_2 \end{smallmatrix}>$ , is obtained when a solution of orthonitrobenzenesulphonic chloride in benzene is mixed with hydriodic acid diluted with glacial acetic acid. The crystalline product is washed with alcohol and crystallised from boiling glacial acetic acid from which it separates in slender, yellow needles melting at  $193^\circ$ ; it is sparingly soluble. *Metasulphimidobenzene*,  $C_6H_5NSO_3$ , prepared in a manner similar to the ortho-compound, crystallises in yellow needles very readily soluble in boiling alcohol. It melts at  $83^\circ$ . The *para*-compound is an oily substance very readily soluble in glacial acetic acid.

*Sulphimidonaphthalene*,  $C_{10}H_6<\begin{smallmatrix} SO_2 \\ NH \end{smallmatrix}>$  [ $? SO_2 : NH = 1 : 4'$ ], is prepared from  $\alpha$ -nitronaphthalenesulphonic chloride, and forms a very sparingly soluble, crystalline powder melting at  $167^\circ$ .

$\beta$ -*Sulphimidonaphthalene*, [ $NH : SO_2 = 1' : 2$ ], crystallises in slender,

yellow needles, very sparingly soluble in glacial acetic acid and alcohol. It melts at  $180^{\circ}$ .

$\gamma$ -*Sulphimidonaphthalene* forms lustrous, slender, lemon-coloured needles melting at  $124^{\circ}$ . It is very sparingly soluble.

$\delta$ -*Sulphimidonaphthalene* resembles its isomerides, and melts at  $173^{\circ}$ . N. H. M.

**Ethyl Benzoic Sulphinide and Ethyl Orthosulphaminebenzoate.** By C. FAHLBERG and R. LIST (*Ber.*, 20, 1596—1604).—

*Sodium benzoic sulphinide*,  $C_6H_5 < \begin{smallmatrix} CO \\ SO_2 \end{smallmatrix} > NNa + 2H_2O$ , is formed when pure benzoic sulphinide is exactly neutralised with aqueous soda or sodium carbonate. It crystallises in large, rhombic tables, is extremely soluble in water, sparingly soluble in hot alcohol, and has an intensely sweet taste. If the anhydrous salt is heated with ethyl iodide for some hours at  $230^{\circ}$ , an almost quantitative yield of *ethyl benzoic sulphinide*,  $C_6H_5SO_3N$ , is obtained; this crystallises in long, white needles, begins to fuse below its melting point, and melts at  $93$ — $94^{\circ}$ . It is very readily soluble in alcohol and ether, and, unlike benzoic sulphinide and its salts, is without taste. When heated with hydrochloric acid, the ethyl salt undergoes hydrolysis and yields ethylamine and orthosulphobenzoic acid: a reaction which affords confirmatory evidence in favour of the above formula for the sulphinides.

*Potassium orthosulphethamidobenzoate*,  $COOK \cdot C_6H_4 \cdot SO_2NEtK$ .—Ethyl benzoic sulphinide is not attacked by boiling with concentrated aqueous potash, but when heated in alcoholic solution with alcoholic potash at  $100^{\circ}$ , is converted into the potassium salt of orthosulphamidobenzoic acid, which crystallises in nacreous scales, is strongly alkaline, and extremely soluble in water. The *sodium* salt crystallises in tufts of slender needles; the *silver* salt forms aggregates of needles and is soluble in water; the *copper* salt crystallises with 2 mols. of  $H_2O$  in dark-green prisms, sparingly soluble in water. The *acid* is obtained as an oil on the addition of an acid to the aqueous solution of the potassium or sodium salts; it crystallises in needles, is soluble in water, readily soluble in alcohol and ether, and has no definite melting point, inasmuch as it begins to fuse at  $102^{\circ}$ , and is not completely fluid below  $116^{\circ}$ .

*Ethyl orthosulphaminebenzoate*,  $COOEt \cdot C_6H_4 \cdot SO_2NH_2$ , is obtained when a solution of benzoic sulphinide in absolute alcohol is saturated with hydrogen chloride. It crystallises in long, white needles, melts at  $83^{\circ}$ , and is readily soluble in boiling water, alcohol, and ether. On saponification with potash, it yields potassium benzoic sulphinide and alcohol, and similar products are obtained by the action of ammonia, lime, barium hydroxide, and even sodium carbonate in the cold. The ethyl salt is formed if a mixture of ethyl iodide, sodium ethoxide, and orthosulphaminebenzoic acid in molecular proportions is heated for some hours, but cannot be obtained by saturating an alcoholic solution of the acid with hydrogen chloride, inasmuch as in this case benzoic sulphinide is the sole product.

An alcoholic solution of sulphaminebenzoic sulphinide (*Abstr.*, 3 k 2

1881, 816), when saturated with hydrogen chloride, yields *ethyl disulphaminebenzoate*,  $\text{COOEt} \cdot \text{C}_6\text{H}_3(\text{SO}_2\text{NH}_2)_2$ , which is converted into the *potassium salt*  $\text{NHK} \cdot \text{SO}_2 \cdot \text{C}_6\text{H}_3 < \begin{smallmatrix} \text{CO} \\ \text{SO}_2 \end{smallmatrix} > \text{NK}$ , when treated with alcoholic potash, and into *sulphaminebenzoic sulphinide* with aqueous potash.

W. P. W.

**"Saccharin."** By E. MAUMENÉ (*Bull. Soc. Chim.*, **47**, 92—94).—Fahlberg's "saccharin," as prepared by his patent, is not a definite compound, but is composed of at least two components, which appear to be mixed in equal proportions; neither the mixture nor either of its components agree in composition with the formula given by Fahlberg.

A. P.

**Indole from Dichlorether and Aniline.** By J. BERLINERBLAU (*Monatsh. Chem.*, **8**, 180—186).—Indole is prepared by heating 50 grams of aniline with an equal volume of water in a reflux apparatus, and gradually adding 25 grams of dichlorether. After being boiled for one hour, the excess of aniline is boiled off, and the residue heated for four to six hours at 210—230°. The indole is obtained by steam distilling.

The formation of indoles from dichlorether and aromatic amines is a general reaction.

N. H. M.

**Synthesis of Indonaphthene-derivatives.** By W. ROSER (*Ber.*, **20**, 1574—1576).—*Methylindonaphthenecarboxylic acid*,

is obtained when ethyl benzylacetoacetate is gently heated with about six times its weight of concentrated sulphuric acid for a short time. It crystallises from alcohol in needles, melts at 200°, and when reduced with sodium amalgam is converted into *methylhydrindonaphthene-carboxylic acid*,  $\text{C}_6\text{H}_4 < \begin{smallmatrix} \text{CHMe} \\ \text{CH}_2 \end{smallmatrix} > \text{CH} \cdot \text{COOH}$ , which melts at 76°.

*Methylindonaphthenecarboxylic acid*, when suspended in chloroform and treated with bromine (1 mol.), is converted into a bromine-derivative,  $\text{C}_{10}\text{H}_8\text{Br} \cdot \text{COOH}$ . This acid crystallises in needles, melts at 245°, and is sparingly soluble in alcohol.

The dihydronaphthoic acid obtained by v. Pechmann (*Abstr.*, 1883, 808) by the action of sulphuric acid on ethyl benzylacetoacetate is most probably identical with methylindonaphthenecarboxylic acid.

W. P. W.

**Preparation of Paradinitrobenzyl.** By W. ROSER (*Annalen*, **238**, 363—366).—Paradinitrobenzyl is formed when paranitrobenzyl chloride is treated with a strongly alkaline solution of stannous chloride.

W. C. W.

**Triphenylmethane-derivatives.** By E. KOCK (*Ber.*, **20**, 1562—1566).—Attempts to form derivatives of triphenylmethane by the condensation of primary amines of the meta-series and aromatic

aldehydes with or without the addition of zinc chloride, led either to no result or to the formation of resinous products from which crystalline compounds could not be isolated; the substitution of the corresponding hydrochlorides for the bases, or of meta- or para-nitrobenzaldehyde for benzaldehyde produced no difference. When, however, tertiary amines of the meta-series are employed, condensation compounds are readily obtained.

*Tetramethdiamidoditololnitrophenylmethane,*

is formed when dimethylmetatoluidine (8 parts) and paranitrobenzaldehyde (5 parts) is heated with zinc chloride and hydrochloric acid at  $110^\circ$  for four hours. It crystallises from a mixture of alcohol and benzene in glistening, golden-yellow scales, and melts at  $224^\circ$ . The *picrate*,  $\text{C}_{37}\text{H}_{35}\text{N}_9\text{O}_{16}$ , forms small, bright-yellow crystals, melts at  $199^\circ$ , and is sparingly soluble in alcohol, ether, benzene, and light petroleum. On reduction, preferably with stannous chloride, the *leuco-base*,  $\text{C}_{25}\text{H}_{31}\text{N}_3$ , is obtained, and crystallises from alcohol in greyish aggregates melting at  $139^\circ$ . The colour remains unaltered after lengthened exposure to the air, but the alcoholic solution of the base after addition of acetic acid gives with chloranil a wine-red colour quickly changing to a dull-brown. A platinochloride of constant composition could not be obtained.

*Tetramethdiamidodichloronitrotriphenylmethane,*

is formed under similar conditions from dimethylmetachloraniline and paranitrobenzaldehyde, and crystallises from benzene in citron-yellow scales melting at  $208^\circ$ . The *picrate*,  $\text{C}_{35}\text{H}_{29}\text{N}_9\text{O}_{16}\text{Cl}_2$ , melts at  $189^\circ$ . When reduced with zinc-dust and acetic acid the corresponding *leuco-base*,  $\text{C}_{23}\text{H}_{25}\text{N}_3\text{Cl}_2$ , is obtained, and crystallises from a mixture of alcohol and benzene in almost colourless aggregates melting at  $181^\circ$ . It is unaltered on exposure to the air, yields no coloration on oxidation with chloranil or lead dioxide, and does not form a platinum salt of constant composition.

Metanisidine and paranitrobenzaldehyde readily form a condensation compound without the addition of zinc chloride; the yield, however, is a proportionately small one. The base,

crystallises from benzene in yellowish-brown scales, melts at  $189^\circ$ , and on reduction yields a readily oxidisable *leuco-base*, which assumes an intense bluish-violet colour on exposure to the air. W. P. W.

**$\gamma$ -Dichloronaphthalene and Monochlorophthalic Acid.** By I. GUARESCHI (*Gazzetta*, **17**, 119—126).—The chlorine atoms in  $\gamma$ -dichloronaphthalene, considering the methods of its formation, must be situated in two different nuclei, both being probably in the  $\alpha$ -position. On oxidation with chromic acid in presence of acetic acid, dichloronaphthalene yields a *monochlorophthalic acid*,  $\text{C}_6\text{H}_3\text{Cl}(\text{COOH})_2$  [ $\text{Cl} : (\text{COOH})_2 : \text{O} =$

1 : 2 : 3], together with a quinone-derivative. The acid crystallises in long, colourless needles, which melt at  $184^{\circ}$ , and are at the same time converted into the anhydride. When heated with phenol and concentrated sulphuric acid, it yields a phthalein, dissolving in potash with violet coloration. The *silver* salt is a crystalline precipitate; the *anhydride* sublimes in colourless needles. This acid is not identical with the monochlorophthalic acids previously described.

The dibromonaphthalene, melting at  $130^{\circ}$ , yields on oxidation with chromic acid, under conditions similar to those used with the chloro-derivative, a monobromophthalic acid, identical with that obtained by the author in the oxidation of monobromonaphthalene.

V. H. V.

**Action of Bromine on Diamido- $\alpha$ -naphthol.** By T. ZINCKE and C. GERLAND (*Ber.*, **20**, 1510—1516).—*Bromamido- $\alpha$ -naphthaquinoneimide*,  $\text{NH}_2 \cdot \text{C}_{10}\text{H}_4\text{Br} < \begin{smallmatrix} \text{O}^- \\ \text{NH} \end{smallmatrix} >$ , is formed when the zincchloride of diamidonaphthol (10 grams) is finely rubbed with glacial acetic acid and 5 to 6 c.c. of bromine added. It is washed with glacial acetic acid, stirred with strong ammonia, filtered and crystallised from alcohol. It forms orange-yellow needles which melt at  $200.5^{\circ}$ , and dissolves readily in hot alcohol and hot benzene; it is insoluble in water. The platinochloride,  $(\text{C}_{10}\text{H}_7\text{BrN}_2\text{O})_2, \text{H}_2\text{PtCl}_6$ , crystallises in brown needles.

*Bromamido- $\alpha$ -naphthaquinone*,  $\text{NH}_2 \cdot \text{C}_{10}\text{H}_4\text{BrO}_2$ , is obtained by boiling the above imide with much water with repeated additions of sulphuric acid. It crystallises in intensely orange-coloured needles of a silky lustre, which melt at  $205^{\circ}$  and sublime without decomposition. When boiled with alkali it is converted into bromohydroxyquinone. The *acetyl compound* crystallises in sulphur-coloured plates melting at  $136-137^{\circ}$ .

*Bromohydroxy- $\alpha$ -naphthaquinoneoximide*,  $\text{OH} \cdot \text{C}_{10}\text{H}_4\text{Br} < \begin{smallmatrix} \text{O}^- \\ \text{NH} \end{smallmatrix} >$ , is best prepared by boiling bromamido- $\alpha$ -naphthaquinoneimide with dilute aqueous soda, and adding alcohol from time to time. It is then allowed to settle, and the residue again boiled with soda. It forms deep, brownish-red, slender, lustrous needles, and melts at about  $265^{\circ}$ ; it is sparingly soluble. It does not decompose carbonates. The *sodium salt* crystallises in red needles. The *acetyl compound* forms hair-like, red needles melting at  $270^{\circ}$ . The oximide is identical with that formed by the action of ammonia on bromo- $\beta$ -naphthaquinone.

Bromohydroxy- $\alpha$ -naphthaquinone (Diehl and Merz, *Ber.*, **11**, 1066) is formed when bromamidonaphthaquinone is boiled with dilute alkali, when bromohydroxynaphthaquinoneoximide is boiled with strong hydrochloric acid, and when bromo- $\beta$ -naphthaquinone is treated with alkali.

N. H. M.

**Derivatives of  $\beta$ -Naphthylamine.** By L. MASCHKE (*Chem. Centr.*, 1886, 824).— $\beta$ -Naphthylamine (6 mols.) when heated with acetic chloride (3 mols.) and phosphorous chloride (1 mol.) at  $150^{\circ}$  is converted into ethenyl- $\beta$ -dinaphthylamidine,  $\text{C}_{10}\text{H}_7 \cdot \text{NH} \cdot \text{CMe} : \text{N} \cdot \text{C}_{10}\text{H}_7$ , melting at  $168^{\circ}$ . The corresponding benzenyl-derivative, melting at

155°, is prepared in like manner. A mixture of  $\beta$ -naphthylamine (15 grams) and ethylene bromide (3 grams) heated at 150° yields  $\beta$ -ethylenedinaaphthylamine,  $C_2H_4(C_{10}H_7NH)_2$ , which melts at 153°.

*Dinitro- $\beta$ -acelnaphthalide*,  $C_{10}H_5(NO_2)_2 \cdot NAc$ , is obtained in two isomeric forms, melting at 185° and 235° respectively, by the action of fuming nitric acid on  $\beta$ -acelnaphthalide. These compounds resist the action of reducing agents.

*Phthal- $\beta$ -naphthylimide*,  $C_{10}H_7N \begin{smallmatrix} CO \\ < \\ CO \end{smallmatrix} C_6H_4$ , melting at 218°, is obtained by heating together  $\beta$ -naphthylamine (1 mol.) and phthalic anhydride (1 mol.).

The  $\alpha$ -derivative, melting at 182°, is obtained in like manner.

C. F. C.

**Substituted Naphthylenediamines.** By J. ANNAHEIM (*Ber.*, 20, 1371—1374).—The author has investigated the action of aniline, &c., on dihydroxynaphthalene.

When dihydroxynaphthalene and aniline are mixed together, some aniline hydrochloride or aqueous hydrochloric acid added, and the whole heated at 160°, *diphenylnaphthylenediamine*,  $C_{10}H_6(NHPh)_2$ , is obtained. It forms small, glistening crystals soluble in ether, benzene, boiling alcohol, &c. It melts at 163—164° (uncorr.), easily enters into reaction, and when slightly warmed with zinc chloride gives a violet coloration, which disappears on the addition of water.

*Paraditolynaphthylenediamine*,  $C_{10}H_6(NH \cdot C_7H_7)_2$ , obtained in like manner from paratoluidine, crystallises in small needles melting at 236—237° (uncorr.). It is almost insoluble in the ordinary solvents, but dissolves in boiling xylene and cumene. It reacts with zinc chloride in the same way as the phenyl-derivative.

L. T. T.

**Amidonaphthyl Mercaptans.** By A. W. HOFMANN (*Ber.*, 20, 1798—1805).—*Benzenylamido- $\alpha$ -naphthyl mercaptan*,  $C_{10}H_6 \begin{smallmatrix} N \\ < \\ S \end{smallmatrix} CPh$ , is prepared by heating 2 parts of naphthylbenzamide with 1 part of sulphur. The yield is only about 10 per cent. It crystallises in tufts of needles, melts at 100—101°; can be distilled without decomposition at high temperatures, is readily soluble in alcohol and acetic acid, and is practically destitute of basic properties.

*Methenylamido- $\alpha$ -naphthyl mercaptan*,  $C_{10}H_6 \begin{smallmatrix} N \\ < \\ S \end{smallmatrix} CH$ , prepared in like manner from  $\alpha$ -naphthylformamide, is a colourless oil insoluble in water; it distils with steam. The platinochloride,

crystallises in needles.

When  $\alpha$ -naphthylacetamide is heated with sulphur, hydrogen sulphide is evolved, *ethenylamido- $\alpha$ -naphthyl mercaptan* distils, whilst the residue consists mainly of the oxalyl-compound. The former resembles the methenyl-compound, but does not distil so readily with steam; its platinochloride,  $(C_{12}H_9NS)_2, H_2PtCl_6$ , is more soluble, and crystallises in needles.

*Oxalyldiamido- $\alpha$ -naphthyl mercaptan*,  $C_{10}H_6 \begin{smallmatrix} N \\ \diagdown \\ S \end{smallmatrix} \begin{smallmatrix} \diagup \\ N \end{smallmatrix} C \cdot C \begin{smallmatrix} N \\ \diagup \\ S \end{smallmatrix} \begin{smallmatrix} \diagdown \\ N \end{smallmatrix} C_{10}H_6$ , crystallises in golden-yellow plates, which melt far above  $300^\circ$  with considerable carbonisation; it can be sublimed, but the greater part is always destroyed in the operation. It is scarcely soluble in the ordinary solvents, but can be dissolved in high-boiling petroleum, aniline, or best, nitrobenzene. When fused with potash it yields oxalic acid and *amidonaphthyl mercaptan*,  $NH_2 \cdot C_{10}H_6 \cdot SH$ , but from the extreme readiness with which this is converted into the bisulphide it could only be obtained in an impure condition as a viscid oil. The bisulphide is a golden-yellow powder, insoluble in alcohol and ether.

*Benzenylamido- $\alpha$ -naphthyl mercaptan* crystallises in interlaced needles melting at  $107^\circ$ . Its alcoholic solution shows a green fluorescence. The platinochloride,  $(C_{17}H_{11}NS)_2 \cdot H_2PtCl_6$ , and aurochloride were prepared.

*Oxalyldiamido- $\alpha$ -naphthyl mercaptan* forms yellow, crystalline plates, and closely resembles the  $\alpha$ -compound. *Amido- $\beta$ -naphthyl mercaptan* also could only be obtained in admixture with the bisulphide.

A. J. G.

**Naphthoic Acids.** By Å. G. EKSTRAND (*Ber.*, 20, 1353—1361).—The dinitro- $\alpha$ -naphthoic acid (m. p.  $265^\circ$ ), previously described (this vol., p. 373, and *Abstr.*, 1886, 948), when reduced with tin and hydrochloric acid yields, Aguiar's diamido-acid, obtained from the so-called  $\beta$ -dinitronaphthalene, which the author showed (*Abstr.*, 1886, 155) to be the  $\alpha$ - $\alpha$ -compound. This naphthoic acid must therefore have the constitution  $[NO_2 : NO_2 : COOH = 1 : 1' : 4]$ .

$\alpha$ -*Mononaphthoylhydroxamic acid*,  $C_{10}H_7 \cdot CO \cdot NH \cdot OH$ , is formed by the reaction of equal molecular proportions of hydroxylamine and  $\alpha$ -naphthoic chloride. It crystallises in glistening scales, soluble in boiling water, almost insoluble in alcohol, and melts at  $186$ — $187^\circ$ . It forms a potassium salt, but this decomposes very readily with formation of  $\alpha$ -naphthylamine. When treated with  $\beta$ -naphthoic chloride the above acid yields  $\alpha$ - $\alpha$ -dinaphthyl-carbamide. Together with the above mono-acid,  $\alpha$ - $\alpha$ -dinaphthoylhydroxamic acid,  $OH \cdot N(CO \cdot C_{10}H_7)_2$ , is always formed. This crystallises in needles melting at  $150^\circ$ , and soluble in boiling alcohol. Its *potassium salt* crystallises in needles soluble in alcohol.

$\beta$ -*Mononaphthoylhydroxamic acid*, prepared from  $\beta$ -naphthoic chloride, forms small, quadratic scales, easily soluble in alcohol, and melting at  $168^\circ$ .  $\beta$ - $\beta$ -*Dinaphthoylhydroxamic acid* yields small needles melting at  $171^\circ$ . The *potassium salts* of both acids are crystalline.  $\beta$ - $\beta$ -*Dinaphthoylcarbamide* crystallises in needles melting at  $286^\circ$ .

$\alpha$ - $\beta$ -*Dinaphthoylhydroxamic acid* is obtained by heating the  $\beta$ -mono-derivative with  $\alpha$ -naphthoic chloride at  $100^\circ$ . It crystallises from boiling alcohol in needles melting at  $160^\circ$ .

L. T. T.

**Action of Sodium on Alcoholic  $\beta$ -Naphthonitrile.** By E. BAMBERGER and O. BOECKMANN (*Ber.*, 20, 1711—1712).—*Tetrahydro- $\beta$ -naphthobenzylamine*,  $C_{10}H_{11} \cdot CH_2 \cdot NH_2$ , is obtained by gradually adding 10 grams of sodium to a hot solution of 10 grams of  $\beta$ -naphthonitrile

in 100 grams of alcohol. It is a colourless liquid of odour closely resembling that of the  $\alpha$ -compound (this vol., p. 719), boils at  $270\cdot2^\circ$  (corr.) under 729 mm. pressure, and does not fluoresce when pure. It is a strong non-acid base, which absorbs carbonic anhydride from the air. The hydrochloride,  $C_{11}H_{16}NCl$ , crystallises in tufts of needles and melts at  $228\cdot5$ — $229^\circ$ ; the platinochloride,  $(C_{11}H_{16}NCl)_2PtCl_4$ , forms small, lustrous, yellow needles; the sulphate crystallises in long, lustrous, thin prisms. The bye-products of the reaction are dihydronaphthalene, identical with that obtained from the  $\alpha$ -compound (*loc. cit.*), ammonia, hydrogen cyanide,  $\beta$ -naphthoic acid, and frequently  $\beta$ -naphthamide. Of these, the first alone occurs in any considerable quantity.

A. J. G.

**Trimethylnaphthalene.** By L. MASCHKE (*Chem. Centr.*, 1886, 824).— $\beta$ -Naphthylamine was heated with methyl iodide and methyl alcohol at  $100^\circ$ , and the resulting ammonium iodide heated for some hours at  $300$ — $335^\circ$ . From the resinous product, the hydrocarbon was isolated by distillation with steam. It boils at  $275^\circ$ , and yields a well defined picrate melting at  $132$ — $133^\circ$ .

C. F. C.

**2 : 3 Dimethylantraquinone.** By K. ELBS and H. EURICH (*Ber.*, 20, 1361—1363).—2 : 3 *Dimethylantraquinone* was obtained by heating F. Meyer's orthoxylenephthalic acid,

(*Abstr.*, 1882, 848). It is best crystallised from xylene, and melts at  $183^\circ$ . It resembles anthraquinone in properties. When heated with nitric acid (sp. gr. 1.1) at  $210$ — $220^\circ$  it yields 2 : 3 *anthraquinonedicarboxylic acid*; this crystallises in yellow needles, is sparingly soluble in the usual solvents, and melts at  $340^\circ$ . It dissolves in ammonia to a red solution, which, however, cannot be evaporated without decomposition. Its salts all have a reddish colour. When treated with water it is converted into yellow needles of the *anhydride* which melt at  $290^\circ$ . The ammoniacal solution is reduced by zinc-dust to 2 : 3 *anthracenedicarboxylic acid*, which forms a crystalline powder melting at  $345^\circ$ . The quinone yields with ammonia and zinc-dust 2 : 3 *dimethylanthracene* melting at  $246^\circ$ . The *picrate* forms unstable, red needles.

L. T. T.

**1 : 3 Dimethylantraquinone.** By K. ELBS and M. GÜNTHER (*Ber.*, 20, 1364—1367).—This compound has already been briefly described by Elbs (*Abstr.*, 1886, 557). When oxidised with dilute nitric acid it yields 1 : 3 *anthraquinonedicarboxylic acid*, which is sparingly soluble in the usual solvents, crystallises in needles, and is still solid at  $330^\circ$ . When reduced with zinc-dust in ammoniacal solution, this acid yields 1 : 3 *anthracenedicarboxylic acid*. This is a crystalline powder, sparingly soluble in the usual solvents, and still solid at  $330^\circ$ . When the quinone is reduced with zinc-dust in ammoniacal solution no dimethylanthracene is formed, but a compound of the composition  $C_{16}H_{12}$  is obtained; this is readily soluble in boiling alcohol, crystallises in scales, and melts at  $85^\circ$ . It

forms a compound with picric acid, crystallising in brownish-red scales melting at  $135^{\circ}$ . Chromic acid in acetic solution reconverts it into the quinone. Its constitution is not yet definitely settled.

L. T. T.

**Derivatives of Camphor.** By L. BALBIANO (*Gazzetta*, **17**, 95—99).—When bromocamphor is heated with phenylhydrazine it yields camphyldiphenyldehydrazine,  $\text{N}_2\text{PhH}_2\cdot\text{C}_{10}\text{H}_{15} : \text{N}_2\text{HPh}$ .

Four monochlorocamphors have been described; it is here shown that one of the physically isomeric chlorocamphors obtained by Cazenueve by the direct chlorination of camphor, is identical with that obtained by Schiff and Puliti by the decomposition of chlorocamphor-carboxylic acid. This compound, which melts at  $92\text{--}92.5^{\circ}$ , when heated with phenylhydrazine yields a camphyldiphenyldehydrazine, melting at  $55\text{--}56^{\circ}$ , and identical with that obtained from bromocamphor. The other physical isomeride, melting at  $100.5^{\circ}$ , but softening at  $94.5^{\circ}$ , yields under similar conditions the same phenylhydrazine-derivative. These experiments further confirm the view that camphor contains the ketonic group.

V. H. V.

**Isomeric Mononitro-camphors.** By P. CAZENEUVE (*Compt. rend.*, **104**, 1522—1525).—600 grams of granulated zinc is treated with 1000 c.c. of a 10 per cent. solution of copper sulphate, and when the copper is deposited, the metal is washed and mixed with 1500 grams of alcohol of  $93^{\circ}$  and 300 grams of the chloronitrocamphors obtained by the action of fuming nitric acid on monochlorocamphor. The mixture is heated to boiling for five minutes, and the alcohol decanted off in order to stop the reaction. When the brown liquid has cooled, it is mixed with zinc-dust, filtered, concentrated to two-thirds, mixed with a warm concentrated solution of 120 grams of sodium carbonate, heated with agitation, diluted with 2000 c.c. of water, boiled with animal charcoal, and filtered. The nitrocamphors are precipitated by adding hydrochloric acid, and the precipitate is treated with cold alcohol of  $60^{\circ}$ , which dissolves the  $\beta$ -nitrocamphor, but leaves the  $\alpha$ -derivative undissolved.

The  $\alpha$ -nitrocamphor is crystallised from boiling alcohol of  $93^{\circ}$ , and then from benzene. It forms large, rhombic prisms, insoluble in water but soluble in strong alcohol, and very soluble in benzene. It melts at  $100\text{--}101^{\circ}$ , and decomposes at  $160^{\circ}$ ; it burns quietly on platinum foil, and does not detonate when rapidly heated. Its solution in benzene is lævogyrate, the rotatory power diminishing as the concentration increases.  $\alpha$ -Nitrocamphor reddens litmus and decomposes carbonates, forming well-defined salts. An alcoholic solution of the copper salt is maroon-coloured, of the ferrous salt garnet-red, of the ferric salt blood-red. The quinine salt crystallises readily with alcohol.  $\alpha$ -Nitrocamphor forms ethereal salts. It is not affected by concentrated potash or soda, but when heated with water in sealed tubes it yields ammonia and nitric acid. With a mixture of sulphuric acid and fuming nitric acid it seems to form a dinitro-derivative, which is decomposed by water with evolution of nitric oxide and formation of camphoric anhydride.

$\beta$ -Nitrocamphor crystallises with difficulty in microscopic, arborescent

forms. It is very soluble in dilute alcohol and in benzene, the alcoholic solution being dextrogyrate, whilst the benzene solution is feebly lævogyrate. It alters readily and becomes yellow when heated. It is decomposed by boiling alkalis, and its salts are much more soluble than those of the  $\alpha$ -derivative.

Another isomeride exists, and will be described in a subsequent paper.  
C. H. B.

**Anemonin.** By HANRIOT (*Compt. rend.*, 104, 1284—1286).—Anemonin was obtained by Heyer from various species of anemones. The author prepared it by distilling *Anemone pulsatilla* in a current of steam until the distillate no longer gave a yellow coloration with potash. The distillate was redistilled and allowed to remain in a cool place for several months, when it deposited the anemonin, which was purified by solution in alcohol and recrystallisation from benzene, from which it separates in slender needles of the composition  $C_{15}H_{12}O_6$ . A product is also obtained which has practically the same composition, but is insoluble in alcohol.

Anemonin melts at  $156^\circ$ , and decomposes at  $270^\circ$  with partial sublimation of anemonin and a liquid which appears to be an aldehyde. With zinc-dust or with hydriodic acid in sealed tubes, it gives no distinct reaction, but a small quantity of a hydrocarbon is formed which seems to be cymene or cumene.

If anemonin is dissolved in chloroform and treated with excess of bromine it yields the compound  $C_{15}H_{12}O_6Br_4$ ; this crystallises from benzene in octahedra which do not melt without decomposition.

When treated with nascent hydrogen in an acid solution anemonin yields hydroanemonin,  $C_{15}H_{20}O_6$ , which crystallises from boiling petroleum in large, colourless lamellæ which contain 1 mol.  $H_2O$ , melt at  $78^\circ$ , and distil without decomposition at  $210$ — $212^\circ$  under a pressure of 10 mm. Hydroanemonin is much more stable than anemonin. It is insoluble in cold solutions of the alkalis, yields no derivative with acetic anhydride, and no chlorine-derivative with phosphorus pentachloride. The latter reagent only partially converts it into anemonin.

C. H. B.

**Action of Acetic Anhydride on Methylpyrroline and Benzylpyrroline.** By G. CIAMICIAN and P. SILBER (*Ber.*, 20, 1368—1370).—Ciamician and Dennstedt have already described (*Abstr.*, 1885, 378) a monacetyl-derivative of methylpyrroline. By using a very large excess of anhydride and heating for eight hours at  $250^\circ$ , the authors have obtained *diacetomethylpyrroline*,  $C_4NH_2MeAc_2$ . This crystallises in colourless needles melting at  $133$ — $134^\circ$ , and is easily soluble in ether, alcohol, benzene, chloroform, and boiling water.

The authors obtained a *benzylpyrroline* by heating the potassium compound of pyrroline with benzyl chloride. It is solid at ordinary temperatures, but melts with the warmth of the hand to a colourless liquid which boils at  $247^\circ$  (uncorr.). It is almost insoluble in water, easily soluble in alcohol and ether. When heated at  $240^\circ$  for some hours with a large excess of acetic anhydride, it yields *diaceto-benzylpyrroline*,  $C_7H_7 \cdot C_4NH_2Ac_2$ , which crystallises in colourless needles, is soluble in alcohol, and melts at  $129$ — $130^\circ$ .

L. T. T.

**Action of Propionic Anhydride on Pyrroline.** By M. DENNSTEDT and J. ZIMMERMANN (*Ber.*, 20, 1760—1762).—It has been shown that two isomeric acetyl-derivatives are obtained by the action of acetic anhydride on pyrroline; a similar result is obtained by heating pyrroline with propionic anhydride and sodium propionate in a reflux apparatus, when two propionylpyrrolines are obtained, of which one only distils with steam. The yield is not good.

*Propionylpyrroline*,  $C_4NH_3 \cdot COEt$  [ $COEt = 1$ ], is a viscid, yellowish oil which distils at  $192-194^\circ$ , can also be distilled with steam, and is decomposed by alkalis into pyrroline and propionic acid.

The isomeric propionylpyrroline, [ $COEt = 2$  or  $3$ ], crystallises in colourless needles, melts at  $52^\circ$ , boils at  $222-225^\circ$ , is soluble in alkalis without decomposition, and yields a white, crystalline silver-derivative,  $C_4NH_3Ag \cdot COEt$  [ $Ag : COEt = 1 : 2$  or  $3$ ].

*Dipropionylpyrroline*,  $C_4NH_3(COEt)_2$ , obtained by heating 5 grams of pyrroline with 50 grams of propionic anhydride at  $260^\circ$ , crystallises in colourless plates, and melts at  $126-117^\circ$ . A. J. G.

**Preparation of Halogen-derivatives of Pyridine Bases from the Pyridinecarboxylic Acids.** By G. PFEIFFER (*Ber.*, 20, 1343—1353).—It is well known that the pyridine bases are very indifferent towards substitution-reagents, and very few substitution-products are at present known. The author finds that halogen substitution-products may easily be made through the mediation of the carboxylic acids.

Bromine does not act on collidinedicarboxylic acid in either alkaline or acid solution, but when added to a neutral solution of the potassium salt, carbonic anhydride is evolved and *symmetrical dibromocollidine*,  $CMe \begin{smallmatrix} \text{CBr} \cdot CMe \\ \text{CBr} : CMe \end{smallmatrix} N$ , is obtained. This forms snow-white, nacreous crystals soluble in alcohol and ether, almost insoluble in water. It melts at  $81^\circ$  and boils at  $262-263^\circ$  under a pressure of 726 mm. and volatilises slowly even at ordinary temperatures. It is a feeble base, dissolves in hot concentrated hydrochloric acid, and the solution on cooling deposits small, polyhedric crystals of the *hydrochloride*  $C_8NH_9Br_2 \cdot HCl$ . This is easily soluble in water, and the aqueous solution decomposes on boiling. The dry substance sublimes slightly when rapidly heated, but decomposes into its components even at  $100^\circ$ , very rapidly at about  $200^\circ$ . With bromine it yields a dibromide,  $C_8NH_9Br_2 \cdot Br_2 \cdot HCl$ . The *platinochloride* forms orange needles containing 2 mols.  $H_2O$  which it loses at  $120^\circ$ : the *dichromate* melts at  $146^\circ$ ; the *picrate* at  $159-160^\circ$ ; the *aurochloride* forms yellow needles. When oxidised with permanganate the base yields *dibromopyridinetri-carboxylic acid*,  $C_5NBr_2(COOH)_3$ , crystallising in needles soluble in boiling water, sparingly so in alcohol and ether. It melts with decomposition at  $204-206^\circ$ . The *monopotassium salt*,

forms colourless needles soluble in hot water. This salt is not decomposed by mineral acids, and the free acid is best obtained from the *silver salt*,  $C_5NBr_2(COOAg)_3$ , which forms an insoluble, crystalline powder. Ferrous sulphate gives a carmine coloration. When heated

in glacial acetic solution no decomposition takes place; when the acid is heated alone all three carboxyl-groups are eliminated and Hofmann's 3 : 5 dibromopyridine formed. When dibromocollidine is heated with sodium ethoxide, 3 : 5 *diethoxycollidine*,  $C_5NMe_3(OEt)_2$ , is formed; it boils at 217—219° under 726 mm. pressure.

Symmetrical potassium lutidine dicarboxylate yields with bromine *dibromolutidine*,  $C_5NHMe_2Br_2$ . It very closely resembles dibromocollidine in appearance, and melts at 65°.

Quinolinic acid when treated with bromine under like conditions yields 3 : 5 dibromopyridine, and the same compound was formed by the action of bromine on pyridinepentacarboxylic acid.

When quinolinic acid in slightly alkaline solution is treated with iodine, *diiodohydroxypyridine*,  $C_5NH_2I_2(OH)$  [ $OH : I : I = 2 : 3 : 5$ ], is formed. This forms light-brown needles sparingly soluble in alcohol, ether, and boiling water (the latter solution having an acid reaction) and melting at 257—259°. When heated very carefully it sublimes in colourless needles, but decomposes if heated rapidly. It dissolves in moderately strong sulphuric acid, but is reprecipitated unchanged on the addition of water. Its acid character is more marked, the *sodium compound* crystallising with  $3H_2O$  in colourless scales. It also forms well-marked compounds with many other metals. L. T. T.

**Action of Chloral on  $\alpha$ -Picoline.** By A. EINHORN and A. LIEBRECHT (*Ber.*, 20, 1592—1594).—When equimolecular proportions of  $\alpha$ -picoline and chloral are mixed together, rise of temperature occurs, and a white, crystalline mass is obtained which yields *w-trichloro- $\alpha$ -hydroxypropylpyridine*,  $C_5NH_4 \cdot CH_2 \cdot CH(OH) \cdot CCl_3$ , if it is heated for 8 to 10 hours either with or without zinc chloride. This compound crystallises from dilute alcohol in beautiful, six-sided tables, melts at 86—87°, and yields well-characterised salts with acids. The *hydrochloride*,  $C_6H_8NOCl_3 \cdot HCl$ , crystallises in compact, long needles, melts at 201—202°, and is soluble in absolute alcohol. When heated with alcoholic potash, the base is converted into  $\alpha$ -pyridylacrylic acid, which forms a white, crystalline *hydrochloride*,  $C_6H_7NO_2 \cdot HCl$ , melting at 220° with decomposition. W. P. W.

**Behaviour of the Nitrobenzaldehydes towards Ethyl Acetoacetate and Ammonia.** By R. LEPETIT (*Ber.*, 20, 1338—1343).—The author has investigated the action of ammonia and ethyl acetoacetate on the three isomeric nitrobenzaldehydes. When metanitrobenzaldehyde (1 mol.), ethyl acetoacetate (2 mols.), and a slight excess of ammonia are heated in alcoholic solution, *ethyl metanitrophenyllutidinehydrodicarboxylate*,  $NO_2 \cdot C_6H_4 \cdot C_5NH_2Me_2(COOEt)_2$ , is formed. It is easily soluble in alcohol, ether, chloroform, and acetone, crystallises in plates, and melts at 161°. When a small quantity of fuming nitric acid is added to an alcoholic solution and a current of nitrous acid then passed in, *ethyl metanitrophenyllutidinedicarboxylate*,

is produced. It crystallises in colourless plates, soluble in ether and alcohol, and melting at 65°. The *nitrate* forms colourless, acicular

crystals melting at 129—130°; the *platinochloride*, orange crystals melting at 202°. When treated with tin and hydrochloric acid the ethyl salt yields *ethyl metamidophenyllutidinedicarboxylate*, which is soluble in alcohol and ether, crystallises in plates, and melts at 109—110°. This compound is bibasic, and forms a *platinochloride*,

which crystallises in yellow needles, loses water at 110—120°, and decomposes at about 260° without previous fusion. This amido-compound acts as a primary aromatic amine, and may be diazotised, &c.

Paranitrobenzaldehyde reacts in a similar way, but the reaction does not take place so smoothly, a great deal of secondary products and resinous matter are formed, and the yield is very small. The hydro-compound was not obtained quite pure, but is crystalline and melts at about 118—122°.

With orthonitrobenzaldehyde the reaction takes place differently. A substance,  $\text{C}_{19}\text{H}_{20}\text{N}_4\text{O}_5$ , is always formed as well as the hydro-salt, and the yield of these two substances appears to be better when equimolecular proportions of ethyl acetoacetate and nitrobenzaldehyde are taken than when the usual proportion 2:1 is employed. *Ethyl orthonitrophenyllutidinedihydrodicarboxylate* forms pale-yellow, rhombic plates, is soluble in alcohol and ether, and melts at 119—120°. It is insoluble in dilute acids. When oxidised with nitrous acid so little crystallisable substance was obtained that the non-hydrogenised compound could not be obtained in a pure state. The compound,  $\text{C}_{19}\text{H}_{20}\text{N}_4\text{O}_5$  (possibly  $\text{C}_{19}\text{H}_{22}\text{N}_4\text{O}_5$ ), mentioned above is very sparingly soluble in alcohol, crystallises in yellow needles, and melts at 189°: it has basic properties. The *hydrochloride*,  $\text{C}_{19}\text{H}_{21}\text{N}_4\text{O}_5\text{Cl}$ , forms a sparingly soluble, yellow powder, loses hydrogen chloride in dry air, rapidly at 100°, and melts with partial decomposition at 150°; it also forms a *platinochloride*. This compound is unstable, and, when it is boiled with hydrochloric acid, ethyl chloride and carbonic anhydride are evolved, whilst orthonitrobenzaldehyde is amongst the residual products. Attempts at hydrolysis and reduction were unsuccessful. When nitrous acid is passed through alcohol in which the base is suspended, solution takes place, and, after a time, white needles separate which have the same composition,  $\text{C}_{19}\text{H}_{20}\text{N}_4\text{O}_5$ , as the base, but are non-basic in character, and decompose at 192°.

With phenylhydrazine all three nitrobenzaldehydes react in the usual way with formation of hydrazides of the constitution  $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CH}:\text{N}_2\text{HPh}$ . The *ortho*-compound forms small, ruby-red prisms melting at 152°; the *para*-compound dark-red crystals, with a bluish surface fluorescence, and melting at 155°; and the *meta*-compound scarlet crystals melting at 120°.

L. T. T.

**Cinchonic Acid.** By A. CLAUS and M. KICKELHAYN (*Ber.*, 20, 1604—1606).—Whilst engaged in the preparation of a large quantity of cinchonic acid, obtained by the oxidation of 6 kilos. of cinchonine with nitric acid, the authors have observed that it crystallises in three forms: 1, in the well-known, slender, caffeine-like needles with

1 mol. of  $\text{H}_2\text{O}$ ; 2, with 2 mols. of  $\text{H}_2\text{O}$  in the triclinic forms described by Muthmann and Nef (this vol., p. 598); and, 3, in monoclinic tables also with 2 mols. of  $\text{H}_2\text{O}$ . The first form is always obtained when the hot, concentrated solution of the acid is allowed to cool during crystallisation; the third form separates during the slow evaporation of dilute aqueous solutions of the pure acid; whilst the second form, according to the authors' experience, is got by the slow crystallisation of solutions of the acid containing some impurity such as mineral acid, and, after repeated recrystallisation, yields the third form on the slow evaporation of its dilute aqueous solution.

The crystallographic measurements of the third form agree with those of Ditscheiner (*Annalen*, **173**, 84), and, consequently, Muthmann and Nef's conclusions cannot be maintained. The crystals are monoclinic,  $a : b : c = 0.2758 : 1 : 0.5328$ ;  $\beta = 98^\circ 3'$ ; and the following faces were observed:  $\infty R_\infty$ ,  $\infty P$ ,  $R_\infty$ , and  $\frac{1}{3}R_\infty$ . W. P. W.

**Synthesis of Quinoline-derivatives.** By L. KNORR (*Ber.*, **20**, 1397—1399).—When ethyl  $\beta$ -phenylamido- $\alpha$ -crotonate is heated at  $190$ — $200^\circ$  it yields  $\gamma$ -hydroxy-quinoline described by Conrad. By the action of dry sodium ethylate on the crotonate the author obtained a compound,  $\text{C}_{14}\text{H}_{13}\text{NO}_3$ , which appears to be Conrad and Limpach's phenyllutidoncarboxylic acid. L. T. T.

**Reactions of Quinoline.** By H. WEIDEL (*Monatsh. Chem.*, **8**, 120—146).—When a mixture of dry quinoline hydrochloride (from 50 grams of quinoline), 50 grams of quinoline, and 10 grams of platinised asbestos, is heated at  $170^\circ$ , and subsequently at  $200^\circ$ , in a gentle current of dry oxygen, the whole becomes dark in colour and thick. It is then dissolved in dilute hydrochloric acid, filtered, and treated with alkali and steam-distilled. The residue is dissolved in very dilute hydrochloric acid, and fractionally precipitated with a concentrated solution of sodium acetate. The last precipitate yielded on further purification dichinolyl, melting at  $173^\circ$ . The yield is 8 per cent.

When quinoline hydrochloride (from 129 grams of base), 93 dry pure aniline, and 25 grams of platinised asbestos are heated together, first at  $160^\circ$ , then for some hours at  $175^\circ$ , and finally at  $180^\circ$ , paramido- $\alpha$ -phenylquinoline (Jellinek, *Abstr.*, 1886, 1045) and a new diquinolyl are obtained. This melts at  $138^\circ$  (uncorr.). It yields two hydrochlorides; the one (with 2 mols.  $\text{HCl}$ ) is colourless, the other (with 1 mol.  $\text{HCl}$ ) yellow. The yield of base is 25 to 40 per cent. of that required by theory. The acetyl-derivative,  $\text{C}_{15}\text{H}_{11}\text{N}_2\text{Ac}$ , crystallises from alcohol in lustrous plates, melting at  $189^\circ$  (uncorr.).

*Dihydroxyphenylquinoline*,  $\text{C}_{15}\text{H}_{11}\text{NO}_2$ , is obtained, together with parahydroxy- $\alpha$ -phenylquinoline, by the action of potassium nitrite on amido- $\alpha$ -phenylquinoline, in presence of excess of hydrochloric acid. It crystallises in colourless, lustrous, prismatic needles, insoluble in water, readily soluble in benzene, ether, alcohol, chloroform, and acetone; it melts at  $114^\circ$  (uncorr.).

*Parahydroxy- $\alpha$ -phenylquinoline*,  $\text{C}_{15}\text{H}_{11}\text{NO}$ , forms a loose mass of colourless, slender, monoclinic crystals, insoluble in water, readily

soluble in boiling benzene, xylene, and alcohol, in hydrochloric acid, and in aqueous potash. It melts at  $237\text{--}238^\circ$  (uncorr.), and distils without decomposition under 62 mm. pressure. The *hydrochloride* (with 2 mols.  $\text{H}_2\text{O}$ ) crystallises in hair-like crystals of a lemon-yellow colour; the *platinochloride*,  $(\text{C}_{15}\text{H}_{11}\text{NO})_2 \cdot \text{H}_2\text{PtCl}_6$ , crystallises in gold-coloured, thin plates. The *acetyl-derivative* crystallises in large, colourless, thin, rhombic plates, melting at  $123^\circ$ ; it is readily soluble in ether, benzene, and ethyl acetate. When hydroxyphenylquinoline is oxidised with chromic acid, quinaldic acid melting at  $157^\circ$  is formed; when distilled with zinc-dust it is almost quantitatively converted into  $\alpha$ -phenylquinoline. By the action of tin and hydrochloric acid on hydroxy- $\alpha$ -phenylquinoline, *tetrahydrohydroxy- $\alpha$ -phenylquinoline*,  $\text{C}_{15}\text{H}_{15}\text{NO}$ , is formed: this could not be obtained in crystals. The *hydrochloride* forms white, lustrous, prismatic crystals. The solution gives with ferric chloride an intense blood-red coloration; with nitric acid first a red-violet, then a brown-red colour is produced. When fused with potash, parahydroxybenzoic acid is formed. The above reactions point to the following constitutional formula for paramido- $\alpha$ -phenylquinoline:—

The *nitro-derivative* of parahydroxy- $\alpha$ -phenylquinoline,  $\text{C}_{15}\text{H}_{10}\text{N}_2\text{O}_3$ , was also obtained in the product of the action of potassium nitrite and hydrochloric acid on paramido- $\alpha$ -phenylquinoline. It crystallises in microscopic lemon-yellow plates, melting at  $151^\circ$ ; it is rather readily soluble in alcohol and ether.

*Diquinolyl*,  $\text{C}_{18}\text{H}_{12}\text{N}_2$ , is contained in the mother-liquor from the preparation of paramido- $\alpha$ -phenylquinoline. It is best prepared by heating a mixture of 20 grams of paramido- $\alpha$ -phenylquinoline, 20 grams of glycerol, 40 grams of sulphuric acid, and 5 grams of nitrobenzene, at  $180^\circ$ , until frothing ceases. The product is dissolved in water, filtered, neutralised with sodium carbonate, and repeatedly extracted with ether. The residue obtained by evaporating off the ether is converted into the hydrochloride, which is recrystallised several times. The free base crystallises from alcohol (by slow evaporation) in monoclinic crystals of a fatty lustre:  $a : b : c = 1.3685 : 1 : 2.3778$ . It melts at  $144^\circ$  (uncorr.), is readily soluble in benzene, xylene, and alcohol, less in ether. It volatilises without decomposition. The *platinochloride*,  $\text{C}_{18}\text{H}_{12}\text{N}_2 \cdot \text{H}_2\text{PtCl}_6$ , forms a yellowish-white, microcrystalline powder, almost insoluble in water. The *methiodide*,  $\text{C}_{18}\text{H}_{12}\text{N}_2 \cdot \text{MeI} + \text{H}_2\text{O}$ , crystallises in small, bright yellow needles, melting at  $231\text{--}232^\circ$ , very sparingly soluble. The *monosulphonic acid* prepared by heating diquinolyl with 5 parts of sulphuric acid at  $160\text{--}180^\circ$ , forms a white, chalky powder, soluble in dilute alkali solutions. When the sulphuric acid is heated with potash at  $220^\circ$ , *hydroxydiquinolyl*,  $\text{C}_{18}\text{H}_{12}\text{N}_2\text{O}$ , is formed. This forms a crystalline powder, readily soluble in boiling benzene and alcohol; it melts at  $187^\circ$ .

N. H. M.

**Action of Acetamide on Orthochloroquinoline.** By F. MUHLERT (*Ber.*, 20, 1551—1552).—When chloroquinoline is heated

for several hours with acetamide, carbostyrl is formed; the latter is also obtained together with benzonitrile when benzamide is used instead of acetamide.

N. H. M.

**Quinoline-derivatives from  $\beta$ -Diketones.** By C. BEYER (*Ber.*, 20, 1767—1773).—In the method for the preparation of quinoline-derivatives from aromatic amines and the condensation-products obtained by the action of hydrogen chloride on mixtures of fatty aldehydes with certain ketones (*Abstr.*, 1886, 629), it seemed probable that an anilide is first formed, and is converted into the quinoline-derivative in the further course of the reaction. Proof of the truth of this idea is given in the present paper.

*Benzoylacetoneanilide*,

is prepared by heating aniline and benzoylacetone in equimolecular proportions at  $150^\circ$ , or by boiling the mixture with glacial acetic acid in a reflux apparatus for some hours. It crystallises in yellowish-white plates, and melts at  $110^\circ$ . When heated with concentrated sulphuric acid the anilide is converted into  $\gamma$ -phenylquinaldine.

Dibenzoylmethane,  $\text{CH}_2(\text{COPh})_2$ , under like treatment also yields an anilide; this could not be obtained in a state of purity, but the crude product when heated with sulphuric acid yields 2 : 4-diphenylquinoline,  $\text{C}_9\text{NH}_5\text{Ph}_2$ . This forms a white, crystalline mass, melts at  $112^\circ$ , and shows feebly basic properties, its sulphate dissociating readily when treated with pure water. The sulphate, chromate, and platinochloride,  $(\text{C}_{21}\text{H}_{15}\text{N})_2, \text{H}_2\text{PtCl}_6 + 2\text{H}_2\text{O}$ , were prepared.

A. J. G.

**Acridaldehyde and Acridinecarboxylic Acid.** By A. BERNTHSEN and F. MUHLERT (*Ber.*, 20, 1541—1551).—*Methyl acridinechloral*,  $\text{C}_{13}\text{H}_8\text{N} \cdot \text{CH}_2 \cdot \text{CH}(\text{OH}) \cdot \text{CCl}_3$ , is prepared by adding 70 grams of chloral to 60 grams of methylacridine suspended in 600 grams of benzene. The temperature is raised to  $70$ — $75^\circ$ , when the methylacridine is completely dissolved, and a separation of a yellow, sandy precipitate takes place. After some hours it is filtered, washed, and extracted with boiling alcohol or benzene. The yield is almost equal to that required by theory. It is sparingly soluble in alcohol, and crystallises in needles or prisms which melt with decomposition above  $200^\circ$ . It is almost insoluble in dilute acids, and dissolves in strong sulphuric acid without decomposition, yielding a splendid, fluorescent solution.

*Acridylacrylic acid*,  $\text{C}_{13}\text{H}_8\text{N} \cdot \text{CH} : \text{CH} \cdot \text{COOH}$ , is obtained by saponifying the above chloral-compound with an excess of 20 per cent. aqueous soda, mixed with half its volume of alcohol. It forms an almost insoluble, crystalline powder, which decomposes when heated at  $208^\circ$ , with evolution of carbonic anhydride. It has acid as well as basic properties. The solutions of the alkali salts show a green fluorescence. The *potassium salt* forms slender needles very readily soluble; the *sodium*, *ammonium*, and *silver salts* are described. The *hydrochloride* crystallises in well-formed, flat needles. When

this is reduced, *hydroacridylacrylic acid*,  $C_{13}H_{10}N \cdot CH \cdot CH : CH \cdot COOH$ , is obtained. This is readily soluble in alcohol and ether, sparingly in water. The *sodium salt* forms flat needles very readily soluble.

*Acridaldehyde*,  $C_{13}H_8N \cdot CHO$ , is prepared by dissolving 15 grams of acridylacrylic acid in excess of sodium carbonate solution, diluting to 750 c.c., adding 500 c.c. of benzene, cooling the whole to  $0^\circ$ , and shaking vigorously with a not too concentrated solution of 15 grams of potassium permanganate. After some time it is filtered through calico, the aqueous solution separated and extracted with ether. The united benzene and ether extracts are extracted with dilute hydrochloric acid. It crystallises from hot alcohol in slender, yellow needles of a silky lustre, melts at  $139-140^\circ$ , and boils with partial decomposition at a higher temperature. The *hydrochloride* forms gold-coloured, slender needles, which are decomposed by warm water; the *nitrate* crystallises in slender, yellow needles less soluble than the hydrochloride; the *sulphate* forms sparingly soluble, gold-coloured, lustrous needles; the *chromate* forms short, slender prisms. The *phenylhydrazine-compound*,  $C_{20}H_{15}N_3$ , crystallises from alcohol in hexagonal plates, insoluble in water; the *salts* form microscopic violet needles of a green metallic lustre, sparingly soluble in water, more soluble in alcohol; the solutions are violet-blue.

*Acridinecarboxylic acid*,  $C_{13}H_8N \cdot COOH$ , is obtained by adding the finely-powdered aldehyde to a warm 5 per cent. sodium hydroxide solution containing an excess of freshly precipitated silver oxide. It crystallises in lustrous, yellow needles, soluble in alcohol, less soluble in water. When heated at  $300^\circ$  it is decomposed into acridine and carbonic anhydride. The *sodium* and *ammonium salts* are readily soluble; salts with acids do not appear to be capable of existing. When the solutions of the alkali salts are diluted they show a blue fluorescence.

N. H. M.

**Creatines and Creatinines:**  $\alpha$ -*Amidocaprocyamine* and  $\alpha$ -*Amidocaprocyamidine*. By E. DUVILLIER (*Compt. rend.*, 104, 1290—1292).— $\alpha$ -*Amidocaprocyamine* is obtained by mixing an aqueous solution of leucine with at least 2 parts of cyanamide and a few drops of ammonia, and allowing the liquid to remain for several months. The liquid is then evaporated to dryness, repeatedly extracted with alcohol to remove dicyanamide, and the insoluble residue crystallised from water, from which it separates in anhydrous lamellæ of the composition  $NH : C(NH_2) \cdot NH \cdot CH(COOH) \cdot CH_2 \cdot CH_2 \cdot CH_2Me$ . It is very slightly soluble in cold water, more soluble in hot water, very slightly soluble in alcohol.

$\alpha$ -*Amidocaprocyamidine* is obtained by boiling the preceding compound in water for several hours. It crystallises in needles, which are very slightly soluble in cold alcohol, but dissolve more readily in hot alcohol, and are about as soluble in water as the preceding compound. From hot water it crystallises in silky, anhydrous needles. It has the composition  $\begin{matrix} NH & - & CO \\ & \diagdown & / \\ & C(NH) \cdot NH \end{matrix} > CH \cdot CH_2 \cdot CH_2 \cdot CH_2Me$ , and when boiled with water is reconverted into the corresponding cyamine.

It is worthy of note that leucine yields a creatine, whilst  $\alpha$ -methylamidocaproic and  $\alpha$ -ethylamidocaproic acids yield creatinines.

C. H. B.

**Alkaloids.** By O. DE CONINCK (*Compt. rend.*, 104, 1374—1375).—Nicotine was treated with methyl iodide in the same way as with ethyl iodide (this vol., p. 603). The product is a yellow, translucent solid, which is dissolved in warm, absolute alcohol and gradually mixed with potash of 45°, when a ruby-red coloration is produced, which becomes darker with excess of alkali. If the mixture is heated for 2½ hours on the water-bath, and the alcoholic solution decanted off, and concentrated, at a certain degree of concentration the liquid stains the skin like nitric acid. When evaporated to dryness it leaves a deep reddish-brown, viscid residue, and if this is dissolved in alcohol it gives a solution with a green fluorescence. On addition of water or a concentrated acid this solution becomes turbid, but the addition of hydrochloric acid to the diluted alcoholic solution reproduces the original colour. Ammonia changes the colour to dull red, which is converted by hydrochloric acid into a bright orange-red. If an excess of hydrochloric acid is added to the original alcohol solution, and the mixture poured into a large quantity of water, a brilliant green fluorescence is observed. The liquid is orange by transmitted light, and intense green by reflected light.

These reactions afford further proof that nicotine is closely related to the pyridic or dipyridic compounds.

C. H. B.

**Separation of the Opium Alkaloids.** By P. C. PLUGGE (*Arch. Pharm.* [3], 25, 343—354).—The six alkaloids narcotine, papaverine, narceine, thebaine, codeine, and morphine are separated by the use of the following precipitants: sodium acetate, potassium ferricyanide, sodium salicylate, potassium thiocyanate, and ammonia. The alkaloids are obtained as an aqueous solution of the hydrochlorides. The liquid is mixed with a sufficient quantity of concentrated sodium acetate solution, allowed to remain 24 hours, and filtered. The precipitate, washed with a little water, consists of pure narcotine and papaverine; it is dissolved in dilute hydrochloric acid and diluted until the solution contains not more than  $\frac{1}{400}$  of narcotine, when a solution of potassium ferricyanide is added. After remaining 24 hours, filtering and washing with a little water, the precipitate of papaverine ferricyanide is obtained from which the alkaloid may be separated by digesting with aqueous soda, filtering, and if necessary dissolving and reprecipitating with ammonia. The filtrate containing the narcotine yields this alkaloid by precipitation with ammonia. The filtrate containing the remaining four alkaloids together with an excess of sodium acetate is concentrated to a small volume on the water-bath and allowed to remain 24 hours, then filtered. The precipitate washed with a little water consists of narceine separated directly from the liquid as pure alkaloid. The filtrate contains traces of narceine and all the thebaine, codeine, and morphine. It is mixed with a sufficient quantity of sodium salicylate solution. After 24 hours the crystalline precipitate is filtered and washed with a little water. It consists of thebaine salicylate. On washing this on the filter with dilute

ammonia until ferric chloride ceases to indicate salicylic acid in the washings, pure alkaloid remains on the filter. The filtrate contains traces of narceïne, thebaine, the excess of sodium salicylate, and all the codeïne and morphine. It is acidified with hydrochloric acid; after remaining some time the salicylic acid separated is filtered off, and the filtrate is repeatedly shaken with chloroform to remove the remainder of the salicylic acid, narceïne, and thebaine; then the chloroform is removed by a gentle heat, the liquid is carefully neutralised and finally mixed with potassium thiocyanate solution. After 24 hours the precipitate consists of codeïne hydrogen thiocyanate. The filtrate contains the morphine, which can be precipitated by slight excess of ammonia. In many cases the above methods can be employed quantitatively. Mixtures of narcotine and morphine precipitated with sodium acetate gave from 97·15 to 100 per cent. of the narcotine. Narcotine in presence of morphine, codeïne, and thebaine gave 99·43 per cent. Papaverine precipitated by acetate in presence of morphine gave 98·15 per cent. of the total present. The same alkaloid in presence of morphine, codeïne, and thebaine gave 97·02 per cent. In the two experiments where thebaine was present over 90 per cent. of that alkaloid was obtained by precipitating with sodium salicylate. The separation of papaverine by means of potassium ferrieyanide is very complete. Codeïne cannot be quantitatively separated from morphine by means of potassium thiocyanate.

J. T.

**Composition of Papaverine.** By P. C. PLUGGE (*Arch. Pharm.* [3], 25, 421—425).—The composition of this alkaloid is sometimes represented by the formula  $C_{20}H_{21}NO_4$ , as given by v. Merck, its discoverer, and sometimes by  $C_{21}H_{21}NO_4$ . The author shows that the former and older formula most nearly agrees with analytical results obtained both by himself and others.

J. T.

**Strychnine and Brucine Ferro- and Ferri-cyanides.** By HOLST and BECKURTS (*Arch. Pharm.* [3], 25, 313—315).—*Normal strychnine ferrocyanide*,  $(C_{21}H_{22}N_2O_2)_4, H_4Fe(CN)_6 + 4H_2O$ , is precipitated from neutral solutions of strychnine salts by potassium ferrocyanide, forming a white, crystalline powder with a shade of yellow, slightly soluble in cold water, more easily in hot, from which well-formed, prismatic crystals separate on cooling. *Acid strychnine ferrocyanide*,  $(C_{21}H_{22}N_2O_2)_4, H_4Fe(CN)_6$ , is precipitated from a strong hydrochloric acid solution of a salt by potassium ferrocyanide as a white powder with a shade of blue. It is insoluble in cold water and alcohol, but dissolves in hot water with formation of hydrogen ferrocyanide, giving rise to a blue coloration and the formation of hydrocyanic acid. The salt has a strong acid reaction, decomposes carbonates and is decomposed by ammonia and alkalis with separation of strychnine. *Normal brucine ferrocyanide*,  $(C_{23}H_{26}N_2O_4)_4, H_4Fe(CN)_6 + 4H_2O$ , is obtained by adding to a concentrated neutral brucine hydrochloride solution, a concentrated solution of potassium ferrocyanide, as tufts of yellow, prismatic crystals; it gives yellow solutions with water and alcohol. In the air it gradually passes into brucine ferrieyanide with the separation of brucine. *Acid brucine ferrocyanide*,

the salt precipitated from a very concentrated strongly acid solution of brucine by potassium ferrocyanide, forms a white, crystalline powder, as seen under the microscope, which in the air quickly becomes blue. In less concentrated solutions there is no change at first, but after 12—24 hours beautiful, large, white prisms form of the same composition as the powder. The salt decomposes when heated with water with separation of hydrocyanic acid.

Potassium ferricyanide gives only normal salts. *Strychnine ferricyanide*,  $(C_{21}H_{22}N_2O_2)_6, H_6Fe_2(CN)_{12} + 12H_2O$ , precipitated from neutral and acid solutions, forms golden-yellow, flat prisms, somewhat sparingly soluble in water to a yellow liquid. *Brucine ferricyanide*,  $(C_{22}H_{26}N_2O_4)_6, H_6Fe_2(CN)_{12} + 12H_2O$ , is precipitated from acid or neutral solutions of brucine salts as greenish-yellow spangles, sparingly soluble in water to a yellow liquid. Other alkaloids are now undergoing investigation by the authors.

*Estimation of Strychnine and Brucine.*—The authors have based a volumetric method on Dunstan and Short's observation that strychnine is completely precipitated from aqueous solution of its sulphate, whilst brucine is not. If a 0.5 to 1 per cent. solution of the two alkaloids, strongly acidified with hydrochloric acid, is treated with potassium ferrocyanide until a filtered portion of the solution gives a blue stain with ferric chloride paper, the whole of the strychnine is precipitated as acid strychnine ferrocyanide, whilst the brucine remains in solution. The amount of strychnine can thus be determined by using a standard solution of ferrocyanide, 244 parts potassium ferrocyanide corresponding to 334 parts of strychnine. If the solution contain less than 0.5 per cent. the separation is too slow; also the ferric chloride paper should not be allowed to get perfectly dry before use. A mixture containing 0.145 gram strychnine and 0.036 gram brucine gave 0.148 gram of strychnine. To estimate the alkaloids when occurring together in, say, tinctura strychni, the total weight of the two is ascertained, then, according to Schweissinger, an excess of centinormal hydrochloric acid is added and the excess determined by centinormal soda solution. The neutral solution thus obtained is concentrated sufficiently and titrated with standard potassium ferrocyanide. A mixture containing 0.1 gram strychnine and 0.05 gram brucine gave 0.1017 of the former and 0.04915 of the latter.

J. T.

**Sulphonic Acids of Strychnine.** By I. GUARESCHI (*Gazzetta*, 17, 109—115).—Loebisch and Schoop have recently described a mono-sulphonic acid of strychnine; the author finds that if strychnine is warmed with three to four times its weight of sulphuric acid, a mono-sulphonic acid is formed, which is best purified by means of the barium salt. The analyses, though somewhat discordant, point rather to a formula  $C_{21}H_{21}(SO_3H)N_2O_2$ ; it is a yellow, amorphous solid, soluble in acids and alkalis; it does not give the strychnine reaction with potassium dichromate. A solution of its ammonium salt gives precipitates with salts of silver, iron, copper, barium, and lead. Heated at 120—130° it assumes an azure-violet colour. It does not seem to be poisonous.

The disulphonic acid,  $C_{21}H_{20}(SO_3H)_2N_2O_2$ , was not isolated, but the

barium, sodium, and potassium salts are described as amorphous solids, readily soluble in water, sparingly soluble in alcohol.

V. H. V.

**Chelidonine, Chelerythrine, and Sanguinarine.** By A. HENSCHKE (*Chem. Centr.*, 1887, 243).—Chelidonine is a tertiary base; analyses of the free base, its salts and the platino- and auro-chloride, point to the formula  $C_{20}H_{19}NO_3 + H_2O$ .

Chelerythrine and sanguinarine seem not to be identical; the analyses of the latter, its salts and its platinochloride, point rather to the formula  $C_{17}H_{15}NO_4$ , proposed by Naschold, than to  $C_{19}H_{17}NO_4$ , that given in most text-books.

V. H. V.

**The Alkaloïds of Lobelia.** By G. DRAGENDORFF and H. v. ROSEN (*Chem. Centr.*, 1886, 873).—The authors have isolated from the *Lobelia nicotianæfolia* a second alkaloïd additional to the already known lobeline. It is dissolved by chloroform from solutions made alkaline with ammonia. The alkaloïds exhibit no characteristic colour reactions; they are distinguishable by their behaviour towards the group reagents. In physiological properties they are closely similar.

C. F. C.

**Amount of Oxygen taken up in the Decomposition of Hæmoglobin into Albumin and Hæmatin.** By M. LEBENSBAUM (*Monatsh. Chem.*, 8, 166—179).—The amount of oxygen absorbed in the decomposition of oxyhæmoglobin depends on the time allowed for the experiment, the absorption continuing after 55 days. This is probably due to the albumin which is formed taking up oxygen in presence of alkali (Nencki and Sieber, *Abstr.*, 1882, 1307). Carbonic oxide hæmoglobin behaves in a manner similar to oxyhæmoglobin, but the amount of oxygen absorbed is always less.

Oxyhæmoglobin in 0.1 per cent. sulphuric acid solution, absorbs 1.1 per cent. of its weight of oxygen.

N. H. M.

**Compound of Hæmatin with Nitric Oxide.** By G. LINOSSIER (*Compt. rend.*, 104, 1296—1298).—An alcoholic solution of hæmatin or reduced hæmatin readily absorbs nitric oxide, forming a brilliant red, non-dichroic solution. The absorption spectrum of this liquid is similar to that of oxhæmoglobin, and consists of two bands between E and F, the breadth of which depends on the concentration of the solution. It is difficult to distinguish this spectrum from that of oxyazotised hæmoglobin, but the latter is somewhat more intense and its two bands are about equal in intensity. When oxyazotised hæmoglobin is mixed with potash, it is converted into oxyazotised hæmatin, which gives an absorption spectrum identical with that obtained by synthesis.

Oxyazotised hæmatin is less soluble in ammoniacal alcohol than ordinary hæmatin, and reducing agents have no action on this solution. The oxygen of the air converts it into hæmatin and ammonium nitrite. If the solution thus converted into hæmatin by the action of oxygen is treated with a reducing agent, it first forms reduced hæmatin and then oxyazotised hæmatin. The reducing agent acts on the hæmatin and also on the ammonium nitrite, converting the former

into reduced hæmatin, liberating nitric oxide from the latter. The reduced hæmatin and nitric oxide at once combine to form oxyazotised hæmatin, which is not further affected by the reducing agent.

The author points out that hæmatin should by analogy be called oxyhæmatin, whilst the name hæmatin strictly belongs to the compound commonly known as reduced hæmatin (Hoppe-Seyler's hæmochromogen). He proposes to change the names in this way, in order that oxyhæmatin and hæmatin may correspond respectively with oxyhæmoglobin and hæmoglobin.

C. H. B.

**Melanin.** By M. MIURA (*Chem. Centr.*, 1887, 250).—To prepare melanin, an emulsion of a melanotic spleen is diluted with water and treated with calcium chloride and sodium phosphate. The precipitate formed contains the colouring matter, and after frequent washings at 40° is treated with a powerful digestive fluid until the solution ceases to give the peptone reaction. The residue is treated with soda, and washed to remove the nucleïn and fatty acids, and finally treated with alcohol and ether. The melanin forms a brownish-black powder, possessing the properties and composition of the hippomelanin of Berdez and Nencki. Experiments showed that the urine of animals into which melanin had been injected, gave the melanogen reaction. As the injection of melanin produces no increase in the indican reaction of the urine, it is probable that the dye formed in the air or on oxidation is analogous to the dye obtained by Pribram from the urine of a patient suffering from a melanotic tumour, which is allied to or identical with the melanin of Dressler.

---

## Physiological Chemistry.

---

**Action of Oxygen on Animals.** By B. W. RICHARDSON (*Chem. News*, 55, 253).—According to experiments described in this paper, whilst an atmosphere of pure, freshly-made oxygen gas constantly renewed has no narcotic effect on animals, the result is quite otherwise if the oxygen that has passed through the chambers containing the animals be used a second time, and this even when the gas has been dried, and freed from carbonic acid, ammonia, and all appreciable impurities before being returned. In this case the animals become drowsy, and, as the experiment proceeds, the drowsiness passes into a perfectly quiet sleep, which ends in death after several repetitions of the process, although by no chemical tests can any difference be discovered between the lethal and the freshly-prepared oxygen. But the gas that has thus become "devitalised" can readily be "revitalised" by electrical brush discharges from the positive pole of a frictional machine. The lethal oxygen supports combustion as vigorously as ordinary oxygen, and supports life in cold-blooded animals.

R. R.

**Composition of Blood, Liver, and Flesh under varying Conditions.** By H. WEISKE and others (*Bied. Centr.*, 1887, 315—

318).—The action of acidified food on the composition of portions of a lamb was examined. Three lambs of like age were chosen, of which one (3) was immediately killed and analysed, whilst the other two were permitted to live for another six months; but whilst one (1) received ordinary hay, the hay which was given to the other (2) was moistened with dilute sulphuric acid. Analyses of the bones, &c., of these lambs after death showed that the bones of lamb (1) contained 2 per cent. more mineral matter than those of (2), and that this 2 per cent. consisted principally of lime and phosphoric acid. The dry matter of the blood of all three showed no appreciable difference, and the same may be said for the liver, but in the flesh, although nearly all constituents are present in like quantities, the lime in (1) was double in quantity.  
E. W. P.

**Animal Nutrition.** By J. W. SANBORN (*Bied. Centr.*, 1887, 383—386).—Two sets of steers were fed with Timothy hay and with straw, hay, and meal. The result was that an almost like increase in live-weight took place; it was further found that as the time proceeded so was a larger amount of food necessary to produce 1 lb. increase in weight of the skeleton of the animal, although at the same time the nutrient ratio varied considerably, also the increase in fat seemed to be the same. Ensilage seemed to affect the quantity of cream in milk.  
E. W. P.

**Variations in the Proportion of Phosphoric Acid in Milk.** By A. ANDOUARD (*Compt. rend.*, 104, 1298—1300).—The proportion of phosphoric acid in milk diminishes from the beginning to the end of lactation, the degree of reduction varying with different animals. The amount of fat, and especially of sugar, diminishes at the same time. Out of four cows, two showed an increase in the proportion of casein, and two a decrease. The increase in the total solid matter during lactation is not a constant quantity. The age of the cows affects only the quantity of milk given, the youngest giving the least. Contrary to the statement of Kroemer, green fodder gives better results than dry fodder. The best of the foods used in the west are cabbages and legumes; next in order of merit come potatoes, swedes, beetroots, and maize. The abundance and composition of the milk appears, however, to depend mainly on the individuality of the animal.  
C. H. B.

**Excretion of Urea and Uric Acid from the Human System.** By MARES (*Chem. Centr.*, 1887, 339—340).—The author has conducted a series of experiments on the effect produced by starvation on the proportion of urea and uric acid excreted from the human system. As a result from 21 persons it follows that in a state of starvation, a constant quantity of uric acid is excreted within a given time without reference to the quantity of nitrogen excreted within the same period. The quantity of uric acid is conditioned by the age of the individual, being diminished with greater age, but it is not influenced by the greater or less quantity of meat taken by the individual before starvation. The quantity of nitrogen, however, does

not depend on this latter condition, and varies as much as 120 per cent. within the same interval of time, increasing at the sixth to ninth hour after a meat meal, and reaching its maximum at the 24th hour. The explanation given of the results is as follows:—The uric acid is a product of living protoplasm, whilst the urea is derived from absorbed albuminoids. In a state of rest, the protoplasm produces the uric acid, whilst the quantity of urea changes according to the greater or less quantity of albuminoids absorbed. With an albuminoid diet, the protoplasmic cells of the digestive tract are called into instant action, whilst the protoplasm is decomposed for the production of the digestive fluids; the quantity of uric acid is accordingly increased. So soon as the cells are at rest, the production of uric acid decreases, the resorption of the albuminoids begins, and concomitantly the formation of urea. Experiments are given in proof of this point. If then uric acid is considered as a product of decomposition of protoplasm, the quantity of the acid eliminated may be taken as a measure of the amount of the decomposition.

V. H. V.

**Hydroxybutyric Acid in Diabetic Urine.** By WOLFE (*Chem. Centr.*, 1887, 277—278).—The author has examined the urine of 10 diabetic patients for ammonia, hydroxybutyric acid, and acetone. The results show that the proportions of ammonia and hydroxybutyric acid do not vary concomitantly. After a dose of sodium carbonate, the proportion of ammonia is diminished or even disappears, but hydrochloric acid produces sometimes no effect and sometimes an increase, whilst the proportion of hydroxybutyric acid is not thereby diminished. A flesh diet produces an increase of both constituents. Apparently there is no fixed relation between the quantities of acetone and hydroxybutyric acid eliminated; however, the proportion of acetoacetic acid, as shown by the ferric chloride test, and of hydroxybutyric acid, vary in a parallel degree. There is also no relation between the quantity of sugar and the other pathological products. In a case of coma diabeticum, a gas analysis of blood from the veins gave 19·5 instead of 35 volumes per cent. of carbonic anhydride.

V. H. V.

**Physiological Action of Chlorinated Ethyl Sulphides.** By V. MEYER (*Ber.*, 20, 1729—1731).—Dichlorethyl sulphide,  $S(C_2H_4Cl)_2$ , causes intense inflammation and suppuration when in contact with the skin or when breathed. The monochloro-derivative  $SEt \cdot C_2H_4Cl$ , shows similar but feebler action, whilst ethyl sulphide is without action. From this it follows that in these substances the physiological action is entirely and directly dependent on the chlorine.

A. J. G.

**Physiological Action of Tertiary Alcohols on the Animal Organism.** By B. M. SHAPIROFF (*Vrach.*, 19, 1887, 388—389).—Dimethyl ethyl carbinol, when introduced under the skin of a frog, in quantities of from 0·001 to 0·005 gram, produces first stupor (depression of the cerebral hemispheres) and then paralysis of the spinal cord, as shown by the arrest of the lymphatic heart, the centres for which reside in the cord. No direct effect is produced on the blood circulation. In dogs and rabbits the blood pressure is diminished,

the vasomotor centres being paralysed. No direct effect is produced on the heart. The temperature is reduced considerably. Trimethyl carbinol acts in the same way, but less powerfully. The author deduces from his experiments that whilst primary alcohols have a generally stimulating action, tertiary alcohols, even though isomeric with them, act as depressants.

T. M.

**Myoctonine.** By G. DRAGENDORFF and S. SALOMONOWITSCH (*Chem. Centr.*, 1886, 861).—This alkaloid occurs, together with lycaconitine (*Chem. Centr.*, 1884, 29) in *Aconitus lycoctonum*; it differs from the latter in melting point ( $144^{\circ}$ ) and solubilities. It is freely soluble in chloroform, nearly insoluble in ether. Lycaconitine being on the other hand soluble in ether, the separation of the alkaloids is effected by means of this menstruum. The physiological action of the alkaloids is closely similar. The lethal dose of the myoctonine, in the case of frogs, is 0.01 gram; characteristic symptoms of its action are obtainable with 0.00003 gram. These are, in the main, paralysis of the extremities of the motor nerves, the medulla and nerve trunks remaining unaffected, as also the muscular irritability. The injection of 0.025 gram of the nitrate into the vena jugulari of cats caused instantaneous death; the subcutaneous injection of 0.1 gram caused death within 20 to 30 minutes. Twice this quantity introduced per os caused similar results.

For the isolation of myoctonine from animal fluids, the authors recommend shaking with benzene, after the usual preliminary purification, and rendering alkaline with ammonia. After death caused by subcutaneous injection, the alkaloid is found in the coats, but not the contents, of the stomach and intestines; in the blood, liver, and kidneys in relatively large quantity; in small quantity in the pancreas.

---

## Chemistry of Vegetable Physiology and Agriculture.

---

**Nitrification.** By A. CELLI and F. MARINO-ZUCO (*Gazzetta*, 17, 99—103).—In the course of analyses of water from the subsoil of Rome, amongst other organisms a micrococcus of globular form (*Micrococcus cereus*) was discovered; this was found to be a very efficacious nitrifying agent.

Preliminary experiments are quoted to prove that for the process of nitrification the presence of bacteria is not absolutely essential, for if sterilised solutions of ammonium salt are filtered through sterilised sand or platinum sponge, nitrification ensues to an appreciable degree. It is further shown that among the organisms which liquefy nutritive gelatin *Bacillus saprogenus*, *B. fluidificans*, and *Micrococcus luteus*, when thrown on to sand in cultivating liquids, not only do not produce nitrates but destroy them completely; on the other hand these same

organisms, taken from potato-cultures, far from destroying the nitrates, are among the most active agents in producing them.

V. H. V.

**Action of Alkaloids in the Animal and Vegetable Kingdom.** By A. MARCACCI (*Chem. Centr.*, 1887, 248).—Fermentation of milk was promoted by addition of water, potassium and sodium sulphate, sodium chloride, atropine and morphine sulphate, but impeded by veratrine sulphate, quinine hydrochloride, cinchonamine sulphate, and especially by strychnine sulphate. Solutions of the above salts, with the exception of those of cinchonamine and quinine, as compared with the water, promote alcoholic fermentation. In order to study the action of alkaloids on seeds, the latter were either soaked in the solutions and then planted out, or allowed to sprout and grow in powdered glass, and then watered with the solution. The sprouting process was hardly influenced by salts of morphine, but affected by those of strychnine, veratrine, and especially of quinine and cinchonamine. The alkaloid salts have a most injurious effect on maize, beans, and lupines. On already developed plants, morphine salts produce no effect, but salts of strychnine, and especially quinine and cinchonamine, are very detrimental. Strychnine hinders the development of frog spawn, but morphine and atropine favour it as compared with distilled water. Tadpoles are quickly killed in solutions of salts of veratrine, strychnine, and quinine, but more slowly in atropine and distilled water; whilst frogs are more quickly killed by strychnine and veratrine, but will live for several months in a solution of morphine. As regards the effect of poison, there appears to be no marked difference between animal and plant protoplasm, nor a definite classification into animal and plant poisons.

V. H. V.

**Are Nitrates formed in the Organism of Higher Plants?** By E. SCHULZE (*Ber.*, 20, 1500—1504).—Lupin sprouts grown on paraffined gauze stretched over flat vessels filled with distilled water, were found to be free from nitrates. On the other hand, when the lupin sprouts were grown in a moist sand, they were found to contain nitrates. It is shown that nitrogenous substance is taken up by the water, and that this is partially converted into nitrates in presence of sand. The author does not insist that the nitrates found in the sprouts grown in sand can only have been formed from nitrogenous substance separated from the roots, but maintains that the presence of nitrates is no proof of Berthelot and André's view, that nitrates are formed in the organism of higher plants (compare also this vol., p. 686).

N. H. M.

**Carrotene in Leaves.** By A. ARNAUD (*Compt. rend.*, 104, 1293—1296).—Carrotene (Abstr., 1886, 711) is always found in the leaves of plants in full vegetation.

Leaves dried in a dry vacuum contain the whole of the original carrotene, but this is not the case if they are dried by heat. Light petroleum boiling below 100°, and free from benzene, dissolves carrotene, but not chlorophyll. Carrotene dissolves in almost any

proportion in carbon bisulphide, forming a solution with an intense blood-red colour.

A known weight (20 grams) of the leaves dried in a vacuum, is treated with a definite volume (1000 c.c.) of light petroleum boiling below  $100^{\circ}$ , and is allowed to remain at the ordinary temperature for 10 days, with occasional shaking. A definite fraction (100 c.c.) is placed in a dish, allowed to evaporate to dryness, and the residue dissolved in carbon bisulphide so that the solution measures 100 c.c., which will correspond with one-tenth of the total carotene present in the weight of leaves taken. The intensity of the colour of the solution is measured by means of a Duboscq colorimeter, and is compared with a solution of pure carotene of known strength.

The amount of carotene is equal on an average to about 0.1 per cent. of the weight of the dried leaves, and it must exert a considerable influence on the colour of the leaves.

C. H. B.

**Organic and Inorganic Constituents of Grapes.** By E. LIST (*Chem. Centr.*, 1887, 245—246).—The author has made an investigation into the organic and inorganic constituents of grapes of the Franconia district, as influenced by the nature of the soil and the manure applied, and examined the action of various ferments on the pressed juice. Results are given of (i) the composition of 39 various species; (ii) the proportion of mineral matter present in the juice; (iii) the percentage composition of the ash; and (iv) the composition of the fermented juice. From the results it follows (i) that the proportion of each constituent varies within wider limits than hitherto supposed; (ii) the ratio 100:7 of alcohol to glycerol as a minimum is not absolute; and (iii) the ferments abstract from the juice a considerable quantity of phosphates, but these are again returned after some time to the wine on the breaking down of the ferment-cells.

V. H. V.

**Solanine.** By G. KASSNER (*Arch. Pharm.* [3], 25, 402—403).—Siftings from diseased potatoes gave as much as 0.03—0.05 gram of solanine from 120 grams, whilst sound potatoes of the same kind gave scarcely any. The observations were made in January, showing that solanine may be formed in potatoes during the period of winter rest.

J. T.

**Tunisian Soils.** By H. QUANTIN (*Compt. rend.*, 104, 1528—1529).—A series of determinations of nitrogen and phosphoric acid in soils in various parts of Tunis. In the valley of the Medjerdah the soils show a deficiency in phosphoric acid, a result which is due to the growth of cereals from time immemorial without any restitution of phosphates being made. This is the cause of the mediocre crops which are now obtained, and the deposits of phosphates recently found by Thomas in Tunis will be of very great value as a means of restoring fertility to the exhausted soils.

C. H. B.

**Evolution of Ammonia from Vegetable Soils.** By BERTHELOT and ANDRÉ (*Compt. rend.*, 104, 1219—1224).—The soil, which had undergone no previous treatment, was placed in a flask and subjected to a current of air, which was afterwards passed through cotton-wool

and then through bulbs containing dilute standard sulphuric acid. In other cases the soil was placed under a bell-jar, together with a dish containing the acid.

Vegetable soils evolve ammonia spontaneously, in consequence of the slow decomposition of the ammoniacal and amidated compounds present in the soil. This decomposition is partly due to the chemical action of the water, carbonates, &c., and partly to physiological actions such as fermentation, the development and activity of microbes, and vegetation proper. Most of the reactions concerned in the evolution of the ammonia are non-reversible.

A comparison between the amount of ammonia evolved from the soil, and the amount present in the atmosphere, and therefore capable of being absorbed by the soil, was made by supporting a flat dish containing sulphuric acid just above the top of the grass in a grass-field, the dish being protected at night and during rain and the loss by evaporation being compensated by addition of water. A similar dish was supported inside an earthenware cylinder which isolated a portion of the soil and grass from the surrounding soil. Care was taken that the duration of the experiment was not sufficiently long for the grass enclosed in the cylinder to become etiolated. The sulphuric acid was not titrated, but was made alkaline and distilled.

The amount of ammonia existing in the air is extremely variable, and changes with every change in meteorological conditions. The evolution of ammonia from the soil is much more regular; it is in fact conditioned by comparatively regular natural processes. In all cases there is no necessary connection between the tension of the ammonia in the atmosphere and the evolution of this gas from the soil. The two phenomena, the absorption of ammonia by the soil from the air and the evolution of ammonia from the soil into the air, are independent of one another.

C. H. B.

**Agricultural Value of Retrograde Phosphate.** By J. JOFFRE (*Bull. Soc. Chim.*, 47, 312—316).—The coefficient of solubility of ferric phosphate, known as retrograde phosphate, in water is about 0·000002, and therefore differs but little from that of raw, or tricalcium phosphate. Experiments conducted on crops show that the use of tricalcium phosphate has a slight advantage over the retrograde phosphate. The following results were obtained, 22·5 kilos. of combined phosphoric acid being applied per hectare in the form of the different manures:—

|   |   |
|---|---|
| Without any phosphatic manure   | = 1·441 kilos. of grain per hectare.            |
| With retrograde phosphate . . . . .   | = 1·559                   "                   " |
| With insoluble phosphatic nodules = 1·580                   "                   " |   |
| With soluble phosphate . . . . .  | = 1·736                   "                   " |
|   | A. P.   |

## Analytical Chemistry.

---

**Estimation of Hydrogen Peroxide.** By H. THOMAS (*Chem. Centr.*, 1887, 283).—The amount of hydrogen peroxide in a solution is estimated by acidifying with sulphuric acid, adding a solution of potassium iodide free from iodate, and determining the iodine liberated by means of a standard solution of sodium thiosulphate.

V. H. V.

**Volumetric Estimation of Iodine.** By T. SALZER (*Chem. Zeit.*, 11, 754).—The degree of dilution of the sodium sulphite solution used in estimating iodine by Kalmann's process materially influences the result. With a constant degree of dilution, however, the author states that the results agree very well amongst themselves.

J. P. L.

**Determination of Sulphuric Acid in Water.** By FRICKE (*Chem. Centr.*, 1887, 283).—As various methods suggested for the determination of sulphuric acid in samples of water are far from accurate, the following process is proposed; 200 c.c. of the water is boiled with a few drops of a solution of sodium carbonate to precipitate the lime. The volume is again made up and 100 c.c. withdrawn by a pipette, neutralised, and boiled with baryta-water of known concentration; the excess of the baryta is precipitated by carbonic anhydride, and the whole boiled. The precipitate of sulphate and carbonate is filtered off, and the latter decomposed by a decinormal solution of hydrochloric acid. From the quantity of the solution used the excess of the barium hydrate is calculated, and deducting this, the amount of the hydrate required to precipitate the sulphuric acid is calculated. The formation of a soluble acid barium carbonate not decomposed by boiling on passing in the carbonic anhydride, is a source of error too small to be appreciable.

V. H. V.

**Estimation of Nitrogen in Organic Substances.** By RAULIN (*Bull. Soc. Chim.*, 47, 94—97).—A modification of Dumas' process. The tube in which the combustion is conducted is of copper, about 3 mm. thick, and having an internal diameter of 18 mm. The length of the tube is 1800 mm., and arranged along it at equal distances are four small brass water-jackets, each about 100 mm. in length, one of which is placed at either end, and the other two at equal distances between, thus dividing the outside surface of the copper tube into three portions of about 500 mm. each. In each of these uncovered portions of the tube a separate combustion is conducted; the space nearest the front is first charged by introducing a coil of sheet copper about 60 mm. long; with the aid of a glass funnel 60 grams of small fragments of copper oxide are then added, and finally a convenient weight of the organic compound mixed with a small quantity of fine copper oxide and about 20 grams of coarser fragments; the funnel and back part of the tube are then rinsed down with a small quantity of copper oxide, and a second and third charge

successively introduced in a similar manner into the two remaining portions of the tube between the cooling jackets. The whole tube is supported at the four points at which the water-jackets are fixed, and the combustion is effected by a small movable furnace. The back part of the tube is connected with a continuous supply of pure carbonic anhydride, and the front end is fitted with a delivery tube passing into a solution of potassium hydroxide, in which graduated glass collecting tubes are arranged. After driving out all the air from the tube, the combustions are conducted in turn, that at the front of the tube being first performed. A deduction is made in each experiment for gases not absorbable by potash introduced with the carbonic anhydride, which amount varies with the duration of the experiment, and is carefully determined previously by blank experiments. A. P.

**Kjeldahl's Method for Estimation of Nitrogen.** By K. ULSCH (*Chem. Centr.*, 1887, 284).—In a former paper the author has recommended the use of platinic chloride to accelerate the oxidation of organic substances by boiling sulphuric acid; it is here noted that an excess must be avoided as hindering rather than promoting the reaction. If platinum chloride is used, concentrated acid is required, and the solution or extract to be examined must be evaporated; the heating must not be prolonged after the reaction is completed, otherwise a loss of nitrogen occurs; three to four minutes is sufficient. As regards Wilfahrt's modification, it is remarked that before the distillation of ammonia, after saturation with alkali, potassium sulphide must be added. The same result is produced by using a saturated solution of ferrous oxide. V. H. V.

**Estimation of Nitrogen in Urine.** By L. GARNIER (*J. Pharm.* [5], 15, 557—559).—Pflüger and Bohland (*Abstr.*, 1885, 608) have given a method based on the decomposition of the urine when heated with a mixture of concentrated and Nordhausen sulphuric acids. The nitrogenous compounds are transformed into ammonia, which is fixed by the excess of acid. The ammonia is displaced by heating with soda solution, and is collected in standard sulphuric acid. The author has frequently used the method, but as Nordhausen acid often contains ammonia, he employs instead a mixture of one part of pure sulphuric anhydride and three parts of concentrated sulphuric acid. Numerical results given show that the method is very satisfactory.

J. T.

**Organic Nitrogen in Chemical Manures.** By GASSAUD (*Compt. rend.*, 104, 1632—1633).—It is frequently important to ascertain the origin of the organic nitrogen in artificial manures. In a case which came under the author's notice, the behaviour of the manure on heating indicated the presence of hides, or, in other words, the presence of the residues from tanneries. The manure was therefore extracted with water and the solution treated with ferric chloride, potassium dichromate, ferric acetate, and magenta, with which it gave blue, brown, deep bluish-violet, and red precipitates respectively. Similar or identical reactions were obtained with infusions of hides

and of tannin, whilst infusions of horns, flesh, blood, &c., gave no similar results. C. H. B.

**Estimation of Phosphoric Acid.** By C. MOHR (*Chem. Zeit.*, **11**, 417—418).—Solution of the phosphatic substance is effected by means of dilute sulphuric acid. For this purpose, 2 grams of the substance is treated with successive small quantities of 2 per cent. sulphuric acid in a mortar. The residue is added to the extracts and the whole made up to 100 c.c. exactly and allowed to digest for one hour. 10 c.c. of the filtered solution corresponding to 0.2 gram are then treated with potassium ferrocyanide so long as iron is precipitated. After the addition of sodium acetate, the phosphoric acid is titrated in the usual way with a standard solution of uranium acetate. It is stated that the end reaction is not influenced either by an excess of potassium ferrocyanide or by the presence of the Prussian blue. J. P. L.

**Detection of Boron in Milk and other similar Fluids.** By M. KRETZSCHMAR (*Chem. Zeit.*, **11**, 476—477).—5 to 6 c.c. of the sample to be tested is placed in a platinum crucible and gently evaporated to one-third; after the addition of 5 or 6 drops of fuming hydrochloric acid, the residue is again evaporated and a Bunsen burner held over the mouth of the crucible. The presence of boron is easily detected by the intense green colour imparted to the flame. J. P. L.

**Estimation of Potassium in Ashes and Minerals.** By M. KRETZSCHMAR (*Zeit. Chem.*, **11**, 418).—In cases where the estimation of potassium only is required, the following process will be of use.

5 grams or more of the substance is dissolved in a flask with hydrochloric acid if possible, a drop of nitric acid being added to oxidise any ferrous iron. The solution is boiled and the sulphuric acid precipitated with barium chloride; whilst still hot the solution is treated with ammonia and ammonium carbonate in excess. Instead of filtering and washing this cumbersome precipitate, the whole is transferred to a porcelain capsule and evaporated to dryness on the water-bath, the residue being finally heated at 110°. The precipitate which is now of small bulk can be easily exhausted with water and a few drops of ammonia.

The washings are made up to 500 c.c. and 50 or 100 c.c. taken for analysis. If magnesia is present in any considerable quantity, oxalic acid must be added to the liquid before evaporation and ignition; if only small quantities are present this may be omitted.

The determination of potash is made in the usual way after removal of the ammoniacal salts by ignition. J. P. L.

**Estimation of Lithium and Sodium in Mixtures of their Carbonates.** By E. HOLDERMANN (*Arch. Pharm.* [3], **25**, 305—307).—Lithium carbonate when heated to fusion suffers a loss in weight amounting to about 2.15 per cent., but when heated with four times its weight of sodium carbonate no carbonic anhydride is evolved from

the lithium salt. The mixed salts are heated to faint redness until the weight becomes constant. Excess of normal hydrochloric is added, the mixture heated on the water-bath to expel carbonic anhydride, and the excess is titrated with normal potash solution, using phenolphthalein as indicator. Then by known methods of calculation the respective amounts of lithium and sodium can be ascertained.

J. T.

**Calcimetry.** By A. BERNARD (*Compt. rend.*, 104, 1525—1528).—A modification of Scheibler's apparatus for the determination of carbonic anhydride in soils, &c.

**Determination of Lime and Magnesia in presence of Manganese.** By F. STOLBA (*Chem. Centr.*, 1887, 285).—To the solution to be examined, ammonia and ammonium chloride are added to slight alkaline reaction, and the liquid heated to boiling; to remove the manganese, potassium permanganate is added until a slight tint is produced; the manganese is precipitated as a peroxide, and the slight excess of the permanganate removed by protracted boiling. The lime and magnesia are determined in the filtrate. This method is also applicable in presence of iron.

V. H. V.

**Titration of Zinc Powder.** By KUPFERSCHLAEGER (*Bull. Soc. Chim.*, 47, 312).—When samples of zinc powder are examined by Weil's method any cadmium or iron present will be calculated as metallic zinc, the author therefore proposes to dissolve the zinc powder in well-boiled dilute sulphuric acid, add ammonium carbonate, filter, and titrate the zinc in the clear solution with standard sodium sulphide.

A. P.

**Volumetric Estimation of Alumina.** By R. GATENBY (*Chem. News*, 55, 289).—Alumina, having an alkaline reaction with methyl-orange and an acid one with litmus, can be easily determined when dissolved in aqueous soda, by first determining the amount of the latter by normal acid, using phenolphthalein as indicator. A few drops of methyl-orange solution are added to the decolorised liquid, and then the normal acid required to obtain a pink colour gives the amount of alumina and alkaline soda salts together. Litmus solution is then added, and the liquid titrated back with normal caustic soda until a decided blue colour appears.

R. R.

*Note.*—This is essentially K. J. Bayer's well-known method (*Abstr.*, 1886, 281, 651, see also "E. B." *ibid.*, 651) to which, however, no reference is made in the original.

A. J. G.

**Rapid Estimation of Phosphorus in Iron.** By WEDDING (*Chem. Centr.*, 1887, 260).—The iron is dissolved in nitric acid, and to it is added a concentrated solution of ammonium molybdate; the precipitate which separates is transferred into a narrow, calibrated tube, and its amount estimated by the volume which it occupies. This method is an improvement on that proposed originally by Eggertz; sufficiently accurate results can be obtained in half an hour,

but it cannot be applied to samples containing more than 0.12 per cent. of carbon.

V. H. V.

**Determination of Combined Carbon in Iron.** By C. BRAND (*Chem. Centr.*, 1887, 345).—The well-known method of the direct separation of carbon from iron gives too low results; the method here proposed is applicable only for samples of iron rich in carbon. One gram of the sample is dissolved in 30 to 40 c.c. of hydrochloric acid containing 24 per cent. of bromine; the latter is removed in the form of hydrobromic acid by heating with 3 to 4 grams of ammonium oxalate. The removal is completed after one to two hours; the carbon is collected on an asbestos filter, and in the combustion, the small quantity of bromine absorbed by the carbon is retained by interposing in the combustion-tube a small spiral of silver kept at a red heat.

V. H. V.

**Separation of Phosphoric Acid from Tungstic Acid.** By F. KEHRMANN (*Ber.*, 20, 1811—1814).—All orthophosphotungstates are decomposed into basic tungstates and tribasic phosphates by boiling for half an hour with a sufficiency of aqueous soda. After cooling, the solution is mixed with as much ammonium chloride as would suffice to convert all the alkali present into chloride. Magnesia mixture will now precipitate the phosphoric acid perfectly free from tungstic acid.

A. J. G.

**New Chloroform Reaction.** By A. JOLLES (*Chem. Zeit.*, 11, 786).—If potassium manganate is added to chloroform containing alcohol, aldehyde, or other oxidisable substances, it is reduced to potassium manganite. The rate of this reduction furnishes a rough index to the amount of alcohol or other oxidisable substances in the chloroform.

J. P. L.

**Chloral Hydrate.** By G. DRAGENDORFF and H. TIESENHAUSEN (*Chem. Centr.*, 1886, 636).—The authors' experiments show that this substance, when present, may be isolated from urine and the contents of the alimentary organs, by exhaustion with ether, after previous purification by treatment with alcohol and filtration. From 100 c.c. of these fluids containing 5 mgrms. of chloral, sufficient was isolated in this way for identification. The method is inapplicable to fluids containing blood, in which case the distillation test is to be recommended.

The isonitrile test for chloral hydrate: warming the isolated and dry substance with alcoholic sodium hydrate and a trace of pure aniline, is extremely sensitive, the product in question being obtained in perceptible quantity from  $\frac{1}{64000}$  gram. The naphthol test: blue coloration on warming ( $50^\circ$ ) with concentrated aqueous potash and a trace of phenol, is also very sensitive, being well marked with  $\frac{1}{24000}$  gram of substance. The limit of the formic acid test is reached with  $\frac{1}{9000}$  gram of substance; of the lime water and hydrogen sulphide test (pink coloration) with  $\frac{1}{1500}$  gram.

The authors find that these reactions are unaffected by the pre-

sence of urochloralic acid, into which a portion of the chloral is usually converted in its passage through the body. C. F. C.

**Isolation and Detection of Phenol.** By G. DRAGENDORFF and W. JACOBSON (*Chem. Centr.*, 1886, 828).—The authors have investigated, with satisfactory results, the application for this purpose of the method employed by them for the isolation of alkaloïds from animal fluids, namely, a preliminary treatment with alcohol after acidification, filtration, evaporation of the alcohol, and shaking with benzene. From liquids containing 1 mgrm. in 100 c.c., sufficient was isolated for identification. For this the authors recommend the Baumann and Jacquemin reactions. Landolt's reaction (bromine) is useful in distinguishing phenol from thymol, the latter yielding an amorphous bromide.

In certain cases, phenol, in its passage through the body, enters into combinations, which cannot be isolated by direct treatment with solvents. These compounds, however, are resolved by warming with acids, which is therefore a necessary preliminary to the isolation of the phenol. C. F. C.

**Estimation of Starch and Sugars.** By J. EFFRONT (*Bull. Soc. Chim.*, 47, 5—14).—When a solution containing invert sugar, glucose, maltose, and dextrin is heated at 100° with ammonium hydroxide, the sugars are almost completely destroyed; if now the ammonia is boiled off and the residue treated with sodium hypochlorite the whole of the sugars are removed whilst the dextrin in solution is not affected, and retains its rotatory power unaltered. Further, in opposition to Brown and Heron, the author states that the series of dextrins formed when starch-paste is acted on by diastase have one and all the same rotatory power, and on these results the following method for the estimation of starch is based. Ten parts of the starch are made into a paste, cooled to 50°, and the extract from one part by weight of malt added, the solution is then made up to such a strength that every litre contains 100 grams of starch. As soon as this is broken up into maltose and dextrin, a portion of the solution is diluted so that it may contain from 4 to 9 per cent. of sugar, and the rotatory power is observed; 10 c.c. of the solution is then mixed with 10 c.c. of ammonium hydroxide solution (22° Baumé) and 5 c.c. of water, the mixture is digested at 100° for 40 minutes in a corked flask, concentrated to from 5 to 8 c.c., cooled, 10 c.c. of a solution of sodium hypochlorite containing 7 to 8 per cent. of active chlorine is added, the mixture well shaken, and 2 c.c. of concentrated hydrochloric acid run in. The whole is then made up with water to exactly 25 c.c., and the rotatory power of the liquid thus obtained is observed; the alteration of rotatory power between the first and last observation (account being taken of the difference of dilution) is due to the destruction of the maltose, whilst the final rotatory power indicates the amount of dextrin present, and from these data the amount of starch is calculated.

For the rapid determination of starch in crude farinaceous substances such as grain, potatoes, &c., the author advises the use of a

modification of Dubrunfauts' method. Three grams of the starchy material are ground up in a mortar with 20 c.c. of concentrated hydrochloric acid and left for 30 minutes; the solution is then poured into cold water and made up to 200 c.c., filtered, and the rotatory power due to the dissolved starch observed; from this the amount of starch actually present is calculated. Thus conducted this method gives results which may be as much from 2 to 3 per cent. in error. If it is desired to make an accurate determination of the starch in raw products, the author converts the starch into dextrin and maltose according to the directions given by Mercker in his *Handbuch der Spiritusfabrikation*, 2nd edition, he then destroys the maltose by means of ammonia and sodium hypochlorite, and proceeds as in the first of the two foregoing methods. A. P.

**Estimation of Starch.** By A. v. ASBOTH (*Chem. Zeit.*, **11**, 785—786).—This process depends on the fact that barium hydroxide forms an insoluble compound of definite composition with starch.

The estimation is performed in the following manner:—3 grams of finely-ground substance is repeatedly treated with small quantities of water in a porcelain mortar. The washings and residue, which should measure about 100 c.c., are transferred to a 250 c.c. flask. The flask is then heated on a water-bath and frequently shaken during the conversion of the starch into paste. To the starch solution, when cool, 50 c.c. of standard baryta-water is added, and then alcohol to 250 c.c. After the precipitate has settled, the excess of barium hydroxide is determined in 50 c.c. of the clear liquid. The formula for the barium compound is  $(C_6H_{10}O_5)_4BaO$ . Dextrin if present would also be precipitated, and therefore count as starch. A full description of the process, with the results of several test analyses, is given in the *Analyst* for July, 1887. J. P. L.

**Estimation of Starch in Potatoes.** By A. GIRARD (*Compt. rend.*, **104**, 1629—1632).—Pure potato starch gelatinised by heat or by the action of dilute potash or cuprammonium solution, and then acidified with acetic acid and titrated with dilute iodine solution, absorbs a quantity of iodine which is practically constant, and is equal to 0.122 gram per gram of anhydrous starch.

In order to estimate the amount of starch in potatoes, 25 grams of a grated sample is placed in a flask of 750 c.c. capacity, mixed with 50 c.c. of 0.2 per cent. hydrochloric acid, and allowed to remain 2 to 3 hours, 100 c.c. of a solution of cupric oxide in ammonia is added to the acid liquid and the mixture allowed to remain over-night. It is then acidified with acetic acid and titrated with a solution prepared by dissolving 3.05 grams of pure iodine and 4 grams of potassium iodide in 1000 c.c. of water, starch-paper being used as an indicator. 10 c.c. of this normal solution = 0.25 gram of starch, and a decinormal solution is prepared from it. In actual work an approximate estimation is first made with the normal solution, and a second titration is afterwards made, the decinormal solution being used towards the end of the reaction.

A correction is necessary in consequence of the dilution of the

liquid and the absorption of iodine by proteid substances in the potatoes. This may be taken as equivalent to 0.5 part of starch per 100 parts of potatoes.

C. H. B.

**Estimation of Acetic Acid in Acetates by Direct Titration.** By A. SONNENSCHN (Chem. Zeit., 11, 591—592).—The author has devised a rapid and accurate process for the determination of acetic acid in acetates. The process is based on the fact that whereas methylaniline-orange (Orange No. 4) is unaffected by acetic acid it is changed to a red by mineral acids.

The carbonate, which is always present in commercial acetates, can be determined by titration in the same solution employed for the titration of the acetic acid, provided the amount of colouring matter is small. A solution of the acetate is prepared containing 5 grams of acetate in 250 c.c. of water, and 50 c.c. of this solution is taken for analysis. The carbonate is titrated by means of normal hydrochloric acid, using phenacetoline as an indicator. The red colour changes to yellow with an excess of hydrochloric acid. From the hydrochloric acid used the carbonate can easily be calculated. A few drops of methylaniline-orange are now added to the solution and the titration with normal hydrochloric acid continued. So long as acetic acid is present no change of colour takes place, but with an excess of hydrochloric acid, the red colour appears. The amount of acetic acid can readily be calculated from the amount of normal hydrochloric acid used. If the amount of colouring matter masks the phenacetoline reaction, the carbonate can be determined by precipitation with barium chloride. In the case of commercial acetate of lime, the solution is as a rule so strongly coloured that it is necessary to remove the colouring matter before titration. To decolorise the solution the author employs about 3 grams of tutty, and at the same time passes a stream of carbonic anhydride through the solution to remove caustic lime which is sometimes present in the crude commercial acetate.

J. P. L.

**Estimation of Morphine.** By H. GOEBEL (Chem. Zeit., 11, 508).—The process recommended by the United States Pharmacopœia for the estimation of morphine in opium, although one of the few processes that give reliable results, contains some faults which the author has endeavoured to eliminate. The process recommended in the Pharmacopœia is to digest 5 grams of opium in 50 to 60 c.c. of water at 50—60°, after filtration 2 to 3 grams of slaked lime is added and the mixture is again filtered after the lapse of about an hour, during which time it is frequently shaken. To 50 c.c. of the filtrate, 5 c.c. of 95 per cent. alcohol, 25 c.c. of ether, and 3 grams of ammonium chloride are added; the whole is well shaken and set aside for 12 hours or so for the morphine to crystallise out. The ether is filtered off through tared filter-papers, and the alcoholic solution treated with another 10 c.c. of ether. After the ether has been filtered off, the alcoholic solution and crystals are brought on to the filter and finally washed with 5 c.c. of water, dried at 100°, and weighed. The crystals of morphine should be soluble in 100 times their weight of lime-water. The

author draws attention to the following sources of error:—(1.) The incomplete removal of all substances soluble in ether. (2.) 5 c.c. of water are insufficient to wash both filter-papers and crystals, and, in consequence, the outer and counterpoise filter-paper contains more impurity than the inner. (3.) No allowance is made for the morphine in the mother-liquor and washings. (4.) The amount of water used in the exhaustion of the opium is insufficient in the case of opium containing 15 per cent. of morphine.

In order, therefore, to eliminate some of these sources of error the author suggests the following modifications:—5 to 10 grams of opium should be exhausted with 110 c.c. of water, and 4 to 5 grams of slaked lime added without filtration, after the lapse of an hour the mixture is filtered, 50 c.c. of the filtrate is taken for analysis and treated as above. After the first 25 c.c. of ether has been filtered off, both filter-paper and the alcoholic solution are washed with pure ether. Instead of the counterpoised filter-papers a single paper is used which has been previously treated with dilute sulphuric acid. The mother-liquor and washings are measured and an allowance of 0.01 gram morphine made for every 10 c.c.

The filter-paper and crystals finally are well washed with water, dried at 100°, and weighed. The weight of the filter-paper is determined after removal of the morphine with dilute sulphuric acid and water.

J. P. L.

**Morphine Reaction.** By G. VULPIUS (*Arch. Pharm.* [3], 25, 256—257).—Donath (Abstr., 1886, 899) has given a test for morphine founded on the simultaneous action of sulphuric acid and potassium arseniate. Sodium phosphate can be employed in like manner. Some drops of a solution containing at least 0.00025 gram of a morphine salt is placed in a porcelain dish and six drops of sulphuric acid is added, together with some centigrams of sodium phosphate; on warming and agitating the mixture, a violet colour appears when fumes begin to come off. If the heating is continued, the colour passes to brown. On adding water to the cooled mixture drop by drop, a bright red colour appears, which becomes dirty green when 3 to 5 grams of water have been added. On now shaking with an equal volume of chloroform, the latter separates out with a beautiful blue colour. The blue colour produced by ferric chloride in morphine solutions is not taken up by chloroform.

J. T.

**Test for Narceïne.** By P. C. PLUGGE (*Arch. Pharm.* [3], 25, 425—427).—Dilute sulphuric acid poured on a trace of narceïne in a porcelain dish produces no change; but when, by heating on the water-bath, the acid is sufficiently concentrated, a splendid, violet-red colour appears which becomes cherry-red on long heating. If, after cooling, a trace of nitric acid or potassium nitrite is added to this red liquid, blue-violet stripes appear therein. This is characteristic of narceïne. With traces of papaverine, morphine, and codeïne, the liquid remains quite colourless; when relatively large quantities of these bases are present, morphine and codeïne give to the acid at the most only a faint rose-red tint. Thebaïne gives a greenish-yellow to

brown colour, and narcotine a red to reddish-brown. This reaction indicates also that some of the opium alkaloids, by this slow concentration of the sulphuric acid, afford different colour changes from those obtained by the direct addition of concentrated acid. Andromedotoxime gives a similar red colour, but this substance also becomes red on evaporation with 25 per cent. phosphoric acid, and with dilute hydrochloric acid, whilst narceine remains colourless with these acids. Impure aconitine gives the red colour, but also gives it with dilute phosphoric acid. J. T.

**Thallin.** By G. DRAGENDORFF and E. BLUMENBACH (*Chem. Centr.*, 1886, 874).—The characteristic reaction of this alkaloid, the bright green coloration with ferric chloride, is well marked with solutions of  $\frac{1}{100000}$ , and recognisable at a dilution of  $\frac{1}{1000000}$ . Auric chloride gives a similar and equally sensitive reaction.

For the isolation of the alkaloid from solutions such as animal fluids, the authors suggest a preliminary treatment with light petroleum before alkalising; the alkaloid is then exhausted by shaking with benzene after adding excess of ammonia. It was found that from a solution of 1 mgrm. in 100 c.c. of urine, a quantity sufficient for identification could be isolated by this treatment.

The results of the physiological investigation of the alkaloid are given in the original. C. F. C.

**Estimation of Indigo in Textile Fabrics.** By A. RENARD (*Bull. Soc. Chim.*, 47, 41—42).—10 grams of the dyed fibres are treated in a flask with 200 c.c. of a solution made by adding 2 litres of water and 100 c.c. of milk of lime to 100 c.c. of a solution of neutral sodium hyposulphite prepared from a solution of hydrogen sodium sulphite of 35° Baumé. The mixture is heated to from 60—70°, a stream of coal-gas being passed through the flask during the reduction, and when all the colour has disappeared, a portion of the solution is decanted, cooled, its volume measured, the indigo-blue precipitated by the addition of hydrochloric acid, and, after remaining 12 hours, collected on a small filter, washed, dried, and then dissolved with the filter-paper in about 10 c.c. of fuming sulphuric acid, and the solution titrated by Müller's method. A. P.

**Determination by Titration of the Free Acid in Tannin Liquor.** By R. KOCH (*Dingl. polyt. J.*, 264, 395—405).—This method is based on the fact that on treating tannin liquor with albumin, and nearly neutralising the mixture with standard alkali, a light-coloured filtrate is obtained which assumes a dark colour as soon as the point of alkalinity is reached. The mode of procedure is described in detail in the original paper, and the results of several test analyses are given. The numbers obtained do not, however, agree in all cases with those yielded by Kohnstein and Simand's precipitation process (*Abstr.*, 1885, 935). The latter is, in the opinion of the author, not wholly free from error, owing to the formation of sparingly soluble basic salts of magnesium. D. B.

**New Method for the Estimation of Tannin.** By VILLON (*Bull. Soc. Chim.*, 1884, **47**, 97—102).—The solution of tannin is diluted to such a strength that 100 c.c. will contain about 2 grams of tannin; a solution of lead acetate is prepared by dissolving 100 grams of that salt and 20 grams of sodium acetate in a litre of water. 100 c.c. of the tannin solution is then mixed with 100 c.c. of the solution of lead acetate, allowed to remain for five minutes, and the precipitate filtered off. The specific gravity  $D$  of the solution of lead acetate is taken, and the specific gravity  $D'$  of the tannin solution, and finally the specific gravity  $\delta$  of the filtered mixture. From these data the tannin in the original solution is calculated according to the formula  $\left(\frac{D + D'}{2} - \delta\right)A = \Sigma$ , in which  $A$  is a constant factor whose value is experimentally determined, and varies for different kinds of tannin.

The results obtained by this method are very satisfactory, and matters contained in tanning solutions which are absorbed by skin, but which have no tanning action are not precipitated. A. P.

**Estimation of Albuminoids in Liquids from Cysts, &c.** By L. GARNIER (*J. Pharm.* [5], **15**, 459—461).—The author criticises a method described by G. Dumonthiers (*J. Pharm.*, 1 Dec., 1886), and would modify it so that it becomes as follows:—The liquid under examination is diluted with 5 or 6 volumes of water, neutralised with acetic acid, and subjected to a current of carbonic anhydride. The precipitate formed is collected on a tared filter and treated with a 5 per cent. solution of sodium chloride, which dissolves the globulins. The residue is coagulated at  $110^\circ$ , washed with water, alcohol, and ether, then dried at  $105^\circ$ , and weighed. This represents the casein or alkaline albuminate. A certain volume of the original liquid, freed from fibrin, is saturated in the cold with magnesium sulphate. The precipitate is filtered, and consists of casein and globulin. The amount of the latter is obtained by subtracting from the total weight that of the former previously found. The solution of globulins in sodium chloride obtained above may be employed for the qualitative analysis of the globulins as follows:—(a) One-third of the liquid carefully heated on the water-bath gives a precipitate of fibrinogen at  $56$ — $60^\circ$ . The filtered liquid, when heated at  $75$ — $80^\circ$ , deposits serum-globulin in its turn; (b) a second third of the liquid treated with an equal volume of a saturated sodium chloride solution generally gives no precipitate if only serum-globulin is present; whereas fibrinogen becomes insoluble; (c) finally the addition to the globulin solution of Schmidt's fibrin ferment determines the production of insoluble fibrin at the expense of the fibrinogen only. J. T.

## General and Physical Chemistry.

---

**Fluorescence of Manganese and Bismuth.** By L. DE BOISBAUDRAN (*Compt. rend.*, **104**, 1680—1685; see also this vol., pp. 3, 4, and 189). The author has investigated the behaviour of (1) two solid solvents, and an active substance giving fluorescence with each of the solvents, as represented by mixtures of cadmium, zinc, and manganese sulphates, and calcium, magnesium, and manganese sulphates; (2) two solvents and an active substance giving fluorescence with only one of them, as represented by mixtures of barium, calcium, and manganese sulphates; (3) two solvents behaving towards each other as moderately active substances, and an active substance which fluoresces brilliantly with one only of the solvents, as represented by zinc, calcium, and bismuth sulphates, and calcium, cadmium, and bismuth sulphates.

In the first case, the effects of the two solvents are practically equal when they are mixed in the proportions of their molecular weights. In the other cases, the presence of the indifferent substance reduces the brilliancy of the fluorescence, but the latter is still distinctly recognisable, even when the proportion of the active substance is very small.

C. H. B.

**Variations in the Absorption-spectra of Didymium Salts.** By H. BECQUEREL (*Compt. rend.*, **104**, 1691—1693).—The results previously obtained (this vol., p. 537) indicate either that ordinary didymium is a mixture of a large number of elements, or that its compounds as usually obtained are mixtures of the salts and sub-salts of a smaller number of elements in different states of oxidation.

The absorption-spectra of dilute solutions of different compounds of didymium differ but little, whilst the absorption-spectra of the same substance in a crystallised condition are very different. When the water and acid of a hydrated didymium salt are gradually driven off by heating, a series of products is obtained, some of which are transparent, whilst others are pulverulent or opaque, but all of them show absorption-spectra by reflection, and these spectra consist of very different bands. A table is given showing the principal absorption-bands of different didymium-compounds prepared in the way described.

In the spectra of the products obtained by successive alterations of the same compounds, there are series of bands, which are transferred from one spectra to another in such a way that the variations in the number of luminous vibrations or the inverse squares of the wavelengths of corresponding bands are sensibly constant for each series. Each spectrum shows several of these series of bands with constant differences. The bands characteristic of several of these compounds coincide with the variable bands in the spectra of the crystals (*loc. cit.*).

C. H. B.

**Orthochromatic Photography.** By C. H. BOTHAMLEY (*J. Soc. Chem. Ind.*, 6, 423—433).—It is well known that gelatino-bromide plates, that is, plates coated with a dry film of an emulsion of silver bromide in gelatin, fail to give photographic representations of coloured objects with correct gradations, or in other words, with their proper degrees of relative brightness. They show a maximum sensitiveness to blue and violet, are much less sensitive to green, and are only affected by yellow, orange, and red when prepared by special methods, and when the exposure to light is greatly prolonged, whereas the eye is most sensitive to yellow, less sensitive to green and orange, and only slightly sensitive to blue, violet, and red. The term "orthochromatic" photography denotes the photographic representation of coloured objects in monochrome with correct gradations, and it is obvious that in order to attain this end the character of the plates must be altered in such a way that the sensitiveness to yellow, orange, and green is greatly increased, whilst the sensitiveness to blue and violet is reduced.

Vogel (*Ber.*, 6, 1302) discovered in 1873 that the addition of certain dyes, such as corallin, to sensitised collodion films, made them highly sensitive to yellow or greenish-yellow rays, and this observation was confirmed and applied in photographic practice. In 1883 Attout and Clayton patented the application of eosin to gelatin plates, and their observation has since been confirmed and greatly extended by other observers, and the application of dyes to photographic plates has become of great practical importance. Eder has investigated the effect of a large number of dyes (*Sitzungsb. d. Kais. Akad. der Wissensch.*, Vienna, 1884, 1885, 1886; see also *Abstr.*, 1885, 703; 1886, 405, 497, 958). Very few are found to exert any useful sensitising action. Cyanin and some of the eosin dyes produce the greatest effect, whilst naphthol-blue, the neutral blue of the *Frankfort Anilin-Farben-Fabrik*, and coerulein S. are remarkable, because they render the plates sensitive without interruption to the entire length of the spectrum from  $\lambda$  3600 to  $\lambda$  7600. The dyes are either added to the melted emulsion before it is poured on the plate, or the dried plates are immersed in dilute solutions of the dyes and again dried. The curves representing the action of the prismatic spectrum on plates thus prepared show two maxima, one in the blue, corresponding with the ordinary sensitiveness of the gelatino-bromide, the other in the less refrangible half of the spectrum, representing the sensitiveness due to the presence of the dye. This second part of the curve corresponds but does not coincide with the absorption-band in the spectrum of the dye (*Abstr.*, 1886, 958). Between the two maxima there is a region of minimum action, which is generally in the green, and when the exposure to light is short the effect of this part of the spectrum is inappreciable, and the action is represented by two detached curves, one in each half of the spectrum.

Different commercial samples of the dyes have been found to produce very different effects, and the author has compared a number of samples of dyes of the eosin-group by examining their absorption-spectra, &c. The chief eosin colours are eosin, phloxin, erythrosin, and rose Bengal, which are the sodium or potassium salts of tetra-

bromfluoresceïn, dichlorotetrabromfluoresceïn, tetraiodofluoresceïn, and dichlorotetraiodofluoresceïn respectively, the different commercial varieties being distinguished by letters. Eosin A, eosin JJ, eosin VE, and eosin SGF, were found to be practically identical. Erythrosin, erythrosin extra, erythrosin I, and erythrosin RE, are also identical, and rose Bengal is indistinguishable from rose Bengal B. The samples of phloxin on the other hand were found to be variable in their properties. Erythrosin B (Casella and Co.) seems to be a mixture of eosin with either the true erythrosin or rose Bengal, and erythrosin BE is really rose Bengal. One sample of erythrosin lost 8·8 per cent. at 115—120°, whilst another lost 12·5 per cent. Attention is called to the relation between the optical properties of these dyes and their molecular weights. The absorption-band becomes narrower, more intense, and less refrangible, the fluorescence rapidly diminishes, and the tint of the dye becomes bluer as the molecular weight increases. Fluoresceïn and eosin are brilliantly fluorescent; erythrosin and rose Bengal do not fluoresce at all.

The effect of the prismatic spectrum was also investigated. Commercial dry plates were immersed for two or three minutes in water, and then for two minutes in a solution of 1 part of the dye in 10,000 parts of water, and allowed to dry in the dark; others were immersed for two or three minutes in strong ammonia diluted with 100 vols. of water, and then for two minutes in a solution of the dye (1 : 10,000) to which 1 per cent. of ammonia solution had been added. Plates prepared in this way were exposed to the prismatic spectrum of light from burning magnesium, the same length of ribbon being burnt for each exposure. This source of light was selected because it contains a very high proportion of rays of high refrangibility which tend to correct the known defect of the prismatic spectrum, that is, the abnormal extension of the more refrangible rays. When a sufficient length of magnesium ribbon is burnt at a uniform rate, the effect of inequalities is eliminated and a practically constant unit of exposure is obtained. The exposed plates were developed with alkaline pyrogallol in the usual way, and the results are expressed in the form of curves. The general character of Eder's results is confirmed, but important differences of degree were observed. Each curve has two maxima separated by a region of minimum action. Eosin in aqueous solution exerts a comparatively slight though distinct sensitising action, and with commercial phloxin the effect is slightly greater. Erythrosin produces by far the greatest effect of the dyes of this group, and rose Bengal is much superior as a sensitiser to eosin, although inferior to erythrosin. The maximum effect of erythrosin and rose Bengal is exerted somewhat on the more refrangible side of D. Cyanin differs from eosin, &c., in that it sensitises for yellow, orange, and orange-red, instead of for greenish-yellow and yellow, the maximum action being exerted between D and C. The results with this dye entirely confirm those previously obtained by Eder and by Schumann. When ammonia is applied with the dye the magnitude of the sensitising action is increased, and extends to a greater distance on either side of the maximum, thus tending to obliterate the region of minimum action. The difference between the effect of

aqueous and ammoniacal solutions is greatest in the case of eosin, but even in presence of ammonia this dye produces less effect than aqueous erythrosin. Erythrosin in presence of ammonia is the most efficient sensitiser that has yet been suggested. The most important result obtained, however, is that plates dyed with aqueous or ammoniacal erythrosin, ammoniacal rose Bengal, or ammoniacal cyanin, *are more sensitive to the yellow or orange-yellow of the prismatic spectrum than to the blue and violet*, and this even with a source of light which is extremely rich in rays of high refrangibility. When burning magnesium is the source of light, plates dyed with aqueous erythrosin or ammoniacal rose Bengal are about half as sensitive again to the yellow as to any part of the blue or violet; plates dyed with ammoniacal erythrosin are somewhat more than twice as sensitive to yellow as to blue or violet; plates dyed with ammoniacal cyanin are about half as sensitive again to orange as to blue or violet. The difference between these results and those of Eder is probably due to the fact that in most of the latter's experiments the dye was added to the melted emulsion, and the bath solutions used were weaker than those employed by the author.

At present it is not possible to explain why these dyes act as sensitisers whilst others do not. No connection can be traced between the physical and chemical properties of the dyes and their sensitising action. Eder has shown (*loc. cit.*) that the dyed silver gelatinobromide shows an absorption-band identical in position with the sensitising effect, this band being somewhat less refrangible than the absorption-band of the dye alone or mixed with gelatin, owing to the presence of the dense silver bromide. Eder has also found that when the dye is once added to the silver bromide it cannot be removed by prolonged washing, and he concludes that the dye forms a molecular compound with the silver salt, which is decomposed by the rays which it absorbs. Some experiments by Abney indicate, however, that the dye is first decomposed by light, and the products of its decomposition reduce the silver salt when the developing solution is applied. The author points out that the dyes which exert the greatest sensitising action contain a number of atoms of bromine or iodine, have a very high molecular weight, and a complex molecular constitution, and he suggests that the weight and complex structure of the molecules may confer upon them the power of entangling and arresting the ether waves to a greater extent than lighter and simpler molecules.

For practical purposes the results with the spectrum must not be interpreted too literally. The difference between the brightness of pigments is never so great as between the brightness of the corresponding colours of the spectrum, and, moreover, all coloured objects reflect more or less unaltered white light which tends to reduce the contrasts due to differences in colour. The curve representing the action of the spectrum on plates dyed with ammoniacal erythrosin approximates to the curve representing the action of the spectrum on the eye, and this dye is the most useful sensitiser for general purposes. In order to obtain correct gradations it is necessary to reduce the intensity of the blue and violet rays, to which the plates remain very

sensitive, and this is done by interposing a transparent yellow screen between the object and the lens. The depth of tint of the screen determines the proportion of blue and violet cut off, and thus affects the result. With gas or lamp light a yellow screen is unnecessary.

The author has photographed various coloured objects, such as pottery, flowers, paintings, and landscapes, with plates prepared with ammoniacal erythrosin by the method described above, and by a slightly different method previously recommended by Mallman and Scolik (*Photo. Journal*, 1886). With ordinary plates, even under the most favourable conditions, yellow, orange, and red are represented as almost black, whilst green is far too dark, and blue and violet are practically white. With the dyed plates without any yellow screen, yellow, green, and orange are more satisfactorily rendered, but blue and violet remain far too light. When, however, the dyed plates are used with a yellow screen before the lens the results are very satisfactory; yellow objects come next to white in brightness, and the other colours are represented in their proper gradations. The plates are, however, deficient in sensitiveness to red. In landscape work, in addition to the better rendering of foliage, &c., a great advantage is gained by the fact that the yellow screen cuts off the blue atmospheric haze. The interposition of the screen of course necessitates a longer exposure.

Dyed plates have already been largely employed, with great advantage, in the reproduction of pictures, and are also found to be valuable in micro-photography and in stellar photography. Hasselberg, of Pulkowa, has used dyed plates with success in photographing the less refrangible end of the spectrum, and he recommends the following solutions, which are applied to the plates after the latter have been immersed in dilute ammonia:—*from C to  $\lambda$  5600*; alcoholic cyanin solution 1 : 400, 2 parts; ammonia 1 part; water 100 parts: *from  $\lambda$  5600 to F*; chrysaniline solution (1 : 1000) 3 parts; eosin solution (1 : 1000) 5 parts; ammonia 1 part; water 100 parts. Eosin sensitises for yellowish-green and chrysaniline for green. C. H. B.

**Conductivity of Mixtures.** By E. BOUTY (*Compt. rend.*, 104, 1699—1702).—The author explains certain methods of calculating the conductivity of dilute solutions of mixed salts from the known conductivity of its constituents. The methods and results will be more fully developed in a subsequent paper. C. H. B.

**Phosphates of the Alkaline Earths.** By BERTHELOT (*Compt. rend.*, 104, 1666—1667).—A note on a recent paper by Joly.

**Trimetallic Phosphates.** By A. JOLY (*Compt. rend.*, 104, 1702—1705).—The formation of the colloidal modification of sodium strontium phosphate (this vol., p. 637) from trisodium phosphate and strontium chloride develops +15.3 Cal., whilst the formation of the same salt in the crystalline condition,  $\text{NaSrPO}_4 + 9\text{H}_2\text{O}$ , develops +50.4 Cal. When free from sodium chloride, the crystals are very slightly decomposed by cold water. Decomposition takes place more

rapidly at 20°, and at about 70° the double salt splits up into trisodium phosphate and tristrontium phosphate.

When strontium chloride solution is poured into a solution of trisodium phosphate at about 10°, a gelatinous precipitate of tristrontium phosphate is first formed with absorption of heat, but this rapidly changes into crystalline sodium strontium phosphate with development of heat. The rapidity with which crystallisation takes place is doubtless due to the presence in the gelatinous precipitate of a small quantity of colloidal sodium strontium phosphate, which rapidly becomes crystalline, and thus initiates the transformation of the entire mass.

Sodium strontium arsenate (*loc. cit.*) is more stable than the corresponding phosphate; heat of formation in the crystalline condition, +50.2 Cal.

The author was unable to obtain any evidence of the existence of a double sodium calcium phosphate between 10° and 18°.

The corresponding crystalline double phosphate and double arsenate of barium can, however, be readily obtained in a similar manner; their heats of formation are respectively +50.8 Cal. and +50.4 Cal.

Sodium barium phosphate is less stable than the strontium compound. It is more readily decomposed by water, and the tendency to form barium triphosphate is greater. The latter compound seems to exist in a peculiar molecular condition.

The phenomena observed in the case of sodium strontium and sodium barium phosphates are similar to those previously observed with ammonium magnesium phosphate. C. H. B.

**Heat of Combustion of Organic Compounds.** By F. STOHMANN (*Ber.*, 20, 2063—2066).—A reply to Thomsen (this vol., p. 761), in which the author discusses the difference between his results and those of Berthelot and Vieille, and points out that the differences are in the majority of cases less than is indicated by Thomsen.

W. P. W.

**Heat Equivalents of Benzoyl-compounds.** By F. STOHMANN, P. RODATZ, and W. HERZBERG (*J. pr. Chem.* [2], 36, 1—16).—In the following determinations, the substances were burned in free oxygen; the substance was put into a small lamp, which in the case of compounds which melt with difficulty was provided with platinum wires, to conduct the heat from the wick to the substance. Several experiments made with each substance gave the following mean results :—

|                       | Heat equiv. per<br>gram-mol. | Heat of<br>formation. |
|-----------------------|------------------------------|-----------------------|
| Benzic acid .....     | 770467                       | 94533                 |

The difference in heat equivalents of benzene (*J. pr. Chem.* [2], 33, 257) and benzoic acid is —9063 cal. This number is also obtained by adding together the differences in the heat equivalents shown in the conversion of toluene to benzyl alcohol, benzyl alcohol to benzaldehyde, and benzaldehyde to benzoic acid, and subtracting from the whole the heat equivalent of toluene less that of benzene.

The conversion of benzoic acid and the formation of benzoic ether are enthothermic processes; the mean difference in the case of the alkyl ethers (obtained by comparison of the heat equivalents of benzoic acid and alcohol on the one hand, and the heat equivalent of the salt on the other) is —4740 cal. In the case of the aromatic benzoates the mean difference is —10833 cal. (compare this vol., p. 427).

N. H. M.

**Relation between the Boiling Points of the Monatomic Alcohols and their Constitution.** By F. FLAWITZKY (*Ber.*, 20, 1948—1955).—The relation between boiling points and the constitution of monhydric alcohols is discussed, and several tables given. The author considers that although it is not yet possible to show a general dependence of the boiling points on the constitution of alcohols, it is possible to predict approximately a boiling point when the constitution is known.

N. H. M.

**Alteration of the Freezing Point.** By F. KOLÁČEK (*Ann. Phys. Chem.*, 31, 526—536).—In these remarks on Helmholtz' paper on this subject, the author defines the freezing point of a salt solution as the temperature at which the ice and salt solution have the same vapour-tension, and points out that this definition was not put forward as a shrewd conjecture, as Helmholtz supposes, but was the result of general reasoning. The formula given for the freezing point is extended to the case when the heat of solution comes into play. From thermodynamic considerations he finds that—

$$\left[ \log \frac{p_w}{p} \right] = \left[ \log \frac{p_w}{p} \right]_{T_1} + \frac{s}{RA} \int_{T_1}^{T_2} V \frac{dT}{T^2},$$

where  $T$ ,  $T_1$  are arbitrary temperatures,  $p_w$ ,  $p$  the vapour-tensions of water and the salt solution,  $s$  the amount of salt dissolved.

If  $s$  be small, we see that  $\log \frac{p_w}{p}$ , and therefore  $\frac{p_w - p}{p_w}$ , is independent of  $T$ , a law which has already been discovered by Wüllner.

If  $T = 273 - t$  be the freezing point, since (*Ann. Phys. Chem.*, **29**, 349)

$$\log \frac{p_e}{p_w} = -t0.00965(1 + t0.000531 \dots),$$

we find the equation

$$0.00965t(1 + t0.000531) = \left[ \log \frac{p_w}{p} \right]_{T_1} + \frac{s}{RA} \int_{T_1}^T \frac{dT}{T^2} V.$$

Since  $V$  is an unknown function, it might be supposed that the best course would be to take  $T = T_1$  when the term under the integral sign vanishes, but the values of  $\log p_w/p$  below zero are unknown. The next best thing to do is, make this term a minimum.

The present research gives  $\frac{dt}{dp} : R$ ,  $a$ ,  $b$  are known constants, and  $v$  may be calculated from the formula  $p + a/v^2 = RT/(v - b)$ . The ratio  $c_p/c_v$  is known, and  $c_p$  has been found by Wiedemann. On substitution,  $\psi$  turns out to be very nearly constant. Thus integrating the equation

$$f - t \left( \frac{df}{dt} \right)_v c/v^2,$$

we find

$$f = F(t)/v^2 + t\phi(v).$$

Clausius chooses  $\phi(v) = 0$ ,  $F(t) = 1/t$ , Van der Waals  $\phi(v) = 0$ ,  $F(t) = 1$ . Both choose the form of  $f$ , so as to satisfy the above equation. The present experiments, conducted at one temperature, afford no information about the form of  $F(t)$ . We are therefore unable to discriminate between the hypotheses of Clausius and Van der Waals on this point, though the formula of Clausius gives results most in accordance with the numbers obtained from the experiment, unless the value of  $a$  be altered. C. S.

**Cooling of Carbonic Anhydride on Expansion.** By E. NATANSON (*Ann. Phys. Chem.* [2], **31**, 502—526).—The author believes that fresh measurements of the internal work of an expanding gas may supply considerable information about the forces which act between the molecules. The method adopted was the same in principle as that used by Thomson and Joule. The gas was allowed to expand through a porous plug of cotton-wool. Greater care was taken to secure the purity of the gas. This is most essential, for Thomson has pointed out that mixtures of gases behave in a very anomalous manner.

Carbonic anhydride was chosen as the subject of experiment, because the intermolecular forces are large, and the many previous researches supply the requisite data for the calculations.

The gas contained in a strong iron bottle escaped into a sphere (used for the purpose of equalising the pressure), and passed through a series of drying tubes filled with calcium chloride, into a number of copper tubes immersed in a water-bath of very considerable capacity. To increase the effective surface of the tubes, they were filled with

metal turnings. Thus the gas on entering the nozzle containing the porous plug was at a uniform temperature equal to that of the water-bath. The nozzle was of exactly the same construction as the one employed in the experiments of Thomson and Joule. By means of stopcocks placed between the sphere and the plug and at the extremity of the nozzle, the pressure on each side of the plug could be completely controlled. Fifty-three experiments were made at pressures ranging from 2 to 25 atmospheres, with the gas at a mean temperature of  $20^{\circ}\text{C}$ . If  $\Delta T$ ,  $\Delta p$  be the differences of temperature and pressure on the two sides of the plug, the results of the experiments show that at a temperature of  $20^{\circ}\text{C}$ .,

$$\frac{\Delta T}{\Delta p} = 1.18 + 0.0126p,$$

$p$  being the mean of the pressures on the two sides of the plug, measured in atmospheres.

Taking the equation of elasticity to be

$$p = Rt/(v - b) - f(v, t),$$

an attempt is made to determine the form of the function  $f$ . Applying the laws of thermodynamics to the present case of a gas expanding through a porous plug under small differences of pressure, we find

$$0 = c_v dt + \left\{ t \left( \frac{dp}{dt} \right)_v - p \right\} dv + d(pv),$$

which, in virtue of the equation of elasticity, may be reduced to

$$v^2 \left\{ f - t \left( \frac{df}{dt} \right)_v \right\} = v^2 \left\{ - \left( c_v \frac{dt}{dp} + v \right) \frac{dp}{dv} - p \right\}.$$

Since it is our object to calculate merely the numerical value of the right hand side of this last equation, we may use Van der Waals' formula,  $p = Rt/(v - b) - a/v^2$ , which is known to give the compressibility correctly. Expressing  $\frac{dp}{dv}$  by this means in terms of  $\frac{dt}{dp}$  we arrive, on substitution, at a result of the form

$$v^2 \left\{ f - t \left( \frac{df}{dt} \right)_v \right\} = \psi \left( \frac{dt}{dp}, c_v, R, a, b, v \right),$$

where  $\psi$  is a known function.

$$\text{Put} \quad x = \left[ \log \frac{p_0}{p} \right]_{T_1},$$

$$\text{and} \quad y = \frac{s}{RA} \int_T^{T_1} \frac{dT}{T^2} V.$$

Then approximately

$$0.000965t = x + y.$$

Remembering that  $t$  is constant with respect to  $T$ , we see that when

$y$  is a minimum;  $s$  a maximum, and *vice versa*. Supposing  $y$  positive, the required values of  $T_1$  may be found by plotting the curve ordinate and abscissa  $T_1$ ,  $x$ , and selecting by inspection the least maximum value of  $x$ . Then neglecting  $y$ , we obtain from the last equation a near approximation to the value of  $t$ , the temperature of the freezing point. A table of the values of this quantity for some 20 substances is given. The greatest difference between theory and observation is about 17 per cent., a great improvement on the values given by Helmholtz, for which the discordance is as much as 40 per cent. in several cases.

C. S.

**Phosphonium Chloride.** By S. SKINNER (*Proc. Roy. Soc.*, 1887, 283—289).—In order to determine the relations of phosphonium chloride to temperature, volume and pressure, the author compresses equal volumes of phosphine and hydrogen chloride in a Cailletet's apparatus. The critical point was found at  $48^\circ$  under 95 atmos. The maximum vapour-pressure line lies below those of hydrogen chloride and phosphine at all temperatures. From  $-30^\circ$  to  $10^\circ$  it is normal; above this combination begins. At temperatures near the critical points the volume of liquid phosphonium chloride produced is nearly one-half of that of the constituents (liquid).

**Apparatus for Determining Vapour-densities.** By C. SCHALL (*Ber.*, 20, 1827—1830).—A modification of the apparatus lately described by the author (this vol., p. 695).

**Determination of the Vapour-density of High-boiling Substances under Diminished Pressure.** By C. SCHALL (*Ber.*, 20, 2127—2129).—An application of the form of manometer employed by Meier and Crafts (*Ber.*, 13, 851), and by Nilson and Pettersson (*ibid.*, 17, 987) to the apparatus described by the author (preceding Abstract). Results obtained by its use are given in the paper.

W. P. W.

**Influence of Temperature on the Rapidity of the Action of certain Mineral Acids on Marble.** By W. SPRING (*Bull. Soc. Chim.*, 47, 927—933).—The rapidity of action of hydrochloric, hydrobromic, hydriodic, nitric and perchloric acids on marble increases with the temperature, it being about doubled for a difference of every  $20^\circ$  between  $15^\circ$  and  $55^\circ$ .

When an aqueous solution of one of the above acids is allowed to act on marble until action ceases, the author finds that the rapidity of action decreases uniformly with the strength of the acid until three-fifths of the acid has been neutralised; after this point, the decrease of the rapidity of action is rather less than the decrease in the amount of acid present; this bears out the observation of Ostwald, that the rapidity of the action of monobasic acids is increased by the presence of their salts.

A. P.

**Application of the Electrometer to the Study of Chemical Reactions.** By E. BOUTY (*Compt. rend.*, 104, 1789—1791 and 1839—1841).—An application of the measurement of resistances to determine

the effect of mixing solutions of potassium sulphate and sulphuric acid. The observed resistance is greater than that calculated on the supposition that there is no action, and it follows that the normal salt combines with the acid to form potassium hydrogen sulphate; as the solution becomes more and more dilute the quantity of potassium hydrogen sulphate diminishes, and eventually it is completely converted into the normal salt. The molecular resistance of the acid sulphate varies according to the same law as that of other salts; that is to say, it is proportional to a factor  $1 + Km^{\frac{1}{2}}$ , and the proportion of the acid salt in a solution is given by the expression  $y = Ym^{\frac{1}{2}}$ . The dissociation of the acid salt is indicated by the somewhat high value of  $m^{\frac{1}{2}}$  in the formula for the molecular resistance.

Assuming that the molecule of potassium hydrogen sulphate constitutes a single electrolytic molecule, its resistance at the limit will be equal to that of the normal salt, and in solutions containing not more than 0.1 gram-equivalent per litre, the difference between the resistances of the two salts will be negligible compared with the much greater conductivity of the free acid. Calculating from the observed resistances of the liquid, it is found that the proportion of the acid sulphate increases with the temperature, and, combining this with the previous result, it follows that potassium hydrogen sulphate is more stable in warm and concentrated solutions. At the same temperature and with the same degree of concentration, the proportion of the acid salt increases with an increase in the relative proportion of either the free acid or the normal salt, an excess of the normal salt being more favourable to this change than an excess of sulphuric acid. These results agree with the results of Berthelot's thermochemical measurements.

It is possible that the great variations in the resistances of abnormal salts and of free acids may be due to the progressive dissociation of complex electrolytic molecules, according to the same law as the dissociation of potassium hydrogen sulphate. This effect will be added to, but will not modify the law of the variation of the resistances of salts which are normal in all degrees of dilution.

C. H. B.

**Decomposition of Thiosulphates by Acids.** By G. FOUSSEREAU (*Compt. rend.*, 104, 1842—1844).—The decomposition of thiosulphates by acids was investigated by measuring the resistances of the various solutions—the rate and amount of change being measured by the increase in resistance. With solutions containing one-twelfth of a gram-equivalent of sodium thiosulphate per litre, decomposition by hydrochloric acid commences immediately and its velocity increases rapidly, then more slowly, the limit corresponding with complete decomposition. With very dilute solutions, containing only 0.001 to 0.0005 gram-equivalent per litre, decomposition likewise commences immediately, but is at first very slow. The rate of change accelerates gradually during the first few days, attains a maximum in about 40 days, and then the change becomes less rapid, and finally ceases when decomposition is complete. The rate of decomposition is accelerated by increase of temperature and also by adding a small quantity of a similar mixture in which decomposition has taken place and which,

therefore, contains minute particles of sulphur. Under the latter conditions, the small globules of sulphur seem to act in the same way as crystals in a supersaturated solution.

When a liquid in which the decomposition is taking place is examined under a microscope, it is seen to contain very minute globules of sulphur which have a rapid Brownian movement. The reaction, however, is not due to the presence of living organisms, and takes place with equal rapidity in sterilised liquids. C. H. B.

**Apparatus for Fractional Distillation under Reduced Pressure.** By L. MEYER (*Ber.*, 20, 1833—1836).—This apparatus consists of a cylindrical receptacle having four tubulures, two lateral, one at the top, and one (which terminates in a narrow tube) at the bottom. The lateral tubulures serve respectively to admit the end of the condenser and to connect the apparatus by means of a three-way tap with the air-pump. The bottom tubulure is fitted by means of a cork into the receiver. A piece of glass tubing longer than the cylinder and also connected with the pump by a three-way tap, is fitted by means of a cork (air-tight) into the upper tubulure, so that it may at will be depressed until the lower end, which is ground into the lower tubulure, completely shuts off the cylinder from the receiver. When working the lower tubulure is open, and the distillate flows into the receiver. When it is wished to change the receiver, the glass tube is depressed and the distillate accumulates in the cylinder. By means of the three-way tap on the tube air can be admitted to the receiver, and the latter taken off and replaced by a new one. This is then rendered vacuum by help of the three-way tap, and the tube raised. The accumulated distillate flows into the new receiver and the distillation and fractionation may thus be carried on without intermission. The advantage claimed for the apparatus is that by the tube-joint the usual stopcock at the lower tubulure is dispensed with.

**Precipitation of Mixtures of Iodates and Sulphates by Barium Salts.** By CHROUSTCHOFF (*Compt. rend.*, 104, 1711—1714).—The ultimate product of the action of barium chloride on potassium iodate is the iodate,  $\text{BaI}_2\text{O}_6 + \text{H}_2\text{O}$ , which readily loses water. If dried at  $140^\circ$  and then left in contact with a solution of potassium sulphate for 67 hours, 88 per cent. of the salt is converted into barium sulphate. The precipitates obtained by adding barium chloride to mixtures of potassium iodate and sulphate, and by the action of potassium iodate on barium sulphate, and of barium iodate on potassium sulphate, vary in composition with the time of contact, temperature, and other conditions. The recently precipitated compounds are more readily decomposed than the same compounds after drying. In all cases, the composition of the precipitates agrees with the calculations from

thermal observations. The changes are limited by the dissociation of the hydrates of barium and potassium iodates.

Freshly precipitated barium iodate,  $\text{BaI}_2\text{O}_6 + \text{H}_2\text{O}$ , when left in contact with a solution of potassium sulphate for 25 minutes is converted into a mixture of 61 parts of barium sulphate and 39 parts of iodate,  $\text{BaI}_2\text{O}_6$ . Freshly precipitated barium sulphate left in contact with a solution of potassium iodate for 30 minutes yields a mixture of barium sulphate, 86.5 parts, and barium iodate,  $\text{BaI}_2\text{O}_6$ , 13.5 parts.

**Percentage of Oxygen in Air.** By W. HEMPEL (*Ber.*, 20, 1864—1873).—This paper gives the results of analyses of samples of air simultaneously collected by the author in Dresden, by Kreusler near Bonn; by Morley in Cleveland, North America; by Pusinelli in Para (Belem), Brazil (lat.  $1\frac{1}{2}^\circ$  S.); by Schneider in Tromsøe, Norway (lat.  $69\frac{1}{2}^\circ$  N.). The samples were taken daily between April 1 and May 16, 1886, the times being simultaneous in all places, and corresponding to 2.12 P.M. at Bonn. Full tables of the results are given. The mean percentages of oxygen for each place were—Para, 20.92; Bonn, 20.92; Cleveland, 20.93; Dresden, 20.93; and Tromsøe, 20.95. The maximum observed was 21.00 on April 22nd at Tromsøe; the minimum 20.86 on April 26th in Para. The mean percentage of oxygen in the air as deducible from the whole series of observations is 20.93. During the time these observations were being made, the percentage of oxygen was rather greater near the pole than near the equator.

L. T. T.

**Preparation of Hydrogen Sulphide free from Arsenic.** By R. FRESSENIUS (*Zeit. anal. Chem.*, 26, 339—340).—Calcium sulphide (prepared by igniting a mixture of plaster of Paris and coal) yields the pure gas when treated with dilute hydrochloric acid. To evolve the gas in a regular stream a mixture of the calcium sulphide, with one-fourth of its weight of plaster of Paris and enough water to make a cream, is poured into shallow paper trays. As soon as it has set the cake is cut up into blocks, which are dried at a gentle heat. They are then used in a Kipp's or other gas-evolution apparatus. The stream of gas is thoroughly under control.

M. J. S.

**Purification of Hydrogen Sulphide from Hydrogen Arsenide.** By O. JACOBSEN (*Ber.*, 20, 1999—2001).—The method is based on the fact that hydrogen arsenide reacts violently with iodine at the ordinary temperature, arsenious iodide and hydrogen iodide being formed. A narrow tube, 30 to 40 cm. long, is loosely filled with coarsely powdered, air-dried, iodine interspersed with glass-wool. 2 or 3 grams of iodine will remove every trace of arsenic from hydrogen sulphide (prepared from the ordinary impure materials), passing over it for several days. In purifying hydrogen, the latter is subsequently passed over glass wool wetted with potassium iodide solution and then through aqueous potash.

N. H. M.

**Affinity of certain Bivalent Metals for Sulphuric Acid.** By R. FINK (*Ber.*, 20, 2106—2108).—A summary of results obtained in

an investigation to determine the relative affinity of biacid metallic hydroxides insoluble in water for sulphates of metals of the same group. The method adopted was to make one-fifth normal solutions of the pure normal sulphates of the metals, and precipitate 50 c.c. of one of these solutions with 10 c.c. of normal soda solution; the moist hydroxide, after thorough washing, was mixed with 50 c.c. of water and 50 c.c. of the sulphate solution of one of the metals, and digested at  $100^{\circ}$  for three hours with continual shaking. The precipitate and solution were then analysed. A preliminary experiment was made in the case of those metals which form basic salts by treating the hydroxide in exactly the same way with 50 c.c. of the sulphate solution of the same metal; the composition of the precipitate was then determined and was found to be approximately constant and independent of the volume of the one-fifth normal sulphate solution employed. As a result, it was found that instead of containing 1 equivalent of the metal the zinc precipitate contained 1.16 eq. of zinc and 0.22 eq. of sulphuric acid; the copper precipitate 1.275 eq. of copper and 0.301 eq. of sulphuric acid, the cobalt precipitate 0.12 eq., and the nickel precipitate 0.05 eq. of the respective sulphates, whilst the hydroxides of magnesium, manganese, and iron (ferrous) remained unaltered. The hydroxides of those metals forming basic salts, with the exception of nickelous hydroxide, were digested with the sulphate solution of their respective metals, washed with water, and then similarly treated with the sulphate solution of another metal. The results of the experiments are summarised in the following table:—

| Hydroxide or basic salt ( <i>b</i> ). | Sulphate.  | Precipitate contained—       |
|---------------------------------------|------------|------------------------------|
| Zinc ( <i>b</i> ).                    | Copper.    | The whole of the copper.     |
| Copper ( <i>b</i> ).                  | Iron.      | 60.8 per cent. of iron.      |
| Magnesium.                            | Iron.      | 71.2 " " "                   |
| Cobalt ( <i>b</i> ).                  | Manganese. | 14.7 " " of manganese.       |
| Nickel.                               | Manganese. | 12.3 " " "                   |
| Copper ( <i>b</i> ).                  | Magnesium. | No magnesium.                |
| Magnesium.                            | Nickel.    | 60.5 per cent. of nickel.    |
| Iron.                                 | Manganese. | No manganese.                |
| Zinc ( <i>b</i> ).                    | Nickel.    | Small quantity of nickel.    |
| Magnesium.                            | Manganese. | 71.2 per cent. of manganese. |

The experiments with the ferrous salts were conducted in an atmosphere of hydrogen to avoid oxidation. W. P. W.

**Sulphites.** By P. J. HARTOG (*Compt. rend.*, 104, 1793—1796).—When water containing magnesium hydroxide in suspension is saturated with sulphurous anhydride, concentrated in a vacuum at a temperature below  $100^{\circ}$ , and allowed to cool, it deposits crystals of the hexhydrated magnesium sulphite,  $\text{MgSO}_3 + 6\text{H}_2\text{O}$ , described by Rammelsberg and Marignac. If the solution is evaporated at a high temperature, it yields crystals of the tri-hydrate  $\text{MgSO}_3 + 3\text{H}_2\text{O}$ ,

which was prepared by Muspratt, but the existence of which has been denied. The liquid must be mixed with fragments of pumice-stone or glass in order to prevent the separation of the salt in the form of a hard crust adhering firmly to the sides of the vessel. The heats of formation of the sulphite and its hydrates were determined by dissolving them in hydrochloric acid.

Ammonium sulphite,  $(\text{NH}_4)_2\text{SO}_3 + \text{H}_2\text{O}$ , can be obtained in the dry state by means of kaolin. It oxidises more rapidly when solid than when in solution, and therefore cannot be dried in the usual way. Heat of dissolution  $-4\cdot34$  Cal. The anhydrous salt, mixed with some sulphate, is obtained by evaporating the solution at a moderate temperature.

*Ammonium Magnesium Sulphite.*—The hydrate,  $(\text{NH}_4)_2\text{SO}_3\cdot 3\text{MgSO}_3 + 18\text{H}_2\text{O}$ , described by Marignac and Rammelsberg, is obtained by neutralising with ammonia a solution of magnesium sulphite in sulphurous acid, passing sulphurous anhydride into the liquid, evaporating in a vacuum till a white precipitate begins to form, filtering, and allowing to crystallise. The hexhydrate,

is obtained by heating the preceding salt in a current of dry nitrogen at  $115-120^\circ$ . The salt decomposes above  $125^\circ$ , and cannot be obtained in the anhydrous condition. The heat of formation was determined by dissolving in hydrochloric acid:—

It is evident that the formation of these salts is accompanied by a considerable development of heat, a result which supports Berthelot's theory of the existence of ammonio-magnesium bases which unite with acids with a greater development of heat than the bases separately.

C. H. B.

**Density of Nitric Oxide at  $100^\circ$ .** By G. DACCOMO and V. MEYER (*Ber.*, 20, 1832).—The authors filled two like thermometer-tubes, the one with air, the other with nitric oxide, the surfaces of the sealing liquids being at equal heights in the tubes. The two tubes were then placed side by side and cooled in a bath of ether and solid carbonic anhydride. Observations were taken at  $-96^\circ$  and  $-107^\circ$ . The contraction of both gases was exactly the same, thus proving that even as low as  $-100^\circ$ , the density of nitric oxide still corresponds with the simple formula NO.

L. T. T.

**Behaviour of Phosphorus, Arsenic, and Antimony at a White Heat.** By J. MENSCHING and V. MEYER (*Ber.*, 20, 1833).—The authors find that at a white heat the vapour-densities of phosphorous and arsenic are much less than at lower temperatures, and approach but do not quite reach those required for the formulæ  $P_2$  and  $As_2$ .

Antimony volatilises at a white heat, and the vapour-density is lower than that required for  $Sb_4$  or even  $Sb_3$ , but the authors are unable to say definitely whether the density corresponds with a diatomic or a monatomic molecule, as the vapour at the temperature obtained had not yet fully attained the properties of a gas. L. T. T.

**Arsenic.** By A. GEUTHER (*Annalen*, 204, 208—225).—When a mixture of phosphorus and arsenic trichlorides is treated with water the arsenious acid first formed is rapidly reduced to metallic arsenic. Thus obtained arsenic forms a brownish-black amorphous powder of sp. gr. 3.704 at 15°. It remains unchanged and unoxidised when exposed to the atmosphere at ordinary temperatures. Arsenic thus has at least three allotropic modifications, viz., brownish-black amorphous form of sp. gr. 3.704, black amorphous form of sp. gr. 4.71, and steel-grey crystalline form of sp. gr. 5.73. Besides these, Bettendorf described (*Annalen*, 144, 110) a yellow amorphous modification deposited on the coolest parts of the tube during the rapid sublimation of arsenic in a stream of hydrogen. The author is inclined to view this as probably an amorphous variety of still lower specific gravity. The author points out that the specific gravities of the three modifications mentioned above stand to each other in the proportion of 4 : 5 : 6, and suggests that their molecules may very likely be expressed by the formulæ  $(As_4)_2$ ,  $(As_4 + As_6)$ , and  $(As_6)_2$ , or some multiple of these formulæ respectively.

The blackening of metallic arsenic by exposure to the air is generally ascribed to the formation of a suboxide, but the author finds that it is due to superficial oxidation to arsenious anhydride. If crystalline arsenic is finely powdered and exposed to the air it increases in weight for some time. If it is then boiled with water arsenious acid is obtained in solution and pure arsenic left, of which, on further exposure to the air, a fresh portion becomes oxidised.

Realgar, when heated with a solution of sodium sulphide, yields sodium sulpharsenate and free arsenic. It is therefore a subsulphide, and not a normal sulphide as believed by Berzelius. Sodium sulpharsenate has the formula  $Na_3AsS_4 + 8H_2O$ , and not  $2Na_3AsS_4 + 15H_2O$  as generally given.

When realgar is heated with aqueous soda, it yields free arsenic and a normal salt of the formula  $Na_6As_2O_5S_3 + 24H_2O$ . This crystallises in small, colourless needles easily soluble in water. L. T. T.

**Carbonic Anhydride in the Air of Schoolrooms.** By W. FOSSEK (*Monatsh.*, 8, 271—291).—For his determinations, the author used a modification of the Pettenkofer-Hesse method by which the air of the schoolroom can be taken by the teacher at any given time in

an unobtrusive manner, and by which the accuracy of the determinations is not influenced by the temperature and amount of carbonic anhydride in the air of the laboratory. For details of the apparatus, the description and plates of the original paper must be consulted.

The author found that an unventilated schoolroom, the air of which contained on three occasions 0·078, 0·092, 0·088 per cent. by volume of carbonic anhydride respectively before the class met, contained, after being occupied for three hours by a class of 58 scholars, 0·620, 0·637, and 0·557 per cent. by volume respectively. G. H. M.

**Crystallisation of Alkalis from Alcohol.** By C. GÖTTIG (*Ber.*, 20, 1907—1908).—The author finds that the crystals lately described by him (this vol., p. 636) as hydrates of potash contain alcohol of crystallisation. Their true composition has not yet been determined. L. T. T.

**Decomposition of Sodium Thioarsenate by Silver Nitrate.** By C. PREIS and B. RAYMAN (*Bull. Soc. Chim.*, 47, 892—896).—On adding silver nitrate to an ammoniacal solution of the sodium thioarsenate,  $\text{AsS}_4\text{Na}_3$ , silver sulphide is precipitated, and the solution contains arsenic acid, sodium nitrate, and nitric acid, the reaction taking place according to the equation—

When, however, silver nitrate is added to an aqueous solution of sodium thioarsenate, or if the solution contains nitric acid, silver sulphide is precipitated as before, and arsenious but no arsenic acid is found in the solution, nitric acid and sodium nitrate being formed as before. This reaction takes place according to the two following equations:—

The larger the amount of free acid present the more nearly does the reaction conform to equation 1, but in an aqueous solution, which is neutral at the commencement of the reaction, it conforms more closely to equation 2. The oxygen which is formed according to equation 1 is not liberated in the free state, but as the two reactions always take place simultaneously it combines with some of the sulphur thrown down according to 2, and is found as sulphuric acid. These reactions take place immediately, and are not affected by the length of time allowed for the precipitation. A. P.

**Corrosion of Zinc by Ammonium Chloride and Potassium Nitrate.** By J. H. FISHER (*Pharm. J. Trans.* [3], 17, 783—785).—A solution of ammonium chloride, or one of potassium nitrate, even

when concentrated and boiling, has little action on metallic zinc. But if the two solutions be mixed, the action is marked even in the cold, and it becomes very decided on boiling, for the zinc is then quickly attacked, and ammonia, potassium nitrite, zinc chloride, and a double chloride of zinc and ammonium insoluble in water are the products.

R. R.

**Components of the Rare Earths yielding Absorption-spectra.** By G. KRÜSS and L. F. NILSON (*Ber.*, 20, 2134—2171).—The solutions of the nitrates of the rare earths accompanying thorium in the thorite from Brevig and Arendal give absorption-spectra containing bands peculiar to didymium, samarium, erbium, thulium, and Soret's X or holmium, and a careful measurement of these shows that in both solutions each element is represented only by some of its bands, and that the wave-lengths and intensities of those observed in the solution from the first differ in some cases from those observed in that from the second mineral. For example, the band  $\lambda = 428\cdot7$ , regarded as the sixth in decreasing order of intensity of the absorption-bands of Soret's X, is the most intense X line in the Brevig thorite, and the other bands are either absent or scarcely visible, but  $\lambda = 428\cdot7$  is scarcely visible in the absorption-spectrum of the Arendal thorite. Hence it is argued that X must consist of at least two elements, one of which gives the band  $\lambda = 428\cdot7$ , and the other the remaining absorption-bands usually ascribed to X.

The rare earths examined were obtained from the following minerals:—

| Mineral.  | Absorption-spectra indicated the presence of |   |   |   |   |
|---|--|---|---|---|---|
| Thorite from Brevig .....                                       | Didymium, thulium, erbium, X, samarium.      |   |   |   |   |
| "    "    Arendal.....  | "  | " | " | " | " |
| Wöhlerite from Brevig.....                                      | "  |   | " | " | " |
| Didymium and samarium material<br>from cerite from Bastnäs..... | "  |   |   | " | " |
| Fergusonite from Arendal.....                                   | "  | " | " | " | " |
| "    "    Ytterby.....  | "  |   | " | " | " |

and the method by which the material was prepared is described in each case. The fergusonite from Arendal was fractionated 12 times, the euxenite from Hitterö 43 times, and that from Arendal 12 times, and the absorption-spectra of the nitrates of the different fractions were obtained. The wave-lengths of the bands observed in the absorption-spectra of the solutions of the nitrates of the rare earths from each mineral, and their relative intensity (determined in each case in one and the same solution to render the data comparable among themselves) are given at length in tables, and for the sake of comparison the wave-lengths of the bands of the nitrates of the five earths measured by previous observers are also added.

A comparison is then instituted between the seven bands ascribed to Soret's X, and those observed in the absorption-spectrum of the nitrates of the rare earths from each mineral, or from each fraction obtained from a mineral where fractionation has been resorted to, with a result that each band is found to vary in intensity quite independently of the others. By repeated fractionation of X material, Boisbaudran has separated it into dysprosium and a new holmium, each characterised by several absorption-bands (Abstr., 1886, 667); neither of these supposed elements, however, is a simple substance, since the relative intensities of the bands of each vary in the rare earths under investigation just as they vary in the case of the parent substance X. The authors conclude that Soret's X is composed of seven distinct elements, each of which is characterised by a single absorption-band: they are,  $X_\alpha$ ,  $\lambda = 640.4$ ;  $X_\beta$ ,  $\lambda = 542.6$ ;  $X_\gamma$ ,  $\lambda = 536.3$ ;  $X_\delta$ ,  $\lambda = 485.5$ ;  $X_\epsilon$ ,  $\lambda = 474.5$ ;  $X_\zeta$ ,  $\lambda = 451.5$ ;  $X_\eta$ ,  $\lambda = 428.5$ , and are distributed in the foregoing minerals as follows:—

| Mineral.                            | Elements.  |
|-------------------------------------|--|
| Thorite from Brevig .....           | $X_\alpha$ , $X_\delta$ , $X_\eta$ .   |
| „ „ Arendal .....                   | $X_\beta$ , $X_\gamma$ , $X_\epsilon$ , $X_\zeta$ , $X_\eta$ .                           |
| Wöhlerite from Brevig .....         | $X_\gamma$ , $X_\zeta$ , $X_\eta$ .  |
| Cerite from Bastnäs .....           | $X_\alpha$ , $X_\eta$ .  |
| Fergusonite from Arendal .....      | $X_\beta$ , $X_\gamma$ , $X_\delta$ , $X_\epsilon$ , $X_\zeta$ , $X_\eta$ .              |
| „ „ Ytterby .....                   | $X_\alpha$ , $X_\beta$ , $X_\gamma$ , $X_\delta$ , $X_\epsilon$ , $X_\zeta$ , $X_\eta$ . |
| Euxenite from Hitterö and Arendal } |  |

Arguing in the same way from the variation in the intensity of the absorption-bands, and the presence of some and absence of others in the rare earths under investigation, the authors consider that erbium consists of two elements,  $Er_\alpha$ ,  $\lambda = 654.7$ , and  $Er_\beta$ ,  $\lambda = 523.1$ ; that thulium consists of two elements,  $Tm_\alpha$ ,  $\lambda = 684.0$ , and  $Tm_\beta$ ,  $\lambda = 465.0$ ; that didymium consists of at least ten elements,  $Di_\alpha$ ,  $\lambda = 728.3$ ;  $Di_\beta$ ,  $\lambda = 679.4$ ;  $Di_\gamma$ ,  $\lambda = 579.2$  and  $= 575.4$ ;  $Di_\delta$ ,  $\lambda = 521.5$ ;  $Di_\epsilon$ ,  $\lambda = 512.2$ ;  $Di_\zeta$ ,  $\lambda = 482.0$ ;  $Di_\eta$ ,  $\lambda = 469.0$ ;  $Di_\theta$ ,  $\lambda = 445.1$ ;  $Di_i$ ,  $\lambda = 444.7$ , and a tenth,  $Di$ , to which is assigned the remaining didymium bands whose intensity is too feeble to allow them to be differentiated by this method; and that samarium consists of at least two elements,  $Sm_\alpha$ ,  $\lambda = 416.7$ , and a second,  $Sm_\beta$ , having all the remaining samarium bands, inasmuch as these could not be satisfactorily assigned to particular constituents.

In a complete table of the 40 absorption-bands observed, four bands occur which cannot be identified with any hitherto observed lines in the absorption-spectra of the rare earths; they are—

| Absorption-band.  | Source of rare earth.                               |
|-------------------|---|
| $\lambda = 716.4$ | Fractions 8—14 of euxenite from Arendal.            |
| $\lambda = 539.9$ | Wöhlerite and thorite from Brevig.                  |
| $\lambda = 533.6$ | Euxenite from Hitterö and fergusonite from Ytterby. |
| $\lambda = 488.8$ | Wöhlerite and thorite from Brevig.                  |

*Note by Abstractor.*—The entire absence of any reference in this paper to the results obtained by Crookes, in his investigation of the constituents of the rare earths present in gadolinite and samarskite by comparison of the absorption and fluorescent spectra of different fractions (*Proc. Roy. Soc.*, **40**, 504; this vol., p. 334), is remarkable; inasmuch as evidence is there adduced which would show that Boisbaudran's dysprosium is composed of at least two substances, since the band  $\lambda = 451.5$  can be obtained separate from the band  $\lambda = 475.0$ .

W. P. W.

**The Water of Crystallisation of Alums.** By P. DE BOISSIEU (*Bull. Soc. Chim.*, **47**, 494—496).—In criticising Maumené's results (*Abstr.*, 1886, 981, this vol., p. 218), the author states that he has made a large number of very careful estimations of the water of crystallisation in potash and chrome alums, and has never been able to find more than 24 mols.  $H_2O$ , the amounts actually found varying between 23.9 and 24.1 mols.

An examination of the tensions of dissociation of normal crystallised alums and of other samples from which the water has been partially removed, seems to indicate the existence of a definite hydrated alum, containing between 7 and 16 mols.  $H_2O$ .

A. P.

**Chemistry of Manganese and Fluorine.** By O. T. CHRISTENSEN (*J. pr. Chem.* [2], **35**, 541—559).—Manganese ammonium fluoride was prepared by dissolving pure manganese oxide in hydrofluoric acid, and adding a solution of ammonium fluoride to the dilute solution. The double salt separates as a crystalline precipitate; this is treated with a dilute solution of hydrofluoric acid. When dried over sulphuric acid, it forms a homogeneous, red, crystalline powder. The methods employed in preparing the manganese oxide and hydrofluoric acid are described in detail.

In order to determine the atomic weight of fluorine, a solution of sodium thiosulphate (about 25 grams to 1 litre of water) was prepared, and the strength determined by means of iodine. A weighed amount of the double salt was put into a mixture of potassium iodide and hydrochloric acid, the whole weighed, and the sodium thiosulphate added until the solution was decolorised. The difference in weight showed the amount of sodium thiosulphate used, and from this the amount of iodine liberated by the fluorine was calculated. The results of several experiments point to the atomic weight 18.94 ( $H = 1$ ) or 18.99 ( $O = 16$ ).

N. H. M.

**Potassium Manganites.** By G. ROUSSEAU (*Compt. rend.*, **104**, 1796—1799).—When potassium permanganate (1 part) is fused for 12 hours with potassium chloride (5 parts) in a covered platinum crucible heated by a Bunsen burner, and the residue is treated with boiling water, it yields lustrous black lamellæ of the composition  $K_2O, 7MnO_2$ . The same product is obtained from potassium manganate under similar conditions.

If the mixture of permanganate and chloride is heated for six hours at the melting point of copper, the product is  $K_2O, 10MnO_2$ . At

an orange-red heat, with potassium chloride as a flux, the crystals formed contain 60·36—61·82 per cent. of manganese, which indicates a very high degree of condensation of the manganite. In order to ascertain if this result is due to the action of aqueous vapour on manganese volatilised with the alkaline chloride, experiments were made with a flux of potassium sulphate, which is not volatile. Under these conditions, with an open crucible, no manganite is formed, since oxygen is absorbed from the air and regenerates the manganate. If the crucible is closed, the product consists of black lustrous crystals of trimanganese tetroxide with a small quantity of an alkaline manganite.

Potassium manganite polymerises as the temperature rises, the limit being the formation of trimanganese tetroxide. This condensation is analogous to the condensation of hydrocarbons with loss of hydrogen. The manganite forms complex products, the manganese accumulating in the molecule like the carbon in the hydrocarbons, but the energy of the acid diminishes as its molecular weight increases, the change culminating in the formation of the non-acidic oxide  $\text{Mn}_3\text{O}_4$ , with elimination of the alkali.

The tendency of aqueous vapour to decompose manganates is assisted by the tendency to form potassium or sodium hydroxide. When potassium manganate is heated in a current of aqueous vapour, the product at a dull red heat consists of needles of the manganate  $\text{K}_2\text{O}, 7\text{MnO}_2$ ; at a somewhat higher temperature the product is  $\text{K}_2\text{O}, 8\text{MnO}_2$ ; at about  $800^\circ$ ,  $\text{K}_2\text{O}, 10\text{MnO}_2$ ; after two hours at  $1000^\circ$ ,  $\text{K}_2\text{O}, 12\text{MnO}_2$ ; after another hour at the same temperature,  $\text{Mn}_3\text{O}_4$ ; and after half-an-hour at an orange-red heat,  $\text{MnO}$ . C. H. B.

**Action of Sulphuric Acid on Potassium Permanganate.** By B. FRANKE (*J. pr. Chem.* [2], 36, 31—43).—When the green solution obtained by dissolving potassium permanganate in sulphuric acid is exposed to direct sunlight in presence of moist air, manganese heptoxide separates and then decomposes into manganese dioxide, manganese trioxide, and ozone (?), which is given off as a blue gas. The latter is insoluble in water, but disappears when brought into contact with sulphuric acid or absolute ether.

*Manganese trioxide*,  $\text{MnO}_3$ , is formed as a dark-red mass when the green solution of manganese oxysulphate is distilled in presence of water; it is best prepared by decomposing the green solution with potassium carbonate. The red fumes are passed into a U-tube surrounded by a freezing mixture in which they condense to a dark-red amorphous mass. The green solution employed should be free from manganese heptoxide. The trioxide has a peculiar odour, and volatilises at about  $50^\circ$  as a violet vapour, with partial decomposition into crystalline manganese dioxide and oxygen; this decomposition is complete when the substance is heated. It is sparingly soluble in water; a litre of water containing 50 mgrms. of the substance has an intense red colour. When the vapour is passed into aqueous soda or potash, alkaline manganates are produced. The reaction employed for detecting small quantities of manganese by means of potassium chlorate depends on the formation of the trioxide.

*Manganic acid* is formed when manganese trioxide is passed into water; it is very unstable and decomposes into manganese dioxide, oxygen, and dimanganic acid.

When cooled ether containing hydrogen chloride is treated with potassium permanganate, a dark-green solution is obtained which contains manganous manganese chloride,  $\text{Mn} \begin{smallmatrix} \text{Cl} \\ \text{Cl} \end{smallmatrix} \text{MnCl}_4$ . In presence of an excess of ether, the green solution is decomposed and a blue solution formed; the latter contains manganese tetrachloride. When the blue solution is saturated with hydrogen chloride, an oily green liquid containing the compound  $\text{MnCl}_4(\text{HCl})_2$ , is formed (compare Christensen, this vol., p. 335). N. H. M.

**Hydrochlorides of Ferric Chloride.** By ENGEL (*Compt. rend.*, 104, 1708—1711).—Hydrochloric acid produces no precipitate in very concentrated solutions of ferric chloride, and gaseous hydrogen chloride causes the liquefaction of the hydrates  $\text{Fe}_2\text{Cl}_6 + 5\text{H}_2\text{O}$  and  $\text{Fe}_2\text{Cl}_6 + 12\text{H}_2\text{O}$ . These facts indicate the formation of hydrochlorides of the chloride.

When solid commercial ferric chloride is treated with a current of hydrogen chloride, it yields a liquid containing a dark-brown solid of variable composition, which may be separated by decantation or by filtration through glass-wool. If the filtered liquid is evaporated over potash in a vacuum, it yields the hydrate  $\text{Fe}_2\text{Cl}_6 + 12\text{H}_2\text{O}$ ; if heated at  $100^\circ$  for several hours, it gives off hydrogen chloride, and when cooled slowly deposits large, deep garnet-red crystals of the hydrate  $\text{Fe}_2\text{Cl}_6 + 5\text{H}_2\text{O}$ . By this method, the pentahydrate can readily be obtained in large quantity, and constitutes an excellent material for the manufacture of official preparations of ferric chloride.

If the pentahydrate is treated with a current of perfectly dry hydrogen chloride, it rapidly liquefies, and when saturated with the gas at  $25^\circ$  and then cooled to  $0^\circ$ , it yields large, thin, transparent, amber-yellow lamellæ, which, when dried over phosphoric anhydride, have the composition  $\text{Fe}_2\text{Cl}_6 \cdot 2\text{HCl} + 4\text{H}_2\text{O}$ . It is very deliquescent.

All the hydrochlorides of chlorides hitherto obtained contain water. As a rule they are more soluble than the corresponding chlorides.

C. H. B.

**Hydrochloride of Ferric Chloride.** By P. SABATIER (*Compt. rend.*, 104, 1849—1850).—The hydrochloride of ferric chloride,  $\text{Fe}_2\text{Cl}_6 \cdot 2\text{HCl} \cdot 4\text{H}_2\text{O}$ , recently described by Engel (preceding Abstract), was obtained by the author six years ago (*Bull. Soc. Chim.*, 1881, 197), in the form of yellowish-brown, translucent, deliquescent lamellæ, by the action of hydrogen chloride on pentahydrated ferric chloride, or by the action of the gas at the ordinary temperature on a mixture of anhydrous ferric chloride and the pentahydrate.

C. H. B.

**Residues obtained from Steel and Zinc by the Action of Acids.** By OSMOND and WERTH (*Compt. rend.*, 104, 1800—1802).—When annealed steel is dissolved in dilute hydrochloric acid at the positive pole of a Bunsen element, it yields a skeleton of graphitoid plates, which the authors term *cement of steel*. This residue consists

mainly of iron and carbon, but also contains water and oxygen. Tempered steel yields only a small quantity of residue, which contains comparatively little iron. The following table gives the composition of the residues from steel which originally contained 0.49 per cent. of carbon, and had been subjected to different mechanical treatment:—

|              | Crude. | Forged. | Tempered. |
|--------------|--------|---------|-----------|
| Iron .....   | 87.31  | 78.40   | 52.50     |
| Carbon ..... | 6.78   | 12.00   | 18.90     |
| Water .....  | 3.32   | 8.40    | 26.07     |
| Total.....   | 97.41  | 98.80   | 97.47     |

The residues, especially that from tempered steel, explode when dried in a hot-air bath. When dried in a vacuum, they not unfrequently undergo spontaneous combustion. It is obvious that it is not only steel containing platinum that yields the residues first observed by Faraday.

Similar residues are obtained from impure zinc.

|                       | Cast cold.   | Cast hot. |
|-----------------------|--------------|-----------|
| Residue per cent..... | 1.63         | 1.19      |
|                       | Composition. |           |
| Tin.....              | 30.07        | 5.64      |
| Lead .....            | 52.16        | 78.10     |
| Iron .....            | 2.10         | 3.15      |
| Copper .....          | 0.30         | 0.25      |
| Zinc .....            | 14.85        | 12.04     |
|                       | 99.48        | 99.48     |

These residues are graphitoidal in appearance, but contain no water and are not explosive. The first corresponds in composition with the formula  $\text{Pb}_2\text{ZnSn}$ , and the second with the formula  $\text{Pb}_2\text{Zn}$ .

The conditions of cooling modify the proportion, composition, and form of the residue from one and the same alloy. C. H. B.

**Paratungstates.** By C. GONZALEZ (*J. pr. Chem.* [2], 36, 44—56).—The following salts were prepared from sodium paratungstate which is obtained by adding hydrochloric acid to a boiling solution of commercial sodium tungstate ( $\text{Na}_2\text{WO}_4 + 2\text{H}_2\text{O}$ ) until slightly alkaline to litmus. The salts are sparingly soluble or insoluble, and dissolve to clear solutions in water which contains a few drops of hydrochloric acid; after some time, the solution becomes gelatinous from separation of tungstic acid.

*Manganese paratungstate*,  $\text{Mn}_3\text{W}_7\text{O}_{24} + 20\text{H}_2\text{O}$  or  $\text{Mn}_5\text{W}_{12}\text{O}_{41} + 34\text{H}_2\text{O}$ , is a white amorphous powder which does not melt; after ignition, it is yellowish-green. The *cobalt salt*,  $\text{Co}_3\text{W}_7\text{O}_{24} + 25\text{H}_2\text{O}$ , is a bright rose-coloured microcrystalline substance which does not melt at a red heat and acquires on cooling a bluish colour. The *cadmium*

*salt*,  $\text{Cd}_3\text{W}_7\text{O}_{24} + 16\text{H}_2\text{O}$ , is a white, crystalline compound; it cannot be fused, and is orange-coloured after being heated. The *silver salt*,  $\text{Ag}_{10}\text{W}_{12}\text{O}_{41} + 8\text{H}_2\text{O}$ , is a whitish-yellow crystalline substance; it melts at a red heat and solidifies on cooling to a white crystalline mass with a metallic lustre. The *zinc salt*,  $\text{Zn}_5\text{W}_{12}\text{O}_{41} + 37\text{H}_2\text{O}$ , crystallises in white needles; when heated, it is yellow and does not melt.

The following double salts are prepared by adding a solution of the salt to a boiling solution of sodium paratungstate until the precipitate formed no longer redissolves. The solution is quickly filtered from the slight precipitate and left; after 2—3 hours, the double salt separates. *Copper sodium paratungstate*,  $\text{CuNa}_8\text{W}_{12}\text{O}_{41} + 32\text{H}_2\text{O}$ , crystallises in slender, bright-blue needles, melts at a red heat, and solidifies to a black lustrous mass. The *lead sodium salt*,  $\text{PbNa}_8\text{W}_{12}\text{O}_{41} + 28\text{H}_2\text{O}$ , forms slender white needles; it melts at a red heat, and on solidifying forms a white mass with metallic lustre. The *cobalt sodium salt*,  $\text{Co}_2\text{Na}_6\text{W}_{12}\text{O}_{41} + 30\text{H}_2\text{O}$ , is a rose-coloured crystalline compound which melts at a red heat and solidifies to a black mass with a metallic lustre. The *calcium sodium salt*,  $\text{Ca}_2\text{Na}_6\text{W}_{12}\text{O}_{41} + 34\text{H}_2\text{O}$ , is white; it is fusible and solidifies to a black mass. The *strontium sodium salt*,  $\text{Sr}_4\text{Na}_2\text{W}_{12}\text{O}_{41} + 29\text{H}_2\text{O}$ , crystallises in white scales, does not fuse at a red heat, but becomes yellow. (Compare v. Knorre, Abstr., 1886, 597.)  
N. H. M.

**Zirconium.** By O. HINSBERG (*Annalen*, **239**, 253—256).—No organic zirconium-compound is produced by the action of zirconium chloride on zinc ethide. Attempts to prepare zirconium iodide by the double decomposition of zirconium sulphate and barium iodide resulted in the formation of a solution which, on evaporation over strong sulphuric acid, yielded a mixture of iodine and an amorphous powder, soluble in water, probably  $\text{ZrI}(\text{OH})_3 + 3\text{H}_2\text{O}$ . Attempts to prepare zirconium iodide by passing iodine vapour over a red-hot mixture of zirconia and charcoal were also unsuccessful.  
W. C. W.

**Reactions of Vanadic Acid.** By A. CARNOT (*Compt. rend.*, **104**, 1803—1805 and 1850—1853).—The estimation of vanadic acid in the form of ammonium vanadate (this vol., p. 691) can only be carried out under limited conditions.

In presence of alkaline and ammonium salts, vanadic acid is more easily estimated in the form of barium vanadate. The solution, if acid, is exactly neutralised with ammonia, heated to boiling, mixed with excess of barium chloride, agitated, and cooled quickly out of contact with air. Precipitation is complete. The precipitate is collected, washed, dried, heated, and weighed in the form of  $2\text{BaO} \cdot \text{V}_2\text{O}_5$ . If the liquid which contains the precipitate is boiled, the precipitate agglomerates and becomes firmly adherent to the sides of the vessel.

A slightly ammoniacal solution of vanadic acid containing ammonium salts gives no precipitate with strontium salts. By means of this difference, vanadic acid can be accurately separated from phosphoric and arsenic acids, and, approximately, from molybdic and tungstic acids, the latter being incompletely precipitated from boiling

solutions by strontium salts. The difference can also be utilised for the accurate separation of barium and strontium. The liquid is made alkaline with ammonia, mixed with ammonium chloride and an excess of a soluble vanadate, boiled for a few minutes, and then cooled quickly out of contact with the air. The clear liquid is decanted, the precipitate washed with cold water, dissolved in hydrochloric acid, and the barium precipitated as sulphate. The strontium is precipitated by means of ammonia and ammonium carbonate.

Calcium and magnesium salts give no precipitate with dilute solutions of vanadates, but in concentrated and strongly ammoniacal solutions the vanadic acid is partially precipitated.

When an acid solution containing vanadic acid and an aluminium salt is neutralised with ammonia, the aluminium hydroxide carries vanadic acid down with it. The same result follows if the aluminium is precipitated with sodium phosphate or an alkaline sulphide. In the latter case, the presence of vanadic acid is indicated by the brown colour of the precipitate; chromium hydroxide behaves similarly, and, if in sufficient quantity, will retain the whole of the vanadium.

Vanadic acid, like phosphoric and arsenic acids, is completely precipitated by uranic salts in ammoniacal solutions, and also in presence of small quantities of free acetic acid. In order to estimate the acid in this way, the liquid is nearly neutralised with ammonia, mixed with ammonium acetate and excess of uranium nitrate, and heated to boiling. Complete precipitation is recognised by the reaction with potassium ferrocyanide. The precipitate is washed with pure water, dried, and separated from the filter-paper, which is burnt separately. The precipitate when dried at  $100^{\circ}$  has the composition

when heated in presence of air, it loses ammonia and water, becoming  $\text{V}_2\text{O}_5, 2\text{UO}_3$ , in which form it is weighed. Vanadic acid can be estimated by this method not only in presence of alkalis and alkaline earths, but also in presence of many metals, such as manganese, zinc, and copper, the acetates of which are not decomposed by boiling. It cannot, however, be separated by this reaction from phosphoric, arsenic, tungstic, and molybdic acids.

Ferric hydroxide carries down vanadic acid when precipitated in a solution containing it, but the vanadium can be separated by means of ammonia, ammonium acetate, or ammonium hydrosulphide, provided the precipitation is repeated several times.

Manganese forms a well-defined vanadate, by means of which both the acid and the base can be estimated with accuracy. The vanadic acid solution is mixed with a slight excess of ammonia and ammonium chloride, heated to boiling, and then mixed with ammonium chloride and manganese chloride or sulphate, boiled for two or three minutes, and cooled quickly out of contact with air. The precipitate, which is brownish-yellow and should be free from any brown oxidation-product, is collected, washed with cold water, dried and ignited. It then has the composition  $2\text{MnO}, \text{V}_2\text{O}_5$ . This reaction cannot be used for the separation of vanadic acid from phosphoric and arsenic acids, but it will effect a partial separation of vanadic and tungstic acids and a

very accurate separation of vanadic acid from molybdic acid. The vanadic acid is precipitated as manganese vanadate, the excess of manganese is removed by means of ammonium sulphide, and in the filtrate the molybdenum is precipitated as sulphide by adding hydrochloric acid.

In order to separate vanadic acid from its alkaline or ammoniacal solutions, it is precipitated in the form of manganese vanadate, the precipitate is dried and heated with sulphur or in a slow current of hydrogen sulphide, and the residue is treated with hydrochloric acid diluted with 15 to 20 times its volume of water, when manganese sulphide dissolves and vanadium sulphide remains undissolved.

C. H. B.

**Metallic Vanadates.** By A. DITTE (*Compt. rend.*, **104**, 1705—1708).—Metallic vanadates are readily obtained in a crystalline condition by adding ammonium vanadate in excess to a solution of the nitrate of the metal, this solution being hot or cold, neutral or acid, as the case may require.

Normal *magnesium vanadate*,  $\text{MgV}_2\text{O}_6 + 6\text{H}_2\text{O}$ , is obtained in small, transparent needles by boiling magnesium hydrocarbonate with soluble vanadic anhydride and concentrating the filtered solution in a vacuum. It loses water when heated, becomes yellow, and melts at a higher temperature. If a warm saturated solution of ammonium vanadate is mixed with excess of magnesium chloride, acidified with acetic acid and concentrated in a vacuum, it deposits brilliant red, transparent crystals of the bivanadate,  $\text{MgO}, 2\text{V}_2\text{O}_5 + 9\text{H}_2\text{O}$ . *Barium vanadate* is obtained in colourless, transparent, anhydrous prisms, insoluble in water, by adding barium nitrate in excess to a boiling solution of ammonium vanadate. In presence of acetic acid, a red solution is obtained and, if this is concentrated, it deposits transparent, orange-red, rhombic crystals of the composition  $2\text{BaO}, 3\text{V}_2\text{O}_5 + 14\text{H}_2\text{O}$ . *Calcium vanadate*,  $\text{CaO}, 3\text{V}_2\text{O}_5 + 12\text{H}_2\text{O}$ , is obtained in red, lustrous crystals by adding excess of ammonium vanadate to a solution of calcium nitrate containing a very small quantity of free nitric acid. It is very soluble in dilute acids; when heated, it loses water and forms a yellow powder. When calcium chloride is added in excess to ammonium vanadate no precipitate is formed, but on adding ammonia a bulky, white precipitate is produced, and when the liquid is boiled this changes to small, colourless, transparent needles grouped in nodules. It has the composition  $2\text{CaO}, \text{V}_2\text{O}_5 + 2\text{H}_2\text{O}$ , is very soluble in dilute acids, and loses water when heated, forming a yellow powder. *Nickel vanadate* separates in small, greenish-yellow, anhydrous prisms on boiling a mixture of ammonium vanadate with excess of nickel nitrate feebly acidified with nitric acid. It is very soluble in dilute nitric acid. If the brown-green mother-liquor is concentrated, it deposits greenish-brown, transparent crystals of the composition  $\text{NiO}, 2\text{V}_2\text{O}_5 + 3\text{H}_2\text{O}$ . *Cobalt vanadate*,  $\text{CoV}_2\text{O}_6 + 3\text{H}_2\text{O}$ , is obtained in a similar manner; it is very soluble in water, and becomes anhydrous when heated.

*Zinc vanadate*,  $\text{ZnV}_2\text{O}_6 + 2\text{H}_2\text{O}$ , is also obtained in a similar manner in brilliant, pale-yellow, cubic or rhombic crystals which become anhydrous when heated. When a very dilute solution of copper

sulphate is mixed with ammonium vanadate, a precipitate is formed which dissolves on heating but becomes permanent if the copper sulphate is in excess. When boiled with the mother-liquor, it is converted into greenish-yellow, transparent, rhombohedral plates of *copper vanadate*,  $3\text{CuO} \cdot \text{V}_2\text{O}_5 + 3\text{H}_2\text{O}$ . *Lead vanadate*,  $2\text{PbO} \cdot \text{V}_2\text{O}_5$ , is obtained in sulphur-yellow, transparent, anhydrous prisms, terminated by pyramids, by boiling, in the mother-liquor, the precipitate which is formed when ammonium vanadate is added to a solution of lead nitrate acidified with acetic acid. *Silver vanadate*,  $2\text{Ag}_2\text{O} \cdot \text{V}_2\text{O}_5$ , is obtained in brilliant golden-yellow, transparent, rhomboïdal plates, easily soluble in nitric acid, by dissolving in fused silver nitrate the precipitate produced by mixing solutions of silver nitrate and ammonium vanadate; the fused mass is cooled slowly and is then extracted with water. Silver vanadate dissolves in ammonia, and if the solution is evaporated over sulphuric acid it yields the compound  $3\text{AgVO}_3 \cdot 2(\text{NH}_4)_2\text{O}$  in brilliant, yellow, hexagonal needles grouped in mamelons. *Cadmium vanadate*,  $\text{CdO} \cdot 3\text{V}_2\text{O}_5 + 2\text{H}_2\text{O}$ , separates in small, brilliant red crystals on boiling the red liquid obtained by adding ammonium vanadate to a solution of cadmium nitrate acidified with acetic acid.

These crystalline metallic vanadates are analogous in constitution to the alkaline vanadates.

C. H. B.

**Ammoniacal Vanadates.** By A. DITTE (*Compt. rend.*, **104**, 1844—1847).—*Methylamine Vanadates*.—The normal salt,  $2\text{MeNH}_3\text{VO}_3 + \text{H}_2\text{O}$ , is obtained in colourless, transparent needles by concentrating in a vacuum the strongly alkaline, straw-coloured liquid produced by mixing soluble vanadic anhydride with excess of methylamine. It is very soluble in water, and becomes brown when heated, then almost black, and, finally, takes fire and burns, leaving a residue of vanadic anhydride. The acid salt,  $(\text{NH}_3\text{Me})_2\text{O} \cdot 2\text{V}_2\text{O}_5 + 4\text{H}_2\text{O}$ , is obtained in garnet-red rhomboïdal prisms on concentrating a solution of the normal salt acidified with acetic acid. It gives a yellow powder which becomes vermilion when heated, and finally takes fire and burns, leaving a residue of the anhydride.

Ethylamine treated in a similar manner yields a normal salt,  $\text{NH}_3\text{EtVO}_3$ , in the form of small, colourless, transparent, deliquescent crystals which on heating decompose with evolution of an inflammable gas, and leave a residue of vanadic anhydride. The acid salt,  $(\text{NH}_3\text{Et})_2\text{O} \cdot 2\text{V}_2\text{O}_5$ , forms transparent, red prisms which burn like tinder when heated.

No magnesium ammonium vanadate could be obtained. Magnesium vanadate is decomposed by ammonia with formation of ammonium vanadate and magnesium hydroxide. Ammonium vanadate is only slightly soluble in concentrated ammoniacal solutions of magnesium hydroxide owing to the presence of ammonium chloride. In dilute solutions, no precipitate is formed, and when the liquid is concentrated ammonium vanadate and the double chloride,  $\text{MgCl}_2 \cdot 2\text{NH}_4\text{Cl}$ , separate.

If a solution of ammonium vanadate, strongly acidified with acetic acid, is mixed with a cold dilute solution of potassium silicate, also acidified with acetic acid, and the red solution concentrated, the com-

pound  $K_2O, 2(NH_4)_2O, 5V_2O_5 + 9H_2O$  is obtained in red transparent prisms. It may be regarded as a molecular compound of the two salts  $K_2O, 2V_2O_5$  and  $2(NH_4)_2O, 3V_2O_5 + 9H_2O$ . When heated, it loses water, blackens, and gives off ammonia, yielding a residue which melts at a red heat. Sodium silicate yields a similar compound which crystallises with  $15H_2O$  in brilliant, orange-red plates.

Vanadates, whether formed in the dry or wet way, correspond with a few well-defined and simple types, the most important of which are as follows:—

*Acid Vanadates*.— $M_2O, 3V_2O_5$ ;  $M_2O, 2V_2O_5$ ;  $2M_2O, 3V_2O_5$ .

*Normal Vanadates*.— $M_2O, V_2O_5$ .

*Basic Vanadates*.— $2M_2O, V_2O_5$ ;  $3M_2O, V_2O_5$ ;  $4M_2O, V_2O_5$ .

The proportion of water which these salts contain depends on the conditions of crystallisation. The more complex salts,  $3M_2O, 5V_2O_5$ , may be regarded as compounds of a salt,  $M_2O, 2V_2O_5$ , with a salt,  $2M_2O, 3V_2O_5$ , like the double vanadates just described. C. H. B.

**Metallurgy of Bismuth.** By E. MATTHEY (*Proc. Roy. Soc.*, **42**, 89—94).—In order to separate gold and silver from bismuth, the author adds 2 per cent. of zinc to the molten metal, allows the mass to cool gradually, and removes the surface crust. This process is repeated. The whole of the gold and silver is found in the skimmings. The bismuth litharge so obtained is fused in a crucible with borax. The gold sinks to the bottom, being at the same time freed from any base metals by the action of the bismuth oxide. The slag is again fused with addition of bismuth to separate the last traces of gold.

The author separates bismuth from lead by means of repeated crystallisations, alloys of bismuth and lead melting at lower temperatures than bismuth itself. Bismuth holding 12 per cent. of lead contained only 0.4 per cent. after four crystallisations.

H. K. T.

**Products of the Action of Acids on Alloys of the Platinum Metals.** By H. DEBRAY (*Compt. rend.*, **104**, 1667—1669).—The presence of a metal of the platinum group in solution in another metal such as tin, lead, or zinc, causes the latter to be much more readily attacked by dilute acids owing to the formation of innumerable minute galvanic couples. Under these conditions, the more oxidisable metal is dissolved by acids so dilute that they would have no action on it under ordinary circumstances. When the platinum metal combines with the other (*loc. cit.*), this compound forms galvanic couples with the excess of the oxidisable metal. In some cases (for example, the alloys of the platinum metals with tin) the alloy itself is attacked, especially if the acid is somewhat concentrated, and under these conditions some of the platinum metal is dissolved at the same time as the tin, &c.

When an alloy of zinc and osmium is treated with hydrochloric acid, or an alloy of lead with iridium or ruthenium is treated with nitric acid, the platinum metal is left undissolved in the form of minute crystals, since it is simply dissolved in the oxidisable metal. When combination has taken place between the metals, with development of heat, as in the case of lead and rhodium, the innumerable

galvanic currents which are developed when the regulus is treated with an acid give rise to the formation of a complex residue containing oxygen, nitrogen, and water in addition to rhodium and some lead. Unlike the alloys with tin, this particular alloy gives no definite compound when treated with an acid.

The formation of complex residues under the influence of galvanic currents which are due to the heterogeneity of metallic substances which are being dissolved in acids, is analogous to the formation of a silver peroxide or nitroxide when a solution of silver nitrate is electrolysed with silver electrodes.

C. H. B.

## Mineralogical Chemistry.

**Graphite from Ceylon.** By F. SANDBERGER (*Jahrb. f. Min.*, 1887, ii, Mem., 12—16).—The author has examined a large number of specimens of graphite from the gneiss of Ceylon. The specimens were in the form of irregular masses, 5 to 8 cm. in diameter, forming layers  $1\frac{1}{2}$  to  $2\frac{1}{2}$  cm. thick round other minerals. In some cases, crystals were developed, the planes observed being  $\infty P\infty$ ,  $P$ ,  $\frac{1}{2}P\infty$ . In many places on the principal cleavage plane ( $\infty P\infty$ ), needles were observed crossing one another at angles of  $60^\circ$  and  $120^\circ$ . These needles are mostly colourless, sometimes black. They resemble those in the mica of Ontario, and in the biotite from the mica diorite of Vöhrenbach. The colourless needles consist of rutile, whilst the few dark ferri-ferous needles appear to be pseudomorphs of titaniferous iron ore after rutile. Colourless massive quartz with conchoidal fracture is the most frequent of the minerals which are surrounded by the graphite. Granular quartz is of rarer occurrence. In two specimens, the centre consisted of green orthoclase. In another case, the centre consisted of olive-green apatite; whilst in other cases the centre consisted of kaolin, formed from the alteration of triclinic felspar. (Compare Abstr., 1886, 774.)

B. H. B.

**Recent Formation of Marcasite at Marienbad.** By E. PALLA (*Jahrb. f. Min.*, 1887, ii, Mem., 5—7).—Hollow tubes of pyrites are found in the peat bog of Marienbad. They are casts of plant remains, and are found to be composed of marcasite. Their sp. gr. is 4.46. Analysis of the bog water gave the following percentages:—

|                                  |                   |      |      |
|----------------------------------|-------------------|------|------|
| Fe <sub>2</sub> O <sub>3</sub> . | SO <sub>3</sub> . | CaO. | MgO. |
| 0.02                             | 0.11              | 0.04 | 0.01 |

The water of the bog containing the pyrites-mass is thus remarkable for the percentage of ferrous sulphate and of gypsum. The recent formation of the pyrites appears to be due to the reduction process brought about by the presence of plants in the ferrous sulphate.

B. H. B.

**Percylite, Caracolite, and Phosgenite from Chili.** By F. SANDBERGER (*Jahrb. f. Min.*, 1887, ii, Mem., 75—77).—A specimen of galena in a dark quartzose gangue, from the Sierra Gorda in Chili, is covered with yellow, blue, colourless, and white crusts of substances of more recent formation. Careful examination shows that these crusts occur in regular order, the blue substance being older than the colourless, and the colourless older than the white. The blue substance is lead-copper oxychloride, or percylite. The colourless substance is caracolite. The white mineral occurring above this appears to be a new compound of phosgenite ( $\text{PbCO}_3, \text{PbCl}_2$ ) with sodium sulphate. All these minerals are undoubtedly products of the action of a salt solution on a mineral vein containing bournonite and galena. B. H. B.

**Minerals from the Sjö Mine, Sweden.** By L. J. IGELSTRÖM (*Jahrb. f. Min.*, 1887, ii, Mem., 8—11).—The Sjö mine, in the parish of Grythyttan, Örebro, Sweden, is a small mine only a few fathoms in depth. Exploratory workings, however, have shown that the ore deposit extends for a considerable length. The mine is a very ancient one, and, after having been abandoned for centuries, it was re-opened in 1885. The ore bed has a thickness of 5 metres, and the ore, braunite and hausmannite, is very rich and pure. Adjoining this manganese ore bed is a bed of iron ore, hæmatite, and magnetite of poor quality. Both ore beds are enclosed in dolomite, which forms a bed in the granulite nearly a mile in length, and several hundred yards in width. The braunite and hausmannite of the Sjö mine are accompanied by a large number of remarkable minerals, such as xanthoarsenite (Abstr., 1886, 25), hæmatostibiite, polyarsenite, and pyrrhoarsenite. The minerals usually met with in this mine are the following:—Tephroite, iron glance, magnetite, calcite, garnet, rhodonite, specular iron ore. Barytes, chlorite, neotocite, and galena are of rare occurrence.

Pyrrhoarsenite, a mineral discovered by the author in July, 1886, is an anhydrous arsenate of manganese, calcium, and magnesium, containing 17 per cent. of manganous oxide. B. H. B.

**Mineralogical Notes.** By V. v. ZEPHAROVICH (*Jahrb. f. Min.*, 1887, ii, Ref., 21).—1. *Pyroxene from the Krimlerthal.*—On the crystals, the predominating planes are  $\infty P\infty$ ,  $\infty P\infty$ ,  $P\infty$ ,  $\infty P$ . The plane  $-P$  is very small, and the planes  $\infty P3$ ,  $\infty P3$ ,  $2P\infty$ ,  $+P$ ,  $+2P$ , are of rare occurrence. Analysis gave the following results:—

| $\text{SiO}_2$ . | $\text{Al}_2\text{O}_3$ . | $\text{Fe}_2\text{O}_3$ . | $\text{FeO}$ . | $\text{MnO}$ . | $\text{MgO}$ . | $\text{CaO}$ . | $\text{Na}_2\text{O}$ . |
|------------------|---------------------------|---------------------------|----------------|----------------|----------------|----------------|-------------------------|
| 52.08            | 1.36                      | 2.56                      | 8.93           | 0.49           | 10.60          | 21.59          | 2.06                    |

The angle made by the direction of extinction with the vertical axis on cleavage plates parallel to  $\infty P\infty$  is  $46^\circ 40'$ .

2. *Scheelite from the Krimlerthal.*—The crystals exhibit the planes  $\frac{1}{2}P\infty$ ,  $P\infty$ ,  $3P3$ ,  $P$ ,  $P3$ ,  $2P2$ , the last being new for this mineral.

B. H. B.

**Dipyr from Connecticut.** By A. ARZRUNI (*Jahrb. f. Min.*, 1887, ii, Ref., 9—10).—The author describes some crystals of dipyr from Canaan, Connecticut, presented to the University of Breslau by A. D. Roe. The crystals average 2 cm. long and 1 cm. thick. They are sometimes colourless and transparent, sometimes grey. The crystals-forms observed are  $\infty P\infty$ ,  $\infty P$ ,  $P$ . The edges and angles are rounded. The axial ratio is  $a : c = 1 : 0.4401$ , being that of meionite. The mineral exhibits a faint basal cleavage. There is no distinct prismatic cleavage as is usually stated in works on mineralogy.

B. H. B.

**Heulandite.** By P. JANNASCH (*Jahrb. f. Min.*, 1887, ii, Mem., 39—44).—The author gives the results of analyses of heulandite (I and II) from St. Andreasberg and (III) from the Fassathal.

| III. | trace              |                                  | 15.89                            |      | 100.62 |       | 2.196             |                    |

All the varieties of heulandite analysed by the author contain strontium. (Compare Abstr., 1887, 453.)

B. H. B.

**Mineralogical Notes.** By H. TRAUBE (*Jahrb. f. Min.*, 1887, ii, Mem., 64—70).—1. *Laubanite*, a new Zeolite.—The author has analysed a specimen of a zeolite supposed to be desmine occurring with phillipsite on an unaltered basalt from Lauban in Silesia. The hardness of this mineral was greater than that of desmine, and the mineral exhibited no lustre. Analysis showed that this mineral is a new zeolite having the composition  $Al_2Ca_2Si_5H_{12}O_{21}$ . The name of *laubanite* is proposed for it after the locality where it is found. Analysis gave the following results:—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | FeO. | CaO.  | MgO. | H <sub>2</sub> O. | Total. | Sp. gr. |
|--------------------|----------------------------------|------|-------|------|-------------------|--------|---------|
| 47.84              | 16.74                            | 0.56 | 16.17 | 1.35 | 17.08             | 99.74* | 2.23    |

In chemical composition laubanite approaches nearest to laumontite; whilst it differs from phillipsite in the absence of sodium silicate, as well as in its proportion of water. Laubanite is snow-white in colour. It is transparent only in thin sections, and has no lustre. Its hardness is 4.5 to 5. It forms small monoclinic crystals, 3 to 5 mm. in size.

2. *Laumontite and Scolezite from Striegau.*—Colourless crystals of laumontite are frequently found at Striegau on orthoclase and quartz, associated with desmine, epidote, and axinite. Externally, this mineral cannot be distinguished from fibrous snow-white scolezite. The latter occurs at the same locality in association with heulandite, but never

\* 97.6 in original.

in crystals on orthoclase. Analyses of the two minerals gave the following results: I, laumontite, II, scolecite:—

|     | SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | CaO.  | Na <sub>2</sub> O. | H <sub>2</sub> O. | Total. | Sp. gr. |
|-----|--------------------|----------------------------------|-------|--------------------|-------------------|--------|---------|
| I.  | 51·09              | 21·36                            | 11·76 | —                  | 15·35             | 99·56  | 2·28    |
| II. | 46·48              | 25·53                            | 13·38 | 0·68               | 13·69             | 99·76  | 2·31    |

B. H. B.

**Trachytic Rocks from the Island of San Pietro.** By F. EIGEL (*Jahrb. f. Min.*, 1887, ii; Ref., 92—93).—San Pietro, an island on the south-west coast of Sardinia, is composed principally of recent eruptive rocks. Analyses are given of (I) red liparite from Spalmatore, consisting of a dense fibrous ground-mass with sphaerolites of chalcedony and disseminated sanidine and biotite, (II) black obsidian with sanidine and augite, and sphaerolites of quartz.

|     | SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | FeO. | MnO. | CaO. | MgO. |

| II. | 3·15                                 | 4·28              | 98·92  |

B. H. B.

**The so-called Trachyte-dolerites of the Vogelsberg.** By J. M. LEDROIT (*Jahrb. f. Min.*, 1887, ii; Ref., 81—82).—According to Tasche and Ludwig, the trachyte-dolerites of the Vogelsberg are rocks intermediate between trachyte and dolerite, containing oligoclase, labradorite, hornblende, augite, and magnetite. The author considers the name of trachyte-dolerite unsuitable for these rocks, and distinguishes two varieties, dolerite and plagioclase-basalt. The latter has a sp. gr. of 2·884, and is composed of olivine, plagioclase, augite, magnetite, apatite, and a colourless glass. Analyses are given of a trachyte-dolerite from Laubach (I), of a basalt from Michelneu (II), and of a basalt, very rich in augite, from Gedern (III).

|      | SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | FeO. | CaO.  | MgO. | K <sub>2</sub> O. | Na <sub>2</sub> O. |

**The Pallasite from Campo de Pucará.** By E. COHEN (*Jahrb. f. Min.*, 1887, ii, Mem., 45—52).—The author has received a fragment, weighing 37 grams, of the pallasite found in 1879 at Campo de Pucará, in the State of Catamarca, in the Argentine Republic. From its remarkable resemblance to the pallasite of Imilac, Atacama, the author was induced to submit this meteorite to a careful investigation.

He found that the similarity of the two pallasites extends to their microscopic structure and chemical composition.

Two analyses of the metallic portion of the Campo de Pucará pallasite gave the following results (I and II):—

| Residue. | Fe.   | Ni.   | Co.  | Cu.   | Total. |
|----------|-------|-------|------|-------|--------|
| I. 0.09  | 90.81 | 9.02  | 0.53 | trace | 100.45 |
| II. 1.11 | 89.72 | 8.67  | 0.57 | trace | 100.07 |
| III. —   | 88.01 | 10.25 | 0.70 | —     | —      |

For comparison, Frapolli's analysis of the Imilac pallasite (III) is added. The remaining 1.04 per cent. consists of magnesium, calcium, sodium, potassium, and phosphorus.

## Organic Chemistry.

**Substitution-derivatives of Methylene Chloride.** By R. HÖLAND (*Annalen*, **240**, 225—243).—Alcoholic ammonia and methylene chloride heated together at 125° yield hexamethylenamine and ammonium chloride. Chlorine, both free and as phosphoric chloride, decomposes methylene iodide, yielding methylene chloride and traces of chloroform. With methylene bromide, the same reagents at 190° yield carbon tetrachloride and carbon tetrabromide, iodine chloride and iodine trichloride; with methylene chloride at 220° both yield chloroform and perchlorobenzene; iodine bromide and methylene chloride at 200° yield iodoform and small quantities of *iodomethylene chloride*,  $\text{CHCl}_2$ , and *diiodomethylene chloride*,  $\text{Cl}_2\text{Cl}_2$ . The former is a colourless oil, boils at 131°, and has an irritating odour. The latter crystallises in small scales, melts at 85°, and boils with decomposition at 185°. Iodine tribromide and methylene chloride at 180° yield bromoform, carbon tetrabromide, and perbromethylene,  $\text{C}_2\text{Br}_4$ . The author finds that the latter compound is also formed by heating  $\text{CBr}_4$  at 220°. Potassium iodide and iodine when heated with methylene chloride in alcoholic solution at 200° yield ether, ethyl iodide, and methylene iodide; without alcohol no reaction takes place at 210°. Phosphoric pentiodide has no appreciable action on methylene chloride at 210°; free iodine at the same temperature yields methylene iodide.

When pure dry sodium glycerate,  $\text{NaC}_3\text{H}_7\text{O}_3$ , is heated with methylene chloride at 100° for two hours, diglycerylmethylal (methylene diglyceryl oxide)  $\text{CH}_2(\text{O}\cdot\text{CH}_2\cdot\text{CHOH}\cdot\text{CH}_2\text{OH})_2$  is formed. This is an almost colourless syrup, soluble in alcohol and ether, insoluble in water. It decomposes on distillation.

L. T. T.

**Preparation of Allyl Iodide and Allyl Alcohol.** By A. BÉHAL (*Bull. Soc. Chim.*, **47**, 875—877).—Allyl iodide may be conveniently prepared by the following modification of Berthelot and de Luca's

method (*Ann. Phys. Chim.* [3], **43**, 257). 2000 grams of commercial glycerol, 60 grams of iodine, and 200 grams of red phosphorus are introduced into a tubulated retort and the whole well mixed. The retort is connected with a condenser and heated until frothing occurs, when the heat is regulated so that a gentle ebullition is maintained, and a solution of 440 grams of iodine in 160 grams of allyl alcohol is added drop by drop. The distillate of allyl iodide in the receiver is slightly coloured by iodine, and at the end of the operation is returned to the retort and redistilled, when it is obtained quite colourless. The whole operation lasts about five hours and a half. After its completion, the residue in the retort is further heated, and an aqueous distillate containing a small quantity of allyl iodide and a considerable amount of allyl alcohol (about 100 grams from the above quantities) is obtained; a certain amount of a viscous liquid, which appears to be a mixture of di- and tri-glycerol, is also formed. The yield of allyl iodide is about 637 grams, the theoretical yield being 661 grams. The advantages which the author claims for this process are that a large quantity of allyl iodide may be prepared at a time without any danger of an explosion; that only the merest traces of isopropyl iodide are formed; and that allyl alcohol is obtained as a valuable bye-product.

A. P.

**Sulphuranes.** By R. DEMUTH and V. MEYER (*Ber.*, **20**, 1830—1831).—The authors give the name *sulphuranes* to the class of bisulphides, several members of which have been described by Mansfield (this vol., p. 122) and by V. Meyer (this vol., p. 228). The authors have proved the correctness of the general formula  $C_2H_3 \cdot S \cdot C_2H_4 \cdot SR$ , by obtaining the ethyl vinyl ether of ethylene mercaptan, and proving it to be identical with ethylsulphurane. The compound  $OH \cdot C_2H_4 \cdot S \cdot Et$  was obtained by acting on ethyl hydrosulphide with ethylene chlorhydrin. This was treated with phosphoric chloride and converted into  $Cl \cdot C_2H_4 \cdot S \cdot Et$ , which with potassium hydrosulphide yielded  $SH \cdot C_2H_4 \cdot S \cdot Et$ . The sodium salt of the latter when treated with ethylene chlorhydrin gave  $OH \cdot C_2H_4 \cdot S \cdot C_2H_4 \cdot S \cdot Et$ , which when acted on by phosphoric chloride yielded  $Cl \cdot C_2H_4 \cdot S \cdot C_2H_4 \cdot S \cdot Et$ ; the latter when heated with alcoholic potash forms  $C_2H_3 \cdot S \cdot C_2H_4 \cdot S \cdot Et$ , which is identical with the ethylsulphurane obtained from diethylene disulphide ethiodide.

L. T. T.

**Isodulcitol.** By J. HERZIG (*Monatsh. Chem.*, **8**, 227—229).—The author confirms Fischer's and Will's description of the phenylhydrazine compound of this sugar (*Abstr.*, this vol., pp. 652 and 715). When oxidised with silver oxide, isodulcitol is completely split up into acetic acid. Chromic acid gives the same result.

G. H. M.

**Isodulcitol.** By B. RAYMAN (*Bull. Soc. Chim.*, **47**, 668—677, and 760—761).—Isodulcitol melts at about  $90.9^\circ$ , when heated at  $100^\circ$  to  $105^\circ$  for seven hours it loses a molecule of water, and at  $130^\circ$  it becomes brown and decomposes. Its rotatory power  $[\alpha]_D = +8.61^\circ$ . It reduces Fehling's solution, the reducing power varying with the concentration; it immediately reduces ammoniacal silver solution,

forming a mirror. Knapp's reagent is also reduced. When added to an alkaline solution of picric acid, picramic acid is formed. It decolorises alkaline solutions of indigo or potassium ferricyanide; but gives no reaction with a bleached solution of rosaniline.

When isodulcitol is treated with iodine and potash, a mere trace of iodoform is obtained. With  $\alpha$ -naphthol and concentrated sulphuric acid, it yields a bluish-violet coloration, and on the addition of water a dirty-green precipitate is thrown down; with thymol, it forms a crimson ring which rapidly becomes brown; with resorcinol, it yields a red coloration, a precipitate being formed on the addition of water. On mixing concentrated solutions of phenylhydrazine and isodulcitol, the compound  $C_{12}H_{18}N_2O_4$  is gradually formed; it is very sparingly soluble in alcohol. When phenylhydrazine hydrochloride, sodium acetate, and isodulcitol are heated in aqueous solution, the compound  $C_{18}H_{22}N_4O_3$  is produced; it crystallises from water, is of a yellow colour, melts at  $171^\circ$ , and seems to be identical with the compound described by Fischer and Tafel (this vol., p. 651).

On agitating 5 grams of isodulcitol dissolved in 230 c.c. of a 10 per cent. aqueous solution of sodium hydroxide with 30 grams of benzoyl chloride, an oily substance separates, which on cooling solidifies and may be recrystallised from alcohol; it consists of a mixture of *tribenzoylisodulcitol*,  $C_6H_{11}(C_7H_5O)_3O_6$ , and *tetrabenzoylisodulcitol*,  $C_6H_{10}(C_7H_5O)_4O_6$ . Glacial acetic acid does not seem to have any action on isodulcitol, but 4 parts of acetic anhydride heated at  $120^\circ$  with 1 part of isodulcitol yields *isodulcitol monacetate*,  $C_6H_{11}O_5.C_2H_3O$ , which is obtained as a resin resembling monosuccinin. By heating 1 part of isodulcitol with 5 parts of acetic anhydride at  $140^\circ$ , a mixture of *isodulcitol diacetate* and *triacetate* was obtained in the form of a resinous mass. By heating 1 part of isodulcitol with 10 parts of acetic anhydride and 1 part of sodium acetate for eight hours at  $140^\circ$ , a resinous *isodulcitol tetracetate*,  $C_6H_8(C_2H_3O)_4O_6$ , is obtained.

Isodulcitol dissolves in sulphuric acid without alteration, but nitric acid oxidises it energetically; on treating isodulcitol with a mixture of nitric and sulphuric acids a very unstable *isodulcetyl trinitrate*,  $C_6H_9(NO_2)_3O_5$ , is formed; it is decomposed by water. On heating isodulcitol with dilute hydrochloric acid, humous substances, formic acid, and a non-volatile acid which reduces silver salts are formed. Hydriodic acid and phosphorus have no action on isodulcitol.

From the above results, the author concludes that isodulcitol and arabinose are aldehydes whose corresponding penthydric alcohols are not yet known, but may probably be obtained by the reduction of these two compounds; he further proposes to divide the sugars into the following three classes:—

I. Tetravalent alcohol: erythrol.

II. Pentavalent alcohols: 1. (a) Normal, at present unknown, but possibly may be obtained by the reduction of isodulcitol and arabinose; (b) having a closed ring nucleus: quercitol. 2. The corresponding aldehydes and acetones: arabinose and isodulcitol.

III. Hexavalent alcohols: 1. (a) Normal: the physical isomerides mannitol, dulcitol, and perseïte; (b) having a closed ring nucleus: inosite. 2. The corresponding aldehydes: dextrose and galactose.

3. The corresponding acetone: lævulose. 4. Products of the condensation of the aldehydes: as saccharones, &c. A. P.

**Derivatives of Inosite.** By MAQUENNE (*Compt. rend.*, **104**, 1719—1722).—*Inosite hexacetin*,  $C_6H_6(C_2H_3O_2)_6$ , is obtained by heating inosite with acetic chloride or acetic anhydride at  $120$ — $170^\circ$ , or by boiling anhydrous inosite and acetic anhydride with fused zinc chloride. When the product is treated with water, the acetin is left as a crystalline powder insoluble in water, but soluble in hot alcohol or hot acetic anhydride. It begins to sublime at  $200^\circ$ , melts at  $212^\circ$ , and boils without decomposition at  $234^\circ$  in a vacuum. In presence of air, it rapidly becomes brown when heated, even under reduced pressure. Alcoholic alkalis decompose it rapidly with reproduction of inosite.

The hexacetin is obtained mixed with an amorphous product which is soluble in water and alcohol; this is decomposed by alkalis with production of inosite which yields a crystalline acetin when treated as above. It is probably a mixture of non-saturated acetins.

*Inosite hexabenzoin*,  $C_6H_6(C_7H_5O_2)_6$ , is obtained by the action of benzoic chloride on inosite. The product is treated with water, and then boiled with alcohol, which dissolves out a mixture of intermediate products, and leaves the benzoic derivative in crystals which are insoluble in all ordinary solvents. It melts at  $258^\circ$ , and is readily decomposed by alkalis.

*Inosite hexanitrin* was prepared by Vohl's method (*Annalen*, **101**, 55), and is very unstable, detonating violently when struck. With warm alcoholic potash, it yields potassium nitrite and a yellow amorphous substance which is a product of the oxidation of inosite, and is similar in appearance to the products of the decomposition of the hydroxyquinones. If an alcoholic solution of the nitrin is mixed with potash and saturated with sulphurous anhydride, it yields a copious crystalline precipitate of potassium nitrilosulphite,  $N(SO_3K)_3 + 2H_2O$ . When the nitrin is boiled with ethyl alcohol mixed with sulphuric acid, it yields inosite and ethyl nitrite. These reactions show that it is a true ethereal salt, and not a nitro-phenol.

*Tetrabenzoylquinone*,  $C_6O_2(C_7H_5O_2)_4$ , is easily obtained by boiling tetrahydroxyquinone for a few minutes with benzoic chloride. It crystallises in beautiful yellow needles, and its formation proves that tetrahydroxyquinone contains four OH groups, and has the constitution ascribed to it by Nietzki and Benckiser (*Ber.*, **18**, 499). Acetic chloride yields a similar derivative, which however is very difficult to purify.

Haloid ethers of inosite could not be obtained. Hydrochloric acid has no action even at  $200^\circ$ . Phosphorus trichloride and phosphorus pentabromide attack the inosite at a high temperature, with carbonisation. Phosphorus pentachloride at  $150^\circ$  produces hydrogen chloride and phosphorus acid, together with a white, viscous, unstable product. If inosite hexachlorhydrin exists at all, it must be much less stable than benzene hexachloride. If the latter compound is heated with silver acetate and acetic anhydride at  $170^\circ$  for 30 hours, it yields no trace of inosite hexacetin.

Inosite is a hexahydric alcohol derived from hexamethylene. It must be regarded as a mannitol with a closed chain, and not as a polyhydric phenol.

C. H. B.

**Identity of Dambose with Inosite.** By MAQUENNE (*Compt. rend.*, **104**, 1853—1855).—Dambosc obtained by the action of hydriodic acid on dambonite prepared from caoutchouc (Girard, *Compt. rend.*, **67**, 820; **73**, 426; **76**, 995) is identical with inosite in composition, crystalline form, melting point, and all other properties. The hexacetins obtained from the two compounds are likewise identical.

C. H. B.

**Carbohydrate from Acorns.** By C. VINCENT and DELACHANAL (*Compt. rend.*, **104**, 1855—1858).—In the preparation of quercitol by Prunier's method (*Ann. Chim. Phys.* [5], **15**, 5), if the syrupy liquid which will not crystallise is mixed with dilute sulphuric acid in sufficient quantity to convert the potassium and calcium into sulphates, evaporated in a vacuum on a water-bath until a white saline deposit is formed, and then mixed with an equal volume of alcohol, practically the whole of the calcium and potassium is precipitated, and if the filtered liquid is further concentrated in a vacuum it yields an additional quantity of crystallised quercitol.

During this last crystallisation, crystals separate which differ from quercitol in form, and effloresce rapidly in air or in a vacuum. This substance can be recrystallised from water at a low temperature, and forms bulky, transparent, hexagonal prisms which rapidly become opaque by efflorescence. In a closed tube, the crystals remain transparent at 30°, but give off water, and when examined under a microscope are found to have become converted into small, anhydrous, monoclinic prisms. The effloresced crystals have the same form. This compound has the composition  $C_6H_{12}O_6$ . It is soluble in warm water, from which it separates in anhydrous prisms, the hydrated crystals only being formed at low temperatures. It is comparatively insoluble in cold water, and is insoluble in boiling alcohol. It melts at 340° without decomposition, but at a higher temperature decomposes and emits an odour of burnt sugar. Its solutions are optically inactive.

When treated with acetic anhydride, this compound yields an acetin,  $C_6H_6(C_2H_3O_2)_6$ , crystallising in long, rhombic prisms which melt at 301°, are readily volatile, and are insoluble in water and ether, but can be recrystallised from boiling alcohol. The formation of this derivative indicates that the original compound has the constitution  $C_6H_6(OH)_6$ . It does not ferment with yeast, and does not reduce Fehling's solution even after being boiled with a dilute acid. It gives no coloration with boiling soda solution, and forms no compound with phenylhydrazine in warm acetic acid. It reduces ammonio-silver nitrate after addition of soda. When evaporated with nitric acid on platinum-foil, treated with ammoniacal calcium chloride, and again evaporated, it yields a red coloration similar to that produced by inosite, so that this reaction is not characteristic of inosite.

This compound, for which the authors propose the name *quercin*, is

isomeric but not identical with inosite, from which it differs in crystalline form, melting point, and solubility, and in the melting point of its hexacetin.  
C. H. B.

**Polyiodides.** By A. GEUTHER (*Annalen*, **240**, 66—85).—The tri- and penta-iodides were prepared by dissolving the simple iodide and the necessary amount of iodine in warm alcohol.

*Tetramethylammonium enneaiodide*,  $\text{NMe}_4\text{I}_9$ , crystallises in thin plates melting at  $110^\circ$ .

*Tetrethylammonium heptiodide*,  $\text{NEt}_4\text{I}_7$ , is obtained crystallising in dark-violet plates which melt at  $108^\circ$ .

Phenyltrimethylammonium triiodide forms brown plates melting at  $115^\circ$ . The penta-iodide crystallises in green needles with a metallic lustre; it melts at  $82^\circ$ . The *heptiodide* melts at  $65^\circ$ .

*Phenyldimethylethylammonium triiodide*,  $\text{NPhMe}_2\text{EtI}_3$ , is dark violet, and melts at  $81^\circ$ . The *penta-iodide*,  $\text{NPhMe}_2\text{EtI}_5$ , forms dark bluish-green plates with a metallic lustre which melt at  $50^\circ$ . The *heptiodide* crystallises in dark bluish-violet plates which melt at  $45^\circ$ .

Trimethylethylammonium pentiodide melts at  $26^\circ$  (not  $68^\circ$ ; Müller, *Annalen*, **108**, 1).

*Trimethylethylammonium enneaiodide*,  $\text{NMe}_3\text{EtI}_9$ , is dark green, and melts at  $38^\circ$ .

*Triethylmethylethylammonium pentiodide*,  $\text{NEt}_3\text{MeI}_5$ , crystallises in dark-green plates melting at  $16^\circ$ . The *heptiodide*,  $\text{NEt}_3\text{MeI}_7$ , forms dark brown-violet plates melting at  $42^\circ$ .

Tables are given containing the formulæ, melting points, colour, and crystalline form of the polyiodides. The tri- and penta-iodides are reddish-brown or violet-blue, the hepta- and ennea-iodides green. The constitution of the polyiodides, and the number of atoms contained in the mols. of crystallised, liquid, and gaseous iodine respectively is discussed.  
N. H. M.

**Crystallographic Examination of some Polyiodides.** By O. LÜDECKE (*Annalen*, **240**, 85—92).—Tetramethylammonium enneaiodide forms tabular crystals, probably rhombic.

Tetrethylammonium heptiodide forms dark-brown rhombic crystals.

Phenyltrimethylammonium triiodide crystallises in brown rhombic plates.

Phenyltrimethylammonium pentiodide forms monoclinic crystals;  $a : b : c = 1.7943 : 1 : 1.2511$ ;  $\beta = 69^\circ 43'$ .

Phenyltrimethylammonium heptiodide crystallises in plates, probably monoclinic.

Phenyldimethylethylammonium triiodide forms rhombohedric crystals.

Phenyldimethylethylammonium pentiodide forms dark-green plates.

Trimethylethylammonium pentiodide crystallises in plates which seem to be rhombic.

Trimethylethylammonium triiodide forms regular crystals. (Compare Müller, *Annalen*, **108**, 1.)  
N. H. M.

**Action of Hydroxylamine on Acetamide.** By C. HOFFMANN (*Ber.*, 2204—2205).—Ethenylamidoxime is formed when aqueous solutions of acetamide and hydroxylamine are mixed and left for some time at the ordinary temperature, the reaction even occurring if hydroxylamine hydrochloride is substituted for the free base.

A. J. G.

**Glyoxal- $\alpha$ -naphthylamine and its Derivatives.** By M. KARCZ (*Monatsh. Chem.*, 8, 218—223).—Glyoxal- $\alpha$ -naphthylamine was prepared by Radziszewski's method (*Abstr.*, 1883, 1086). It is a snow-white substance consisting of microscopic crystals, it melts at 50—51°, and boils at 294—296°. It is easily soluble in alcohol, ether, and benzol, insoluble in water. It differs in melting point from the substance described by Radziszewski (*loc. cit.*); this the author ascribes to the fact that the substance exists in two allotropic forms. The *hydrochloride* and *hydrobromide* crystallise in long, thin, colourless needles, which instantly deliquesce in the air; the *oxalate* forms snow-white crystals melting at 121°. The *platinochloride* forms yellow needles, easily soluble in water, alcohol, and ether; the *platinobromide* is a purple-red crystalline powder, also soluble in water, alcohol, and ether.

*Oxalmethyl- $\alpha$ -naphthylamine*,  $C_9H_{15}MeN_2$ , is obtained by digesting a solution of glyoxal- $\alpha$ -naphthylamine in methylic alcohol with methylic iodide in a reflux apparatus, and after distillation of the methylic alcohol treating the residue with potash. It is a colourless, oily liquid of unpleasant smell, boils at 261—263°; sp. gr. at 16.5°, 0.9282; it is insoluble in water, soluble in alcohol and ether. It gives all the reactions of an alkaloïd. The *platinochloride* crystallises in bright yellow plates with a golden lustre, and is soluble in water, alcohol, and ether.

*Oxalethyl- $\alpha$ -naphthylamine*,  $C_9H_{15}(Et)N_2$ , is prepared in the same way from glyoxal- $\alpha$ -naphthylamine and ethylic bromide. It is a colourless oily liquid, its sp. gr. at 16.5° is 0.9210, and it boils at 270—272°. The *platinochloride* resembles the corresponding salt of oxalmethyl- $\alpha$ -naphthylamine.

*Oxalpropyl- $\alpha$ -naphthylamine*,  $C_9H_{15}(Pr)N_2$ , is obtained in a manner similar to the above; it is a colourless oily liquid boiling at 285—286°; its sp. gr. at 17° is 0.9192. The *platinochloride* crystallises in yellow, lustrous plates, is easily soluble in alcohol and ether, less readily in water.

The above oxalines behave in all respects exactly like those described by Radziszewski.

G. H. M.

**Triethyl Formate and various Methylals.** By M. ARNHOLD (*Annalen*, 240, 192—208).—The author has examined the action of reagents on triethyl formate,  $CH(OEt)_3$ , in the hope of obtaining derivatives which might help to determine the equality or non-equality of the various carbonyl-affinities. He finds, however, that this salt is too unstable to allow of the formation of such intermediate or mixed derivatives. Phosphoric and phosphorous chlorides, bromine, iodine, nitric acid and nitrous anhydride cause decomposi-

tion of the compound. Hydrochloric acid yields monethyl formate and ethyl chloride.

The author has prepared a number of methylene ethers (methylals),  $\text{CH}(\text{OR})_2$ , by the action of the corresponding sodium alcoholates on methylene chloride. The lower homologues are colourless mobile liquids of pleasant odour, the higher homologues thick oily liquids or solids, often pale-yellow in colour and of unpleasant odour. The following table gives their chief characteristics.

|                                | M. p. | B. p. (corr.). | Sp. gr.      |                    |

| „ dithymyl oxide..             | 36    | „ „            | 0·979 „      | „ „                |

In the hope of obtaining acid derivatives of methylene, methylene chloride, sodium acetate, and alcohol were heated together at 170°. Methylene diethoxyde, ethyl acetate, sodium chloride, and acetic acid were formed. No reaction took place when dry sodium acetate and methylene chloride were heated together, even at 260°.

By the action of bromine on methylene chloride,  $\text{CHBrCl}_2$  and  $\text{CBr}_2\text{Cl}_2$  were formed. The latter is colourless, melts at 38° and boils at 150·2°.

L. T. T.

**Preparation of Ethyl  $\alpha$ -Bromopropionate.** By N. ZELINSKY (*Ber.*, 20, 20—26).—400 grams of bromine is added by drops to 300 grams of propionic acid in presence of 31 grams of amorphous phosphorus, and the whole left until no more hydrogen bromide is evolved. It is then heated on a water-bath and gradually treated with 640 grams of bromine. When no more bromine-vapour is visible in the condenser the product is allowed to become cool, treated with absolute alcohol, the ethyl salt precipitated with water, washed and fractionally distilled. The yield of ethyl  $\alpha$ -bromopropionate is 640 grams.

N. H. M.

**$\beta$ -Dichloropropionic Acid.** By G. FROMME and R. OTTO (*Annalen*, 239, 257—272).— $\beta$ -Monochloracrylic acid, prepared by Wallach's process from chloralide, is converted into  $\beta$ -dichloro-

propionic acid by the action of hydrochloric acid (40 per cent.) in sealed tubes at  $80^{\circ}$ .

*Dichloropropionic acid* crystallises in colourless prisms and melts at  $56^{\circ}$ . The acid dissolves freely in alcohol, ether, chloroform, benzene, and water. The *ethylic* salt,  $C_2H_3Cl_2 \cdot COOEt$ , is a colourless liquid, possessing a fruit-like odour. It is slightly heavier than water and boils between  $171^{\circ}$  and  $175^{\circ}$ . When saponified with alcoholic potash, it yields  $\beta$ -monochloracrylic acid, showing that the dichloropropionic acid is really the  $\beta$ -compound. The *amide*,  $C_2H_3Cl_2 \cdot CONH_2$ , crystallises in white needles or plates. It melts at  $140^{\circ}$ , and is soluble in water and alcohol, forming fluorescent solutions. W. C. W.

**Acids from Drying Oil.** By K. HAZURA (*Monatsh. Chem.*, 8, 260—270. Compare this vol., pp. 359, 798).—Peters (this vol., p. 126, Dieff and Reformatzky (this vol., p. 716), and the author (this vol., p. 359) have on different grounds concluded that the formula of linoleic acid is  $C_{18}H_{32}O_2$  and not  $C_{16}H_{28}O_2$ . In order to set this point at rest, the author has undertaken the present research. When sativic acid (*Abstr.*, 1886, 868) is oxidised with alkaline potassium permanganate, the only solid product obtained is azelaic acid.

When linoleic acid is treated with bromine, the hexabromo-compound,  $C_{18}H_{30}Br_6O_2$ , is the only product. When the tetrabromo-derivative of the acid from hemp oil is treated with excess of bromine, no further bromination takes place, showing that the above-mentioned hexabromo-compound is not derived from this.

The linoleic acid from linseed oil gave an "iodide value" which corresponds with a mixture of two acids, one with the formula  $C_{18}H_{32}O_2$ , the other with the formula  $C_{18}H_{30}O_2$ . The formation of a tetra- and hexa-bromo-derivative and of linusic acid and sativic acid on oxidation also support the view that linoleic acid is a mixture. The author prepared the  $C_{18}H_{32}O_2$  acid from the tetrabromo-compound and the  $C_{18}H_{30}O_2$  from the hexabromo-derivative; for the former, he proposes the name *linolic acid*, for the latter *linolenic acid*.

If *linolic acid*, prepared from the tetrabromo-derivative, is oxidised with alkaline potassium permanganate, it yields sativic and azelaic acids, but no linusic acid; when treated with bromine, it gives *tetrabromolinelic acid*, melting at  $114$ — $115^{\circ}$ .

*Linolenic acid*,  $C_{18}H_{30}O_2$ , prepared from the hexabromo-compound melting at  $177^{\circ}$ , has an "iodine value" of 245, and yields on oxidation no solid acid but linusic acid (m. p.  $201^{\circ}$ ). With bromine, nothing but the *hexabromolinelic acid* is formed.

These experiments clearly show that the acids from drying oils contain both linolic acid,  $C_{18}H_{32}O_2$ , and linolenic acid,  $C_{18}H_{30}O_2$ . The author proposes to examine the acids from poppy oil, hemp-seed oil, and nut oil, which give only sativic acid on oxidation. He enunciates the following law for the oxidation of the unsaturated fatty acids: these acids when oxidised in alkaline solution with potassium permanganate add as many (OH)-groups as they contain free valencies, and form saturated acids which contain the same number of carbon-atoms in the molecule. On this law, he founds an exact qualitative method for the examination of fats and oils.

G. H. M.

**Turkey-red Oil.** By R. BENEDIKT and F. ULZER (*Monatsh. Chem.*, 8, 208—217).—The authors review previous work on this subject (see Abstr., 1884, 946; 1885, 313 and 315) and have prepared the sulpho-acid of a higher fatty acid in order to compare its behaviour with that of the Turkey-red oil soluble in water.

*Sulpholeic acid* was prepared by heating pure oleic acid (10 parts) at 200—220° with sulphur (1 part). Sulphuretted hydrogen is copiously evolved, and the sulphur is completely dissolved. The sulpho-acid was separated from the unaltered oleic acid by means of the barium salt. When sulpholeic acid is oxidised with potassium permanganate in alkaline solution, it yields a sulpho-fatty acid—*sulphohydroxystearic acid*; this substance and the soluble fatty acid of Turkey-red oil from olive oil behave in many respects in the same manner. Both are miscible with water in all proportions, and are precipitated by sodium chloride and dilute acids; neither are decomposed when boiled for some hours with aqueous potash. In other respects the two acids differ in behaviour, and the author concludes that the Turkey-red oil is the acid sulphate of hydroxystearic acid, thus confirming Liechti and Suida's results (*loc. cit.*). The authors are satisfied by repeated experiments that the soluble fatty acid of Turkey-red oil from olive oil, and that from oleic acid are absolutely identical, and that in each case the pure acid is not decomposed by boiling with water.

In order to compare the turkey-red oil from olive, cotton-seed and castor oil respectively, the authors prepared the "total fatty acids" from these Turkey-red oils; in order to do this, it was necessary to saponify the triglyceride and also to decompose the sulphates of the fatty acids. This was effected by first boiling the washed crude Turkey-red oil with potash, and then with dilute acid. The resulting fatty acids, of which those from cotton-seed and olive oils were solid whilst that from castor oil was fluid, were then examined by the method proposed by the authors in a former paper (this vol., p. 620). The results are expressed in the following table. It will be seen that the "acetyl-values" of the acids from olive and cotton-seed oils correspond with the conversion of the unsaturated acids in these oils into hydroxy-acids, whilst the number for castor oil remains nearly the same. The table also shows the "acetyl-values" of the fatty acids from different commercial Turkey-red oils and also for the insoluble and soluble portion of Turkey-red oil from castor oil.

The difference in the behaviour of olive oil and castor oil is explained by the different constitution of oleic and ricinoleic acid, the latter being an hydroxy-acid which reacts with sulphuric acid with the elimination of water forming a sulphate, which is again decomposed into the hydroxy-acid and sulphuric acid, whilst the former combines with sulphuric acid forming hydroxystearic sulphate. The acid from Turkey-red oil from olive oil does not take up any iodine, whilst the iodine value of the acid from Turkey-red oil from castor oil is 77.3, and that of the ricinoleic acid is 85.3. The authors conclude from this that Turkey-red oil from castor oil is of much greater value as a mordant than that from olive oil.

**Action of Sulphur Dichloride on Ethyl Acetoacetate.** By A. DELISLE (*Ber.*, 20, 2008—2009).—When ethyl acetoacetate (2 mols.) is treated with sulphur dichloride, a vigorous reaction takes place with evolution of hydrogen chloride, and the whole solidifies to a crystalline mass. The new *compound*, which has the formula  $C_{10}H_{14}O_6S$ , crystallises from alcohol in thin, lustrous, colourless prisms, sparingly soluble in ether, insoluble in water, soluble in baryta-water with formation of a barium salt. It softens at  $75^\circ$ , and melts at  $90$ — $91^\circ$ .  
N. H. M.

**Constitution of Ethyl Propiopropionate.** By A. GEUTHER (*Annalen*, 239, 386—388).—As Israel (*Abstr.*, 1886, 334) has recently shown that ethyl propiopropionate is decomposed by treatment with sodium ethoxide and ethyl iodide, yielding ethyl propionate and  $\alpha$ -ethylpropionic acid or methylethylacetic acid, the author concludes that the constitution of ethyl propiopropionate is correctly represented by the formula  $OH\cdot C_{Et} : CMe\cdot COOEt$ .  
W. C. W.

**Action of Phosphoric Chloride on Chloralide.** By R. ANSCHÜTZ and A. R. HASLAM (*Annalen*, 239, 297—300).—Ethereal oxalates are converted into ethereal salts of dichloroglycollic acid by the action of phosphoric chloride (*Abstr.*, 1886, 786 and 1011); but when chloralide is heated with phosphoric chloride at  $290^\circ$  for several days, the product is an oily liquid of the composition  $C_5HCl_4O_3$ . The new compound boils at  $134$ — $136^\circ$  under 12 mm. pressure, and its density at  $20^\circ$  is 1·7426.  
W. C. W.

**Dissociation of Hydrated Oxalic Acid.** By H. LESCOEUR (*Compt. rend.*, 104, 1799—1800).—Crystallised oxalic acid readily

becomes anhydrous, its vapour-pressure at 45° being 10·6 mm. No intermediate hydrate is formed. In moist air, the dehydrated acid not only absorbs 2 mols.  $\text{H}_2\text{O}$ , but at 5° the absorption continues until the acid has the composition  $\text{H}_2\text{C}_2\text{O}_4 + 2\cdot41\text{H}_2\text{O}$ , and has a vapour-pressure of 5·5 mm. The vapour-pressures of the dihydrate at different temperatures are as follows:—

|         |      |      |      |        |
|---------|------|------|------|--------|
| 20°.    | 30°. | 40°. | 67°. | 78·6°. |
| 1·3 mm. | 2·8  | 7·1  | 44·5 | 84·0   |

At 100°, the phenomenon becomes complicated by the decomposition of the oxalic acid, the vapour-pressure increases continually and becomes equal to 980 mm. after 24 hours.

In order to obtain oxalic acid of constant composition for the preparation of standard solutions, the ordinary crystals must be dried over sulphuric acid of 55° B. C. H. B.

### Action of Iodine on Derivatives of Ethyl Sodiomalonate.

By C. A. BISCHOFF and A. HAUSDÖRFER (*Annalen*, **239**, 110—131).—By the action of iodine on ethyl benzylsodiummalonate in ethereal solution, *ethyl benzyliodomalonate* is produced. It is a colourless oil, and decomposes on hydrolysis, yielding benzaldehyde, alcohol, acetic acid, and carbonic anhydride, that is, the products of decomposition of ethoxybenzylmalonic acid. Iodine replaces the sodium in ethylsodiummalonate, and the product on saponification with alcoholic potash yields potassium ethylethoxymalonate,  $\text{OEt}\cdot\text{CEt}(\text{COOK})_2$ , and on treatment with baryta-water yields barium ethyltartronate. *Ethyl dicarbonditetracarboxylate* is formed by the action of iodine on the ethylic salt of sodium acetylenetetracarboxylate.

The properties of the product have been previously described by Bischoff and Rach (*Abstr.*, 1885, 244). W. C. W.

**Isomerism of Fumaric and Maleïc Acids.** By R. ANSCHÜTZ (*Annalen*, **239**, 161—184).—The author is in favour of the following formulæ for fumaric and maleïc acids:—

His reasons for regarding maleïc acid as the dioxy-lactone of  $\gamma$ -hydroxycrotonic acid are as follows:—The formation of maleïc acid when trichlorophenomalic acid is decomposed by baryta, and the occurrence of maleïc and not fumaric acid in the products of decomposition of bromopyromucic acid,  $\llbracket \begin{array}{c} \text{CBr}\cdot\text{CH}(\text{OH}) \\ \text{CBr}\text{---} \text{CO} \end{array} \rrbracket \text{O}$ . The author, in conjunction with Wirtz, has just shown that maleïnanil is decomposed by baryta, yielding the salt of fumaranilic acid (p. 934). The relation between mesaconic and citraconic acids is probably similar to that between fumaric and maleïc acids—

Mesaconic acid.

Citraconic acid.

The conversion of maleïc into fumaric acid by the action of hydrochloric acid is explained by the following equation:—

This also explains why fumaric and maleïc acids yield the same product when treated with hydrobromic acid. W. C. W.

### Conversion of Fumaric and Maleïc Acids into Aspartic Acid.

By ENGEL (*Compt. rend.*, 104, 1805—1807).—Fumaric or maleïc acid is heated for 20 hours at 140—150° with an excess of alcoholic ammonia, the ammonia is expelled, the residue dissolved in water, and the solution acidified with hydrochloric acid. After a short time, white crystals separate and are recrystallised from boiling water. Aspartic acid is the product in both cases; it crystallises in long, rhombic prisms which are identical with the inactive aspartic acid obtained by Dessaignes, and not with the active acid obtained from asparagin. The yield is not theoretical, owing to the fact that aspartic acid is somewhat readily decomposed when heated in sealed tubes at 140—150° with aqueous ammonia or even with water. If active aspartic acid is heated under these conditions for 20 hours, 60—70 per cent. of the acid is decomposed and the remainder becomes optically inactive.

C. H. B.

**Synthesis of Xeronic Acid from  $\alpha$ -Dibromo-normal-butyric Acid.** By G. FROMME and R. OTTO (*Annalen*, 239, 272—285).—By the action of molecular silver on  $\alpha$ -dichloropropionic acid, Otto and Beckurts (Abstr., 1885, 753) obtained  $\alpha$ -pyrocinchonic (dimethylfumaric) acid. By the same process, the authors convert  $\alpha$ -dibromobutyric acid into xeronic and butyric acids. These acids are separated by the difference in the solubility of the calcium salts in hot water. The butyrate is more soluble than the xeronate. By the action of hydriodic acid at 180°, xeronic anhydride is converted into diethylsuccinic acid. This confirms the accuracy of Roser's hypothesis (Abstr., 1882, 1114) that xeronic acid is diethylfumaric acid.

The silver and copper salts of diethylsuccinic acids,  $\text{C}_6\text{H}_{12}(\text{COOAg})_2$  and  $\text{C}_6\text{H}_{12}(\text{COO})_2\text{Cu} + \text{H}_2\text{O}$ , are amorphous powders sparingly soluble in hot water. W. C. W.

**Action of Ethyl Oxalate on Acetone.** By L. CLAISEN and N. STYLOS (*Ber.*, 20, 2188—2191).—*Ethyl acetopyruvate*,  $\text{CH}_2\text{Ac}\cdot\text{COOEt}$ , is formed by adding a mixture of acetone and ethyl oxalate drop by drop to an alcoholic solution of sodium ethoxide cooled in ice; much heat is developed, and a yellow crystalline sodium compound separates, which yields the ethyl salt on treatment with a dilute acid. It is a colourless oil of sp. gr. = 1.124 at 21°, boils at 134—135° under 40—41 mm., and at 213—215° under the ordinary pressure, and solidifies

to a crystalline mass melting at  $18^{\circ}$ . With ferric chloride, it gives a dark-red coloration showing a yellowish-red tinge; with phenylhydrazine, it forms a thick oil, and on treatment with aniline yields a liquid phenylimide; copper and zinc compounds were also obtained. Sulphuric acid dissolves the salt with a pale yellow colour, and on shaking the solution with ordinary benzene containing thiophen it gives an intense dark, red colour changing to violet-red. The acid has not been obtained pure, but is probably formed when the sodium compound of ethyl acetopyruvate is treated with water, and the product after treatment with a mineral acid is extracted with ether; this impure product is sparingly soluble in water, but cannot be crystallised from a hot solution, inasmuch as carbonic anhydride is evolved, and a crystalline compound,  $C_5H_{12}O_6$ , obtained, which melts at  $90-91^{\circ}$ .

W. P. W.

**Carbamide-derivatives of Dibromopyruvic Acid.** By E. FISCHER (*Annalen*, 239, 185—194).—*Dibromopyruvureid*,  $C_4H_2O_2Br_2N_2$ , is deposited in colourless crystals when equal weights of carbamide and dibromopyruvic acid are heated at  $100^{\circ}$  with sulphuric acid. The compound is sparingly soluble in alcohol, water, and acids; it dissolves in alkalis, but it is rapidly decomposed on boiling the solution. Ammonia converts dibromopyruvureid into a sparingly soluble ammonium salt, which slowly changes into dibromopyruvamide and ammonium oxalate. The quinidine salt is sparingly soluble in cold water. *Tribromopyruvine*,  $C_4H_3Br_3N_2O_3$ , is prepared from dibromopyruvureid by oxidation with nitric acid or by treatment with warm concentrated hydrobromic acid. It crystallises in colourless glistening plates soluble in hot alcohol, melts at  $247^{\circ}$  (uncorr.) with decomposition, and on treatment with ammonia splits up into bromoform and oxaluric acid. *Dibromopyruvamide*,  $C_4H_5Br_2N_3O_2$ , melts between  $170^{\circ}$  and  $180^{\circ}$  with decomposition. It is soluble in hot water and in hot alcohol, but the aqueous solution is decomposed on boiling. Ammonia at  $100^{\circ}$  eliminates the bromine and forms an amorphous compound. A warm solution of baryta-water decomposes dibromopyruvamide, forming tartronic acid and small quantities of mesoxalic acid and amidouracil.

W. C. W.

**Sodium and Potassium Ethyl Tartrates.** By LASSER-COHN (*Ber.*, 20, 2003—2004).—Iodine has no action on sodium ethyl tartrate. When treated with bromine, ethyl tartrate and sodium bromide are formed. When potassium ethyl tartrate is treated with iodine dissolved in benzene, potassium iodide, iodoform, and a resinous substance are formed.

N. H. M.

**Synthesis and Constitution of Uric Acid.** By J. HORBACZEWSKI (*Monatsh. Chem.*, 8, 201—207; comp. Abstr., 1883, 179; 1885, 1050).—When trichlorolactamide (1 part) and carbamide (10 parts) are melted together in small quantities over a small flame, a brownish-yellow mass is obtained, which when treated with potash, &c., as in the author's former method for the synthesis of uric acid (Abstr., 1883, 179) yields a white crystalline powder exhibiting all the properties, reactions, and the composition of uric acid. The yield of

uric acid by this method is not very good, this is accounted for by the partial decomposition of the acid when formed, and by the loss of the easily decomposable trichlorolactamide. This synthesis confirms the formula for uric acid suggested by Medicus, and shows it to be a

**Solubility of Uric Acid.** By C. BLAREZ and G. DENIGÉS (*Compt. rend.*, 104, 1847—1849).—The dissolved uric acid was estimated by means of potassium permanganate (this vol., p. 621).

The number of milligrams of uric acid dissolved by 100 grams of water at different temperatures is given by the equation—

$$x = 2 + 0.15t + 0.0020t^2 + 0.000025t^3.$$

The following are some of the numbers actually observed :—

|                            |     |     |     |      |
|----------------------------|-----|-----|-----|------|
| Temperature .....          | 0°  | 10° | 20° | 100° |
| Milligrams of uric acid in |     |     |     |      |
| 100 grams water .....      | 2.0 | 3.7 | 6.0 | 62.5 |

The determinations are rendered difficult by the tendency of uric acid to form supersaturated solutions, and the formation of hydrated products, which absorb variable amounts of permanganate. If the solution is heated to a high temperature and then cooled, the proportion of permanganate absorbed by the cooled liquid increases with the time of cooling. Constant results can only be obtained by agitating the uric acid with water at the particular temperature at which the determination of solubility is to be made, care being taken that contact is not too prolonged, especially at high temperatures.

C. H. B.

**Synthesis of Compounds of the Uric Acid Series.** By R. BEHREND (*Annalen*, 240, 1—23).—*Nitromethyluracil*,  $\text{C}_5\text{H}_5\text{N}_3\text{O}_4$ , is prepared by gradually adding 4 grams of methyluracil to a mixture of 15 c.c. of fuming nitric acid and 15 c.c. of sulphuric acid. The temperature should not rise above 30—40°. The product is poured into water, and the crystalline precipitate recrystallised from water, from which it separates in prismatic crystals. It dissolves readily in hot water, sparingly in alcohol. Alkalis dissolve it with yellow colour. Potassium nitrouracilcarboxylate (*Annalen*, 229, 32) is prepared by adding methyluracil to a mixture of fuming nitric and sulphuric acids, previously heated at 80°. The carboxylic acid separates on cooling; this product is dissolved in 100 c.c. of water, and 15 grams of caustic potash added. The potassium salt separates on cooling in lustrous plates. When this is heated at 170°, it is converted into potassium nitrouracil, from which nitrouracil is obtained by treatment with hydrochloric acid.

Hydroxyxanthin is obtained by adding zinc to a solution of nitrouracil in hot dilute hydrochloric acid. When cold, it is filtered, neutralised with sodium carbonate, treated with a slight excess of potassium cyanate, and made acid with hydrochloric acid, when the hydroxyxanthin separates as a white crystalline precipitate.

*Potassium nitrouracil*,  $C_4H_2N_3O_4K + H_2O$ , is prepared by neutralising a hot solution of nitrouracil with hydrogen potassium carbonate. It separates in pale yellow prisms. The *ammonium salt* forms aggregates of prismatic crystals, and is sparingly soluble. The *calcium salt* (with 6 mols.  $H_2O$ ) forms large plates. The *barium salt* (with 5 mols.  $H_2O$ ) crystallises in long slender needles of a slightly silky lustre. The *zinc* (with  $3\frac{1}{2}$  mols.  $H_2O$ ), *copper* (with 7 mols.  $H_2O$ ), and *silver salts* are also described.

*Nitrobromohydroxyuracil*,  $NO_2 \cdot CBr < \begin{smallmatrix} CH(OH) \cdot NH \\ CO \cdot NH \cdot CO- \end{smallmatrix} >$ , is formed when 10 grams of bromine is added to 6 grams of very finely powdered nitrouracil suspended in water and cooled with ice. After 24 hours, it is filtered, and the white precipitate washed with water and alcohol. It cannot be recrystallised, as it decomposes when warmed with water or alcohol. When distilled with steam, a brominated nitromethane and *nitrouracil-carbamide*,  $C_5H_7N_3O_5$ , are formed. The latter is also obtained by adding 1.5 gram of urea to a solution of 2 grams of nitrouracil in hot water. It is very sparingly soluble in water, and is decomposed by alkaline carbonates.

*Amidouracilcarboxylic acid* (Köhler, this vol., p. 128) is prepared by dissolving potassium nitrouracilcarboxylate in hot water, adding an alkaline solution of stannous chloride, filtering, and treating with hydrochloric acid. The yield is 80 per cent. of the theoretical.

*Bromouracilcarboxylic acid*,  $C_5H_3N_2BrO_4 + 2H_2O$ , is obtained by adding bromomethyluracil to fuming nitric acid so long as it dissolved readily. It crystallises from hot water in plates. It decomposes at above  $170^\circ$ .  
N. H. M.

**Action of Phosphoric Sulphide on Ethyl Dimethylpyrone-dicarboxylate.** By M. GUTHZEIT and W. EPSTEIN (*Ber.*, 20, 2111—2113).—*Ethyl thiodymethylpyrondicarboxylate*,

is obtained when ethyl dimethylpyrondicarboxylate (this vol., p. 502) is heated with phosphoric sulphide at  $100^\circ$  for half an hour. It crystallises in orange needles, melts at  $109$ — $110^\circ$ , and is insoluble in water, readily soluble in ether, hot alcohol, and benzene. The salt does not give the thiophen-reactions with isatin and phenanthraquinone, and on treatment with aqueous baryta yields acetone and barium acetate, carbonate and sulphide, together with a small quantity of a sparingly soluble red barium salt containing sulphur, whilst *ethyl thiophenyllutidinedicarboxylate*,  $C_{19}H_{21}O_4SN$ , is formed when it is treated with aniline in acetic acid solution. This crystallises in slender yellow needles, melts at  $245^\circ$ , dissolves in alcohol, and is identical with the compound obtained by the action of phosphoric sulphide on ethyl phenyllutidinedicarboxylate.

Lutidone when heated at about  $160^\circ$  with phosphoric sulphide yields *thiolutidine*,  $C_7H_9SN$ ; this crystallises in needles, begins to fuse at  $205^\circ$ , melts at  $210$ — $215^\circ$ , and is readily soluble in hot water and alcohol, insoluble in ether.  
W. P. W.

**Thiophen-group.** By N. ZELINSKY (*Ber.*, **20**, 2017—2025).—*Metathioxen*,  $C_4SH_2Me_2$  [ $Me_2 = 2 : 4$ ], is obtained by distilling a mixture of 20 grams of  $\alpha$ -methyllevulinic acid (Bischoff, *Annalen*, **206**, 319) and 30 to 35 grams of phosphorus trisulphide in a capacious retort. The fraction boiling below  $160^\circ$  is boiled for some hours with caustic potash, dried with calcium chloride, and distilled. It is a clear, colourless, strongly refractive oil, having an odour of petroleum. It boils at  $137$ — $138^\circ$  (corr.); sp. gr. at  $20^\circ = 0.9956$ . The yield of pure product is 20 per cent. of the weight of the  $\alpha$ -methyllevulinic acid. It shows the same colour reactions as thiophen. The *acetyl-derivative*,  $C_4SHMe_2Ac$ , is prepared by adding a mixture of 6 grams of metathioxen, 6 grams of acetic chloride, and 15 grams of light petroleum to 20 grams of light petroleum containing 8 grams of aluminium chloride in suspension. The whole is heated for a short time on a water-bath, the petroleum poured off, and the residue treated with cold water and steam-distilled. It is a clear liquid, boiling at  $226$ — $228^\circ$  (uncorr.), has an odour of acetophenone, and becomes dark when exposed to air. It gives a red coloration with sulphuric acid and isatin. The *hydroxylamine-derivative* of the acetyl compound,  $C_8H_{11}SNO$ , crystallises from aqueous alcohol in thick needles melting at about  $70^\circ$ ; the *phenylhydrazine-derivative*,  $C_{14}H_{16}SN$ , forms bright yellow needles melting at  $70^\circ$ .

*Methylthiophencarboxylic acid*,  $C_4SH_2Me \cdot COOH$  [ $Me : COOH = 2 : 4$  or  $4 : 2$ ], is obtained, together with thiophendicarboxylic acid, by oxidising 1 gram of thioxen in a solution of 12 grams of sodium hydroxide, and 5.7 grams of potassium permanganate in 800 c.c. of water. After two days, the product is steam-distilled, and the distillate extracted with ether. It crystallises in needles melting at  $118$ — $119^\circ$ , dissolves readily in ether, sparingly in water, and can be sublimed. The *calcium salt*, with  $2\frac{1}{2}$  mols.  $H_2O$ , crystallises in plates.

*Thiophendicarboxylic acid*,  $C_4SH_2(COOH)_2$  [ $(COOH)_2 = 2 : 4$ ], is formed only in small quantity in the above experiment, and is prepared by oxidising the monocarboxylic acid; a portion of the latter always remains unattacked. It is readily soluble in hot water, and does not distil with steam; when heated at  $280^\circ$ , it sublimes with partial decomposition. The *silver salt* forms a curdy precipitate; the *methyl salt* crystallises in small plates and melts at  $120$ — $121^\circ$ ; the *ethyl salt* forms an oil which gradually crystallises, and melts then at  $35$ — $36^\circ$ . When 5 grams of carbamic chloride is added to 3 grams of  $\beta$ -thiotolen dissolved in 10 grams of carbon bisulphide, the whole gradually treated with 5 grams of finely-powdered aluminium chloride, and then warmed on a water-bath, an amide is obtained which crystallises from hot water in needles melting at  $119^\circ$ . When the amide is saponified with alcoholic potash solution, the potassium salt of an acid melting at  $143^\circ$  is obtained, probably identical with Levi's  $\gamma$ -thiotolenic acid (*Abstr.*, 1886, 540). When oxidised, this acid yields a dicarboxylic acid which is not identical with that described above; it shows the fluorescein reaction, and is therefore probably an ortho-derivative.

*Dimethyllevulinic acid* and *trimethylthiophen* were also prepared, but are not described.

N. H. M.

**Molecule of Crystalline Benzene.** By A. SCHRAUF (*Ann. Phys. Chem.* **31**, 540—543).—Thomsen supposes that the arrangement of atoms is such that they lie in pairs of CH at the six corners of an octahedron. This arrangement does not accord with the fact discovered by Groth, that crystals of benzene belong to the trimetric system and are double refracting. These conditions may be satisfied in the simplest manner by removing two atoms H,H at opposite corners, and placing them one at each of two other opposite corners of the octahedron. This arrangement is shown to give the correct ratio of the axes. C. S.

**Constitution of the Hydrocarbons  $C_nH_{2n}$  from Caucasian Petroleum.** By W. MARKOWNIKOFF and J. SPADY (*Ber.*, **20**, 1850—1853).—The authors have examined the fraction boiling at 118—120°, and giving analytical results and vapour-density corresponding with the formula  $C_8H_{16}$ . Potassium permanganate did not cause oxidation either in acid or neutral solutions. When the hydrocarbon was boiled with sulphur, hydrogen sulphide was evolved, and small quantities of a heavy oil containing sulphur were formed, but the main liquid still boiled at 118—123°. When treated with a mixture of nitric and sulphuric acid, this liquid yielded a small quantity of trinitrometaxylene, whilst much of the original oil was recovered. The authors, therefore, consider that this petroleum fraction is, or contains, hexahydroxylene. When shaken successively with large quantities of sulphuric acid, metaxylene-mono- and di-sulphonic acids appear to be formed.

L. T. T.

**Influence of Light and Temperature on Chlorination.** By H. GAUTIER (*Compt. rend.*, **104**, 1714—1716).—Schramm has recently shown that the substitution of chlorine in the side-chains of benzene hydrocarbons can be effected even at 0°, provided the reaction takes place in sunlight. The author has made experiments in order to ascertain how far the laws of chlorination hold good for compounds other than hydrocarbons.

When a current of chlorine is passed into acetophenone at the ordinary temperature, substitution takes place rapidly with development of heat. The product is a dichloro-derivative with the chlorine exclusively in the methyl-group. If a slow current of the gas is passed into cooled acetophenone in diffused daylight, substitution still takes place almost exclusively in the side-chain, the yield of a derivative with chlorine in the nucleus amounting only to about 1 per cent. The result is the same in complete darkness, the temperature of the liquid exerting no influence.

Since the development of heat is mainly due to the formation of the monochlorine-derivative, the latter was treated with chlorine both in daylight and in the dark. The result was still the same.

It is evident that in this case light has no influence on the nature of the substitution. It does, however, accelerate the change, which requires four times as long in the dark as in diffused daylight. It would seem as if the presence of an electronegative group tends to prevent the introduction of an element of the same nature.

During the winter, *dichloroacetophenone* (this vol., p. 141) was ob-

tained in crystals which melt at  $19^{\circ}$  and boil at  $143^{\circ}$  under a pressure of 25 mm. C. H. B.

**Synthesis of Aromatic Alkyl Polysulphides.** By R. OTTO (*Ber.*, 20, 2089).—When a warm alcoholic solution of benzenesulphinic acid is treated with hydrogen sulphide, a thick yellow oil of unpleasant odour separates, consisting chiefly of *phenyl tetrasulphide*. This compound is readily reduced to the bisulphide by the action of colourless ammonium sulphide in the cold. Paratoluenesulphinic acid yields *toluene tetrasulphide* when similarly treated; it crystallises in small scales, melts at  $75^{\circ}$ , and is not reduced by ammonium sulphide.

Benzenesulphonic chloride also yields phenyl polysulphides under similar conditions. W. P. W.

**Chlorine-derivatives of Phenyl Methyl Ether (Anisoil).** By L. HUGOUNENQ (*Compt. rend.*, 104, 1807—1808).—When a current of chlorine gas is passed over phenyl methyl ether mixed with an equivalent quantity of ethyl alcohol, a solid product is obtained, crystallising from alcohol in long, white needles, which are soluble in ether, chloroform, benzene, carbon bisulphide, and glacial acetic acid. It melts at  $59$ — $60^{\circ}$ , sublimes readily even at the ordinary temperature, and boils without decomposition at  $240^{\circ}$ , under a pressure of 738.2 mm. It is a trichloro-derivative, and is not attacked by boiling alcoholic potash, which indicates that substitution has taken place in the benzene-ring only. If the anisoil is heated and treated with chlorine in presence of iodine, it yields another trichloro-derivative, which forms small needles melting at  $56^{\circ}$ . Other chlorine-derivatives and various oxidation products have been obtained, and will be described subsequently. C. H. B.

**Carvole-derivatives.** By H. GOLDSCHMIDT and E. KISSER (*Ber.*, 20, 2071—2078; compare this vol., p. 475).—If carvole is treated with hydrogen bromide, *hydrobromocarvole*,  $C_{10}H_{15}OBr$ , is obtained as a thick oily compound, which decomposes at about  $50^{\circ}$ , and resinifies in the moist state with the evolution of hydrogen bromide. The *oxime*,  $C_{10}H_{15}Br : NOH$ , is formed by acting on hydrobromocarvole with the theoretical quantity of hydroxylamine, or by saturating a solution of carvoxime in methyl alcohol with hydrogen bromide; it crystallises from light petroleum in colourless, glistening prisms, and from alcohol in tufts of needles, melts at  $116^{\circ}$ , and when allowed to remain for some time darkens in colour, and eventually forms a viscid mass. The *phenylhydrazide*,  $C_{10}H_{15}Br : N_2HPh$ , crystallises in slender, yellow needles, and melts at  $119^{\circ}$ .

*Isocarvoxime*,  $C_{10}H_{14} : NOH$ , is obtained, together with a small quantity of carvoxime, when hydrobromocarvole or hydrobromocarvoxime in alcoholic solution is treated with an excess of hydroxylamine. It crystallises in needles, melts at  $142$ — $143^{\circ}$ , and is sparingly soluble in alcohol. Isocarvoxime dissolves in acids and alkalis, and is more basic in its properties than carvoxime, but unlike that base it does not form additive compounds with hydrogen

chloride and hydrogen bromide. The *benzoyl*-derivative forms stellate, white, glistening scales, melts at  $112^{\circ}$ , and is readily soluble in alcohol, ether, and benzene.

The authors have not succeeded in obtaining an isomeride of carvole corresponding with isocarvoxime from either hydrochlorocarvole or hydrobromocarvole, and find that carvole and carvacrol are the end-products when the elements of hydrogen bromide are separated from the latter compound by repeated distillation, by heating with a mixture of anhydrous sodium acetate and acetic acid, or by the action of alcoholic potash in the cold. Isocarvoxime, when heated with dilute sulphuric acid, yields not the expected isocarvole (comp. Abstr., 1885, 1058) but carvacrol, hydroxylamine, and a compound,  $C_{10}H_{15}NO$ , isomeric with carvoxime. This crystallises from hot water in glistening, transparent prisms, melts at  $94^{\circ}$ , has an odour resembling that of indole, and is insoluble in cold water, soluble in ether.

The remainder of the paper is devoted to a discussion of the possible formulæ for isocarvoxime, and of these the formula

is adopted as the most probable.

W. P. W.

**Bromine-derivatives of Resorcinol.** By J. ZEHENTER (*Monatsh. Chem.*, **8**, 293—298).—*Monobromoresorcinol*,  $C_6H_3Br(OH)_2$ , is obtained by boiling monobromo- $\alpha$ -dihydroxybenzoic acid (1 part) with water (5 parts) for some hours in a reflux apparatus, adding excess of dilute sulphuric acid, and extracting with ether. The ethereal extract is then treated with a little dilute ammonium carbonate to remove any unaltered acid, and, after separation, slowly evaporated. The monobromoresorcinol remains as a solid crystalline mass, which, when purified, forms slightly yellow, more or less nodular groups of crystals. It melts at  $91^{\circ}$ , and cannot be sublimed without decomposition; it is readily soluble in water and ether, less so in alcohol, chloroform, benzene, &c. The aqueous solution gives with ferric chloride a bluish-violet coloration, which, after a time, gives place to a reddish-brown precipitate. It reduces alkaline silver solutions; with bromine-water, it gives a precipitate of tribromoresorcinol. When heated in a sealed tube with water, it gives up the whole of its bromine. When heated with water, potassium carbonate and tin chloride, it gives resorcinol and  $\alpha$ -dihydroxybenzoic acid.

*Dibromoresorcinol*,  $C_6H_2Br_2(OH)_2$ , is prepared by adding to resorcinol suspended in carbon bisulphide sufficient bromine dissolved in the same solvent, the greater part of the resorcinol is dissolved, and hydrogen bromide is given off, the liquid is quickly filtered, and the filtrate sets after a time to a crystalline mass. When purified by recrystallisation from water, dibromoresorcinol forms long, white needles, melts at  $110$ — $112^{\circ}$ , and sublimes without decomposition. The air-dried crystals contain one mol.  $H_2O$ . Dibromoresorcinol is sparingly soluble in cold water, readily in hot water, alcohol, and ether; with ferric chloride, the aqueous solution gives a pure blue coloration, which, after a time, gives place to a dark pre-

precipitate; with neutral and basic lead acetate, it gives a white precipitate; with bleaching powder, a violet coloration, which changes first to red and then to gold. Bromine-water throws down a precipitate of tribromoresorcinol. It is soluble in alkalis, and is reprecipitated on adding an acid to the solution. In other respects, it resembles the monobromoresorcinol in behaviour.

This dibromoresorcinol differs from  $\alpha$ -dibromoresorcinol prepared by Hofmann from eosin (this Journ., 1875, 571), and also from  $\beta$ -dibromoresorcinol previously described by the author (*loc. cit.*), both in its higher melting point, its reaction with ferric chloride, and also its readier solubility in water. From experiments made with  $\alpha$ - and  $\beta$ -dibromoresorcinol, the author concludes that they are identical.

G. H. M.

**Action of Chlorine and Bromine on Pyrogallol.** By A. HANTZSCH and K. SCHNITER (*Ber.*, 20, 2033—2040).—When chlorine is passed into an aqueous or alkaline solution of pyrogallol, and the product after removal of the excess of chlorine by a current of air is treated with ether, an oil is obtained which contains chlorine, is acid in reaction, and is soluble in water. It cannot be distilled unchanged, and is readily reduced to pyrogallol by the action of zinc and sulphuric acid. Leucogallol, obtained by Stenhouse and Groves (this Journ., 1875, 704), by chlorinating pyrogallol in acetic acid solution, has the formula  $C_{18}H_6Cl_{12}O_{12} + 2H_2O$  originally ascribed to it, and yields *trichloropyrogallol*,  $C_6H_3Cl_3O_3 + 3H_2O$ , when dissolved in water and treated with zinc-dust in small portions at a time, rise of temperature being avoided. Trichloropyrogallol crystallises in long, white needles, and melts at  $75^\circ$ , whilst the anhydrous substance melts at about  $185^\circ$  with decomposition. It is very readily soluble in alcohol, ether, and chloroform, soluble in hot water, and dissolves in ammonia with a bright yellow colour. The aqueous solution gives insoluble precipitates of varying colours with most metallic salts, and ammoniacal silver nitrate yields with it a mirror of silver. The *barium* salt,  $(C_6Cl_3O_3)_2Ba_3 + 6H_2O$ , forms indistinct crystals; the *copper* salt,  $(C_6Cl_3O_3)_2Cu_3 + 6H_2O$ , is an amorphous green powder. The *acetyl*-derivative,  $C_6Cl_3O_3Ac_3$ , crystallises in slender needles, melts at  $122^\circ$ , is soluble in alcohol, ether, and benzene, insoluble in water, and is very stable towards sulphuric and nitric acids. Leucogallol, on account of the ease with which it is reduced, cannot be regarded as a derivative of a hydrocarbon,  $C_{18}H_{18}$ , and is most probably formed of three benzene molecules united by oxygen-atoms. With hydroxylamine hydrochloride, it yields a nitrogenous compound which gives Liebermann's reaction, and also reacts with phenylhydrazine acetate, but owing to their great instability neither compound has been obtained pure.

Mairogallol (*loc. cit.*), although it differs from leucogallol by reason of its insolubility in water and greater stability, yields trichloropyrogallol under similar conditions.

Xanthogallol (Stenhouse, this Journ., 1875, 1) is neither reduced by sodium amalgam nor by zinc and sulphuric acid, but yields *trihydroxyxanthogallol*,  $C_{18}H_4Br_{11}O_6(OH)_3$ , when treated with dilute

aqueous soda. The *barium* salt has the formula  $(C_{18}H_4Br_{11}O_9)_2Ba_3$ ; the *acetyl*-derivative,  $C_{18}H_4Br_{11}O_9Ac_3$ , crystallises in nacreous scales, and is soluble in all ordinary solvents, water excepted. Both *xanthogallol* and the trihydroxy-derivative yield compounds with phenylhydrazine acetate.

The second portion of the paper is devoted to a discussion of the probable constitution of these pyrogallol-derivatives, and in conclusion the authors state that the product obtained by Stenhouse on brominating bromanilic acid, and to which the formula  $C_6HBr_{11}O$  was ascribed, is perbromacetone.  
W. P. W.

**Anilic Acids.** By S. SALZMANN (*Ber.*, 20, 1997—1999).—Hantzsch showed (this vol., p. 719) that the acid formed by the bromination of quinonedihydroxyparadicarboxylic acid, which contains both bromine-atoms in the para-position, is identical with ordinary bromanilic acid. By heating symmetrical tribromophenol with fuming sulphuric acid at 100—115°, the third possible bromanilic acid is obtained in which the bromine has the meta-position; this also seems to be identical with ordinary bromanilic acid. Bromanil is also formed in the reaction. The author considers that the chemical identity of the three acids is not established, and refers to  $\alpha$ - and  $\beta$ -thiophencarboxylic acids as examples of compounds possessing the same physical properties.  
N. H. M.

**Nitranilic Acid from Chloranil.** By J. U. NEF (*Ber.*, 20, 2027—2031).—When a hot solution of chloranil in acetone is gradually added to a concentrated aqueous solution of potassium or sodium nitrite heated at 80—90°, a dark reddish-brown coloration is at first produced, and after a short time a dark-yellow crystalline separation of the corresponding salt of nitranilic acid is obtained (*Abstr.*, 1883, 465). The potassium salt forms microscopic crystals, which are probably monoclinic, and show feeble dichroism; the sodium salt forms characteristic dark-red monoclinic octahedra,  $a : b : c = 0.9463 : 1 : 0.98489$ ;  $\beta = 87^\circ 5'$ , and is strongly dichroic. All attempts to isolate the reddish-brown intermediate product have failed.

The action of a concentrated aqueous solution of potassium cyanide on chloranil dissolved in acetone results in the formation of several products, of which one crystallises well from acetic acid, and seems to have the formula  $C_6(OH)_2Cl_2(CN)_2$ .  
W. P. W.

**Cholesterin.** By B. RAYMAN (*Bull. Soc. Chim.*, 47, 898—901).—The analogy of cholesterin to camphor is confirmed by the absence of any action when it is treated with hydroxylamine. The author failed in his attempts to prepare a sodium cholesterate, as also to prepare the cholesterin ether,  $(C_{26}H_{43})_2O$ . On heating cholesterin with acetic anhydride in a reflux apparatus, and cooling, *cholesterin acetate* separates in flocks; on crystallisation from benzene, it forms groups of needles which melt at 113° and decompose at a somewhat higher temperature, losing acetic acid; water acts on it in a similar manner.

Cholesteryl chloride may be prepared by heating cholesterin with

phosphoric chloride; it forms small scales and melts at  $96^{\circ}$ . On slowly evaporating the ethereal solution, it exhibits a fine violet fluorescence.

*Cholesteryl chloride dibromide*,  $C_{26}H_{43}ClBr_2$ , may be prepared by gradually adding bromine to an ethereal solution of cholesteryl chloride, when it is precipitated as a heavy white powder; it is insoluble in ether but soluble in most other solvents, and crystallises from its solution in carbon bisulphide in large, colourless crystals; it melts at  $128^{\circ}$  and is decomposed when heated to  $158^{\circ}$ . By digestion with sodium ethoxide or isobutoxide, or with a solution of potassium hydroxide, the bromine is removed and cholesteryl chloride regenerated.

By the action of potassium chlorate and hydrochloric acid on cholesterin an amorphous substance which appears to have the composition  $C_{26}H_{41}Cl_2O_3$  is formed. The reduction of nitro-derivatives of cholesterin by zinc powder has not yielded any satisfactory results.

A. P.

**Combination of Aniline with Chromic Acid.** By C. GIRARD and L. L'HOTÉ (*Compt. rend.*, 104, 1725—1727).—When aniline is mixed with free chromic acid, oxidation takes place and no chromate is obtained. If, however, equal volumes of well-cooled saturated solutions of potassium dichromate and aniline hydrochloride are mixed together, a yellow crystalline precipitate is formed which must be immediately separated and drained by means of a filter-pump, then washed with small quantities of cold water, and dried on a porous plate over sulphuric acid in a vacuum. Sodium and ammonium dichromates give similar results.

The crystals are yellow monoclinic prisms which act strongly on polarised light and have a bright green lustre. They have the composition  $2NH_2Ph.H_2Cr_2O_7$ , are slightly soluble in cold water, and are decomposed by boiling water. When moist, they decompose on exposure to air and light, but remain unaltered if dry. They are very slightly soluble in alcohol, which they gradually convert into aldehyde. The compound decomposes when heated to a moderate temperature, and it burns with formation of chromic oxide when ignited or struck on an anvil. It takes fire in contact with fuming nitric acid, and if moistened with concentrated sulphuric acid it burns like pyrophoric copper. When mixed with alkalis and agitated with ether or benzene, it gives up aniline. When treated with water, it yields violet colouring matters similar to mauve.

C. H. B.

**Phenylparatoluidine.** By A. BONNA (*Annalen*, 239, 55—64).—*Phenylparatoluidine* melts at  $85$ — $86^{\circ}$  and boils at  $317$ — $318^{\circ}$  (thermometer immersed in vapour). The nitroso-compound,  $NPh(C_7H_7) \cdot NO$ , is deposited from alcohol in yellow needles, soluble in ether and benzene. It melts at  $82^{\circ}$ . On the addition of bromine to the alcoholic solution, nitrosobromophenyltoluidine,  $C_{13}H_{11}BrN_2O$ , is deposited. On recrystallisation from ether or chloroform, it forms yellow needles melting at  $166^{\circ}$ . The acetic derivative is formed when acetic chloride is added to a solution of phenyltoluidine in benzene, and also by the action of acetic anhydride on phenyltoluidine at  $200^{\circ}$ . The acetic derivative melts at  $51^{\circ}$ , and is freely soluble in alcohol and

ether. On exposure to bromine-vapour, a monobromo-compound,  $C_{13}H_{11}BrNAc$ , is obtained. This substance crystallises in plates and melts at  $72^\circ$ . When phenylparatoluidine is exposed to the action of bromine-vapour at the ordinary temperature, the base unites directly with bromine, forming the compound  $C_{13}H_{13}NBr_4$ . This substance melts at  $135^\circ$ , and dissolves in ether, benzene, and chloroform.

*Tetrabromophenylparatoluidine*,  $C_{13}H_9Br_4N$ , is deposited on mixing an alcoholic solution of phenyltoluidine with the theoretical quantity of bromine diluted with glacial acetic acid; it melts at  $156^\circ$ . By the action of excess of bromine at  $280^\circ$  and  $310^\circ$ , compounds containing 7 and 11 bromine-atoms are obtained:  $C_{13}H_6Br_7N$  melts at  $185^\circ$ , and  $C_{13}H_2Br_{11}N$  melts at  $296^\circ$ . A compound of the composition  $C_{13}H_6Br_7N$  is formed by the action of bromine-vapour on the base exposed to bright sunlight. This substance melts at  $254^\circ$ , crystallises in colourless needles, and dissolves in ether and light petroleum.

*Phenylmethyllacridine*, formed by the action of zinc chloride and benzoic acid on phenylparatoluidine at  $260^\circ$ , is a white crystalline substance soluble in alcohol, benzene, and ether with greenish-blue fluorescence. It melts at  $135-136^\circ$ . The *hydrochloride* forms yellow needles, freely soluble in alcohol and water. On the addition of sodium sulphite to the aqueous solution of the hydrochloride, the *sulphite*,  $(C_{20}H_{15}N)_2SO_3H_2$ , is deposited as an orange precipitate. The red-coloured needles of the *picrate*,  $C_{20}H_{15}N + C_6H_2(NO_2)_3OH$ , dissolve in warm alcohol. The *hydriodide*,  $C_{20}H_{15}NHI$ , is precipitated on the addition of potassium iodide to a solution of the hydrochloride. On oxidation with dichromate mixture phenylmethyllacridine yields a

monocarboxylic acid,  $C_6H_4 \begin{array}{c} \diagup CPh \\ | \\ N \\ \diagdown \end{array} C_6H_3 \cdot COOH$ . The acid melts with

partial decomposition between  $252^\circ$  and  $255^\circ$ . The silver salt,  $C_{20}H_{12}NO_2Ag$ , and the barium salt,  $(C_{20}H_{12}NO_2)_2Ba$ , are crystalline.

*Dimethyllacridine* is formed by the action of zinc chloride and glacial acetic acid on phenylparatoluidine at  $220^\circ$ . It melts at  $122-123^\circ$ , dissolves freely in alcohol and benzene, and forms yellow needles or prisms. The *hydrochloride*, *hydriodide*, and *picrate* are crystalline salts soluble in alcohol. The hydrochloride also dissolves in water.

W. C. W.

**Cyananiline, Cyanphenylhydrazine, and Analogous Compounds.** By A. SENF (*J. pr. Chem.* [2], 35, 513-541).—Cyananiline is prepared by passing cyanogen through a solution of 10 grams of aniline in 30 grams of absolute alcohol mixed with 60 grams of water. The crystals thus obtained are treated with dilute sulphuric acid to dissolve the cyananiline, which is subsequently precipitated by ammonia. A red crystalline substance remains undissolved in the acid. Cyananiline is also formed by heating oximidoether,  $OEt \cdot C(NH) \cdot C(NH) \cdot OEt$ , (Pinner and Klein, *Abstr.*, 1879, 46), with aniline. This reaction shows the correctness of the constitution  $NHPh \cdot C(NH) \cdot C(NH) \cdot NHPh$  for cyananiline. Dry nitrous anhydride converts cyananiline suspended in absolute ether into the nitrate; this decomposes violently when melted, yielding phenylcarblyamine. When a solution of cyananiline in acetic acid and water is treated with nitrous acid, phenyl-

carbylamine, oxanilide, and  $\alpha$ -dinitrophenol are obtained; the latter is formed by the action of nitrous acid on oxanilide. Sodium amalgam reduces cyananiline to ammonia, aniline, and formic acid. When bromine is added to a solution of cyananiline in chloroform at  $0^\circ$ , the compound  $C_2(NH)_2(NH \cdot C_6H_4Br)_2, HBr, Br_2$  separates; the latter dissolves readily in water; when distilled with steam, tribromaniline is formed; if ammonia is added to the solution of the bromine-compound in dilute sulphuric acid, the compound  $C_{14}H_{12}N_4Br_2$  is formed. This crystallises from benzene in white plates. *Paradibromocyananiline*,  $C_2(NH)_2(C_6H_4Br \cdot NH)_2$ , is obtained by boiling a solution of cyananiline in glacial acetic acid with bromine. The crystalline product is dissolved in water and precipitated with ammonia. It is also formed when parabromaniline is treated with cyanogen. Phthalic anhydride acts on cyananiline at  $150^\circ$ , yielding phthalanile.

*Cyanxylylide*,  $C_2(NH)_2(NH \cdot C_6H_3Me_2)_2$ , is a yellow substance soluble in alcohol.

No additive products of cyanogen with methylaniline and diphenylamine could be obtained.

*Cyanmetanitraniline*,  $C_2(NH)_2(NH \cdot C_6H_4 \cdot NO_2)_2$ , prepared by the action of cyanogen on metanitraniline, is a brown substance, soluble in alcohol.

*Cyanphenylhydrazine*,  $C_{14}H_{16}N_6$ , is prepared by passing cyanogen through an alcoholic solution of pure phenylhydrazine until the solution begins to become opaque; the whole is left for 12 hours. It melts at  $225^\circ$ , and dissolves sparingly in alcohol. It can also be obtained from cyananiline and phenylhydrazine.

When a solution of cyananiline in chloroform is boiled with phenylhydrazine, and the product is left for 24 hours, the compound  $CHCl(C_{14}H_{15}N_6) \cdot N_2H_2Ph, 2HCl$  is formed. This crystallises in yellow matted needles melting at  $200-212^\circ$ ; it is readily soluble in cold water and alcohol, insoluble in ether, benzene, and chloroform.

Cyanogen has no action on diphenylhydrazine, the constitution of cyanphenylhydrazine is therefore  $C_2(NH)_2(NH_2 : NPh)_2$ .

*Cyanphenylhydrazine hydrochloride* is prepared by passing dry hydrogen chloride through a solution of the base in absolute alcohol; it is very unstable and decomposes in moist air. It dissolves very readily in alcohol.

When cyanphenylhydrazine is warmed with dilute hydrochloric acid, and the product treated with ammonia, the compound

is obtained. The latter crystallises in greyish-white plates melting at  $180^\circ$ ; it dissolves very readily in alcohol and ether, very sparingly in boiling benzene and chloroform. The *hydrochloride* is a yellow substance melting at about  $120^\circ$ .

Cyanphenylhydrazine is decomposed by dilute hydrochloric acid at  $160^\circ$  into phenylhydrazine hydrochloride, ammonium chloride, carbonic anhydride, and carbon oxide.

N. H. M.

**Hexa-derivatives of Benzene.** By R. NIETZKI (*Ber.*, 20, 2114—2118).—A better method for nitrating diacetylmetaphenylenedi-

amine than that previously described (this vol., p. 476) is to mix one-fifth its weight of carbamide nitrate with the base, and to gradually add the mixture to six times its volume of pure nitric acid cooled to  $-2^{\circ}$ ; ordinary fuming nitric acid (sp. gr. = 1.52) cannot be substituted for the pure acid, since the mononitro-derivative is the sole product of its action even at  $20^{\circ}$ .

The *nitrate* of diimidodiamidobenzene,  $(\text{NH})_2\text{C}_6\text{H}_2(\text{NH}_2)_2 \cdot 2\text{HNO}_3$ , is obtained by treating a solution of tetramidobenzene (1 part) in water (15 parts) with ordinary nitric acid (2 parts) and afterwards with an excess of ferric chloride. It crystallises in small, green needles, and when gradually added to an excess of sulphuric acid cooled to  $10^{\circ}$  dissolves with a reddish-violet colour rapidly changing to a brownish-yellow, and on the addition of ice *dinitrodiamidoquinone*,  $\text{C}_6\text{H}_4\text{N}_4\text{O}_6$ , crystallises from the solution in stellate groups of dark-yellow needles. This compound is practically insoluble in all ordinary solvents, and is a feeble base yielding salts readily decomposed by water. Dinitrodiamidoquinone yields potassium nitrilate when heated with dilute aqueous potash, and nitramidotetrahydroxybenzene on treatment with acid stannous chloride, whilst its solution in strongly acid stannous chloride gives on saturation with hydrogen chloride the hydrochloride of a new base crystallising in colourless scales, and having the composition  $\text{C}_6\text{H}_{14}\text{N}_4\text{Cl}_4$ . On the reduction of dinitrodiamidoquinone, the tetrahydrochloride of tetramidodihydroxybenzene or tetramidoquinol is obtained. In its properties, this base shows much similarity to diamidotetrahydroxybenzene (Abstr., 1885, 779), thus it is converted by oxidising agents into compounds containing less hydrogen, and when boiled in alkaline solution with manganese dioxide yields croconic acid. The sulphate is sparingly soluble in water, and the base on exposure to the air rapidly assumes a violet colour. W. P. W.

**Action of Aromatic Diamines on Sugars.** By P. GRIESS and G. HARROW (*Ber.*, 20, 2205—2213; compare this vol., p. 475).—*Digluco-orthodiamidobenzene*,  $\text{C}_6\text{H}_4(\text{N}:\text{C}_6\text{H}_{12}\text{O}_5)_2 + 2\text{H}_2\text{O}$ , is obtained when aqueous solutions of dextrose (2 mols.) and orthodiamidobenzene (1 mol.) are mixed in the absence of acids. It crystallises in slender, white needles, has a bitter taste, carbonises when heated, and is readily soluble in cold water, nearly insoluble in strong spirit and in ether. Its aqueous solution is strongly laevorotatory, reduces Fehling's solution, and gives an intense yellowish-red coloration with ferric chloride. When heated with alkalis and mineral acids, it is decomposed seemingly without a preliminary resolution into its components.

*Anhydrogluco-orthodiamidibenzene*,

is formed, together with gluco-orthodiamidobenzene, by the action of dextrose on diamidobenzene in presence of acids, and separates first on crystallisation. It forms lustrous, white needles, has a bitter taste, reduces Fehling's solution, dissolves readily in boiling alcohol or water, but crystallises out almost entirely on cooling, and is insoluble in

ether. It shows very feeble basic properties, and is decomposed when boiled with acids or alkalis, with formation of an insoluble, red, basic compound.

*Gluco-orthodiamidobenzene*,

forms small, white plates of slightly bitter taste, moderately soluble in cold water and alcohol, nearly absolutely insoluble in ether. It has strongly pronounced basic properties; the hydrochloride crystallises in plates, and is very readily soluble in water. It is not decomposed by acids or alkalis, and does not reduce Fehling's solution.

The action of orthotoluylenediamine on dextrose has been described by Hinsberg (this vol., p. 476). The authors had independently obtained the same results, but have further prepared *glucometapara-diamidotoluene*,  $\text{C}_6\text{H}_3\text{Me} \begin{smallmatrix} \text{NH} \\ < \\ \text{NH} \end{smallmatrix} > \text{C}_6\text{H}_{10}\text{O}_5$ , crystallising in small, white nodules moderately soluble in water.

*Gluco-γ-diamidobenzoic acid*,

prepared by mixing boiling aqueous solutions of dextrose and γ-diamidobenzoic acid, crystallises in small, longish three- to six-sided plates, has scarcely any taste, melts with decomposition when heated, and has a feeble acid reaction. It is sparingly soluble in hot water, insoluble in alcohol and ether, and is not decomposed by boiling with hydrochloric acid or with baryta-water. The hydrochloride crystallises in indistinct white plates. The barium salt is obtained as a snow-white powder. Both acid and alkaline solutions are dextrorotatory.

*Malto-γ-diamidobenzoic acid*,  $\text{C}_{12}\text{H}_{20}\text{O}_{10} \begin{smallmatrix} \text{NH} \\ < \\ \text{NH} \end{smallmatrix} > \text{C}_6\text{H}_3 \cdot \text{COOH}$ , obtained by the action of γ-diamidobenzoic acid on maltose, crystallises in short, white microscopic needles, moderately soluble in hot water, sparingly in cold, and insoluble in alcohol and ether. Its barium salt is described.  
A. J. G.

### Action of Aniline Hydrochloride on Ethylene Cyanide.

By R. BLOCHMANN (*Ber.*, 20, 1856—1861).—When a mixture of aniline hydrochloride and ethylene cyanide is melted, reaction takes place, and the temperature of the mass rises to above 200°, much charring taking place. The compound formed is *diphenylsuccinimidine hydrochloride*,  $\text{C}_2\text{H}_4 \begin{smallmatrix} \text{C}(\text{NH}) \\ < \\ \text{C}(\text{NPh}) \end{smallmatrix} > \text{NPh} \cdot \text{HCl}$ . If excess of aniline hydrochloride is used, the temperature does not rise so high, charring does not occur, and a better yield is obtained. The hydrochloride crystallises in glistening needles, and is soluble in boiling water and alcohol, but in each case with partial decomposition. The *platinochloride*,  $(\text{C}_{16}\text{H}_{15}\text{N}_3)_2 \cdot \text{H}_2\text{PtCl}_6$ , is orange coloured and crystalline. The free base forms pale-green crystals insoluble in water, soluble in alcohol. The *hydrobromide*, *hydriodide*, *sulphate*, and *nitrate* crystallise in needles.

When the hydrochloride is boiled with water, it is decomposed into succinil,  $\text{C}_2\text{H}_4\text{<}\begin{smallmatrix}\text{CO} \\ \text{CO}\end{smallmatrix}\text{>NPh}$ , aniline, and ammonium chloride. With boiling alcohol, *hydrogen ethyl phenylsuccinimide*,

aniline, ammonium chloride, and seemingly small quantities of ethyl-aniline are formed.

Diphenylsuccinimidine unites readily with methyl iodide to form an ammonium base. L. T. T.

**Chlorinating by means of Acetic Chloride.** By P. BECKER (*Ber.*, 20, 2006—2008).—When azobenzene is heated with acetic chloride at 160—170° for three to four hours, a product is obtained consisting of paradichlorazobenzene (Heumann, this Journal, 1873, 167) and parachloracetanilide. The latter when recrystallised from hot water melts at 175·5—176° (not 172·5°, Beilstein and Kurbatow, *Annalen*, 182, 99). N. H. M.

**Orthazoxytoluene.** By A. L. GUITERMANN (*Ber.*, 20, 2016—2017).—The compound obtained by G. Schultz (*Ber.*, 17, 468) by the action of stannous chloride on orthazotoluene is shown to be orthazoxytoluene,  $(\text{C}_7\text{H}_7\text{N})_2\text{O}$ , identical with the compound obtained by Klinger and Pitschke (*Abstr.*, 1886, 53). When reduced in acid solution, orthotoluidine (m. p. 129°, not 112°) is formed.

N. H. M.

**The Hydrazines.** By E. FISCHER (*Annalen*, 239, 248—252).—Phenylhydrazine and methylphenylhydrazine are decomposed by the prolonged action of zinc-dust and hydrochloric acid, yielding ammonia and aniline or methylaniline respectively.

*Acetomethylphenylhydrazine*,  $\text{NMePh}\cdot\text{NHAc}$ , melts at 92—93°, and distils with slight decomposition. It is soluble in alcohol, benzene, and in hot water. *Acetodimethylphenylhydrazine*,  $\text{NMePh}\cdot\text{NMeAc}$ , is prepared by the action of methyl iodide on the product of the action of sodium on a solution of acetomethylphenylhydrazine in xylene. The new compound forms colourless crystals, melts at 68°, and distils without decomposition. It does not reduce alkaline, copper, or silver solutions, nor is it attacked by alkalis. It is decomposed by boiling with hydrochloric acid, yielding acetic acid and monomethylaniline.

W. C. W.

**Compounds of Phenylhydrazine with Acrolein, Mesityl-oxide, and Allylbromide.** By E. FISCHER and O. KNOEVENAGEL (*Annalen*, 239, 194—206).—The compound  $\text{C}_9\text{H}_{10}\text{N}_2$ , which Fischer (*Abstr.*, 1886, 806) obtained by the action of phenylhydrazine on acraldehyde in ethereal solution, is *phenylpyrazoline*. This substance melts at 51—52°, and boils at 273—274°. It is freely soluble in alcohol, ether, benzene, in hot water, and also in strong hydrochloric acid; in the latter case, the greater part is reprecipitated on diluting the acid with water. The dilute acid solution exhibits the characteristic violet or blue coloration with potassium dichromate. When bromine acts on phenylpyrazoline in the presence of chloroform, a

yellow crystalline compound is formed which gives off hydrogen bromide on exposure to the air. On recrystallisation from hot alcohol, colourless crystals of *dibromophenylpyrazoline*,  $C_9H_8Br_2N_2$ , are deposited. This substance melts with decomposition at  $92-93^\circ$ , and dissolves in hot alcohol, chloroform, ether, and glacial acetic acid. It is converted into *bromethoxyphenylpyrazoline*,  $C_{11}H_{13}N_2BrO$ , by alcoholic potash. The new compound melts at  $65-66^\circ$ , and dissolves in ether, chloroform, and hot alcohol, and light petroleum. It is decomposed by heating with strong hydrochloric acid, yielding ethyl chloride and *bromohydroxyphenylpyrazoline*,  $C_9H_7N_2BrO$ , a crystalline compound melting at  $214^\circ$ . The pyrazoline compound forms crystalline salts with ammonium, sodium, and barium. The barium salt is sparingly soluble in hot water.

Sodium amalgam reduces the aqueous solution of bromohydroxyphenylpyrazoline to *hydroxyphenylpyrazoline*,  $C_9H_8N_2O$ , a crystalline compound melting at  $152-153^\circ$ . The compound is soluble in strong hydrochloric and acetic acids, in dilute alkalis, and also in chloroform, benzene, and hot alcohol.

Phenylhydrazine unites with mesityl oxide, forming *trimethylphenylpyrazoline*,  $C_{12}H_{16}N$ , an oily liquid, soluble in ether, alcohol, benzene, chloroform, and in dilute acids. The acid solutions exhibit the pyrazoline reaction with potassium dichromate. The *platinochloride*,  $(C_{12}H_{16}N_2)_2H_2PtCl_6$ , is crystalline, and almost insoluble in water.

*Allylphenylhydrazine*,  $C_9H_{12}N_2$ , is formed by the action of allyl bromide on phenylhydrazine largely diluted with ether. At the commencement of the operation, the temperature must not exceed  $20^\circ$  to  $25^\circ$ . The product is a pale oil boiling at  $172^\circ$  under 60 mm. pressure. It is soluble in dilute acids, and reduces Fehling's solution. On treating the ethereal solution with yellow mercuric oxide, it is converted into *azophenylallyl*,  $C_9H_{10}N_2$ , which closely resembles azophenylethyl in its properties.

W. C. W.

**Hydrazinebenzenesulphonic Acids.** By A. PFÜLF (*Annalen*, 239, 215—220).—Parahydrazinebenzenesulphonic acid readily unites with ketones, aldehydes, and thiocarbimides, but is not attacked by methyl iodide even in presence of alkalis. With nitrous acid, it yields diazobenzenesulphonic acid. *Acetonehydrazinebenzenesulphonic acid* crystallises in glistening plates which are sparingly soluble in hot water. It does not reduce alkaline solutions of copper sulphate. Hydrazinebenzenesulphonic acid dissolves in pyruvic acid, forming a syrupy liquid which slowly crystallises, and dissolves in alcohol and ether. The *sodium salt*,  $C_6H_5N_2SO_3Na + H_2O$ , is deposited from hot dilute alcohol in colourless crystals. A warm solution of sodium hydrazinebenzenesulphonate dissolves benzaldehyde, forming the *sodium benzylidenehydrazinebenzenesulphonate*, which is deposited on the addition of alcohol. The *calcium salt*,  $Ca(C_{13}H_{11}N_2SO_3)_2Ca + 4H_2O$ , crystallises in needles. The free acid is decomposed by boiling water, or more easily by dilute acids, yielding benzaldehyde and hydrazinebenzenesulphonic acid. If phenyl thiocarbamide is substituted for benzaldehyde, a sulphonic acid is obtained which yields crystalline sodium and calcium salts,  $(C_{13}N_3H_{12}S_2O_3)_2Ca + 2H_2O$ .

Methylphenylhydrazine dissolves in strong sulphuric acid (to which 5 per cent. of sulphuric anhydride has been added), forming *methylhydrazinebenzenesulphonic acid*. The sulphonic acid crystallises in plates, dissolves in hot water, and forms condensation products with acetone, benzaldehyde, and pyruvic acid. The sodium and barium salts are soluble in water and sparingly soluble in alcohol.

W. C. W.

### Anilides of Fumaric and Maleïc Acids: Phenylaspartic Acid.

By R. ANSCHÜTZ and Q. WIRTZ (*Annalen*, **239**, 137—160).—*Fumaric dianilide*,  $C_2H_2(CO \cdot NPh)_2$ , is obtained by carefully mixing ethereal solutions of fumaric chloride and aniline. It crystallises in white needles sparingly soluble in alcohol and glacial acetic acid, and decomposes at  $275^\circ$  without melting. It unites directly with two atoms of bromine, and seems to form the aniline of ordinary dibromosuccinic acid. The dianilide differs entirely from the fumaric dianilide which Michael and Wing (*Amer. Chem. J.*, **7**, 280) recently state they obtained together with "maleïc dianilide" by the distillation of monaniline malate. On repeating this experiment, the authors find that aniline malate is decomposed, yielding maleïnanil, phenylaspartanil, and fumaric dianilide, and that Michael and Wing mistook maleïnanil,  $\langle \begin{smallmatrix} CH \cdot CO \\ CH \cdot CO \end{smallmatrix} \rangle NPh$ , for fumaric dianilide, and the anilide of phenylaspartic acid for maleïc dianilide. The yield of maleïnanil is increased if the operation is conducted under reduced pressure. *Maleïnanil* forms long yellow needles, freely soluble in benzene, chloroform, ether, and alcohol. It melts at  $90-91^\circ$ , and boils at  $162.2^\circ$  under 12 mm. pressure. (Under similar conditions citraconanil boils at  $171.7^\circ$ .) Maleïnanil unites with 2 atoms of bromine, forming *dibromosuccinanyl*,  $C_4H_2Br_2O_2NPh$ , a crystalline substance melting at  $158-159^\circ$ . On treatment with baryta-water at  $30-40^\circ$ , maleïnanil yields barium fumaranilate. *Fumaranic acid*,  $C_{10}H_5NO_3$ , is deposited from alcohol in prisms melting at  $187^\circ$ . It is decomposed by alcoholic potash, forming fumaric acid. A solution of aniline acid maleate decomposes at the ordinary temperature, yielding a mixture of maleïc and phenylaspartic acids. The presence of the phenylmaleamic acid of Michel and Palmer (*Abstr.*, 1886, 698) could not be detected. *Phenylaspartic acid*,  $NHPh \cdot C_2H_3(COOH)_2$ , is formed synthetically by boiling an aqueous solution of monobromosuccinic acid with aniline. The pure acid is a white crystalline substance which melts at  $131-132^\circ$  with decomposition, but it begins to change at  $121^\circ$ . The *barium* salt is freely soluble in water. The *hydrochloride*,  $C_{20}H_{26}N_2O_{10} \cdot HCl$ , forms monoclinic crystals [ $a : b = 1.9957 : 1$ ;  $\beta = 75^\circ 1\frac{1}{2}'$ ].

*Phenylasparaginil*,  $NHPh \cdot C_2H_3 \langle \begin{smallmatrix} CO \\ CO \end{smallmatrix} \rangle NPh$ , is formed by boiling an aqueous solution of aniline maleate, and also by heating aniline with maleïc acid, aniline with maleïc anhydride, maleïnanil with aniline, and the aniline hydrogen malate. It forms a convenient starting point for the preparation of phenylaspartic acid. Its properties and its preparation from asparagine and aniline have been previously described by Piutti (*Gazzetta*, **14**, 474).

W. C. W.

**Sebaceodinitranilide.** By G. GEHRING (*Compt. rend.*, **104**, 1716—1717).—Diphenylsebacadamide dissolved in fuming nitric acid or in a mixture of 4 parts concentrated sulphuric acid with 5 parts fuming nitric acid, yields a substance which has not yet been analysed, but which crystallises from water in white, feathery crystals melting at 133°.

*Sebaceodinitranilide*,  $C_{10}H_{16}O_2(NH \cdot C_6H_4 \cdot NO_2)_2$ , crystallises from water in slender, white needles; from ether in needles, and often in somewhat large prisms with a square base. It melts at 116°, and can be sublimed. It has a very sweet taste, but does not reduce Fehling's solution. In order to prepare this compound, 2 grams of diphenylsebacadamide is dissolved in 20 c.c. of nitric acid of sp. gr. 1.32, cooled, and mixed very slowly with 15 c.c. of nitric acid of sp. gr. 1.52 at 15°. The mixture is then heated in sealed tubes at 165° for six hours, and the product poured into water. The concentration of the nitric acid must be carefully regulated, since, if too strong, the diphenylsebacadamide may be completely decomposed. The temperature and time of heating have much less influence on the result.  
C. H. B.

**Metaformotoluide and its Derivatives.** By S. NIEMENTOWSKI and M. OBREMSKI (*Ber.*, **20**, 1891—1895).—*Metaformotoluide*,  $C_6H_4Me \cdot NH \cdot COH$ , boils with partial decomposition at about 278° (bar. 724 mm.), and is still liquid at -18°. Attempts to form a nitro-derivative were unsuccessful, the formic group being in all cases eliminated. *Methenylmetaditolylamidine*,  $C_6H_4Me \cdot N : CH \cdot NH \cdot C_6H_4Me$ , is formed when formotoluide is maintained at the boiling point for some hours, carbonic anhydride being evolved. It crystallises in needles or scales, melts at 123°, and is soluble in benzene, ether, chloroform, and boiling alcohol. The *hydrochloride*, *platinochloride*, and *picrate* are all crystalline. *Dibromomethenylmetaditolylamidine*,

formed by the action of bromine on a carbon bisulphide solution of the base, crystallises in white scales, sparingly soluble in chloroform and glacial acetic acid, insoluble in benzene; it blackens at 150°, and melts with decomposition at 262°.  
L. T. T.

**Introduction of Carboxyl into Aromatic Derivatives by the Action of Diphenylcarbamide Chloride.** By E. LELLMANN and O. BONHÖFFER (*Ber.*, **20**, 2118—2126. Compare this vol., p. 254).—*Diphenylparatoluyllamide*,  $C_6H_4Me \cdot CONPh_2$ , is prepared by acting with diphenylcarbamide chloride on toluene in the presence of aluminium chloride. It crystallises in yellowish prisms, melts at 153—155°, is readily soluble in chloroform, benzene, and acetic acid, sparingly soluble in ether and light petroleum; and when heated with concentrated hydrochloric acid yields paratoluic acid. Under similar conditions, *xylyldiphenylamide*,  $C_6H_3Me_2 \cdot CONPh_2$  [ $CONPh_2 : Me : Me = 1 : 3 : 4$ ], is obtained from orthoxylene. This crystallises in small, yellowish prisms, melts at 134—136°, shows a solubility similar to that of the preceding compound, and on hydrolysis yields paraxylic

acid (m. p. = 164—166°). *Xyloyldiphenylamide*, [CONPh<sub>2</sub> : Me : Me 1 : 2 : 4] is obtained in like manner from metaxylene, and crystallises in yellowish monoclinic prisms,  $a : b : c = 0.9095 : 1 : ?$ ;  $\beta = 83^\circ 2'$ ; observed faces 0P,  $\infty$ P,  $\infty$ P $\infty$ , and a much curved hemidome. It melts at 141—142°, has a solubility similar to that of the foregoing compounds, and on hydrolysis yields xylic acid (m. p. = 126°).

Ortho-, meta-, and para-nitramines react with diphenylcarbamide chloride and yield nitrocarbamides. *Diphenylmetanitrophenylcarbamide*, NO<sub>2</sub>·C<sub>6</sub>H<sub>4</sub>·NH·CONPh<sub>2</sub>, is formed by heating metanitriline (2 mols.) with the chloride (1 mol.) at 120—125° for eight hours. It crystallises in very slender, bright yellow needles, melts at 154—155°, and is readily soluble in alcohol, benzene, chloroform, and acetic acid, sparingly soluble in ether and light petroleum. Under similar conditions, *diphenylparanitrophenylcarbamide* is prepared from paranitriline, but the product has not been obtained free from a green colouring matter which is formed at the same time. It crystallises in pale bluish-green tables, melts at 175—176°, and is soluble in alcohol, &c., insoluble in ether and light petroleum. *Diphenylmetanitroparatolylcarbamide*, [Me : NO<sub>2</sub> : NH·CONPh<sub>2</sub> = 1 : 3 : 4], is obtained in like manner from metanitroparatoluidine, and crystallises in small, yellow needles which melt at 138—139.5°, and are soluble in chloroform, benzene, &c. When it is heated in alcoholic solution with stannous chloride and concentrated hydrochloric acid for three hours in a reflux apparatus, *diphenylmetamidoparatolylcarbamide* is formed; this crystallises from alcohol in slender pale-coloured needles and melts at 135—137°; if, however, it is heated to 165—170° it becomes solid, and fuses a second time between 220° and 260°, decomposing into diphenylamine and toluylenecarbamide, melting at 299—301°; a compound probably identical with Sandmeyer's hydroxymethenyl-toluylenediamine (this vol., p. 135).

*Phenyl diphenylcarbamate*, Ph<sub>2</sub>N·COOPh, is formed when equimolecular proportions of potassium phenate and diphenylcarbamide chloride in alcoholic solution are heated at 100°. It crystallises in short, pale-yellow prisms, melts at 103—104°, and is readily soluble in chloroform, alcohol, ether, benzene, and acetic acid. From potassium orthonitrophenate, under like conditions, *orthonitrophenyl diphenylcarbamate* is obtained; this compound separates at first in slender, yellow needles which soon aggregate to form colourless, monoclinic crystals having a diamond lustre,  $a : b : c = 1.8221 : 1 : 1.6667$ ;  $\beta = 82^\circ 2'$ ; observed faces  $\infty$ P<sup>2</sup>, P,  $\infty$ P $\infty$ , —P $\infty$ , 0P,  $\frac{1}{2}$ P $\infty$ , and —P. The needles melt at 114°, the prisms at 112°, and the salt dissolves in chloroform, benzene, &c. On reduction in alcoholic solution with stannous chloride and concentrated hydrochloric acid, it yields *orthamidophenyl diphenylcarbamate*, Ph<sub>2</sub>N·COO·C<sub>6</sub>H<sub>4</sub>·NH<sub>2</sub>; this crystallises in slender, white needles, melts at 189—191°, dissolves readily in alcohol, benzene, and acetic acid, but sparingly in hot ether, and when heated at 190° for 8—10 hours yields diphenylamine and a compound crystallising in slender, white needles melting at 137—138°, most probably identical with Bender's anhydro-orthamidophenyl carbonate (this vol., pp. 38, 245; compare Abstr., 1883, 1169; this vol., pp. 135, 477).

W. P. W.

**Carbon Thiodichloride.** By H. BERGREEN (*Ber.*, **20**, 1965—1966).—By acting on water, ammonia, ammonium chloride, sodium ethoxide, sodium phenoxide, ethyl acetosodacetate, and ethyl sodiomalonate with carbon thiodichloride the following compounds were obtained: *tetraphenyl thiocarbamide*,  $\text{CS}(\text{NPh}_2)_2$ ; *thiobenzophenone*,  $\text{CSPh}_2$ ; *ethyl thiocarbonate*,  $\text{CS}(\text{OEt})_2$ ; *ethyl chlorothiocarbonate*,  $\text{CSCI}\cdot\text{OEt}$ ; *phenyl thiocarbonate*, *ethyl thiocarboxylacetoacetate*,  $\text{CS}:\text{CAc}\cdot\text{COOEt}$ ; and *ethyl thiocarboxylmalonate*,  $\text{CS}:\text{C}(\text{COOEt})_2$ .

N. H. M.

**Anhydro-compounds.** By S. NIEMENTOWSKI (*Ber.*, **20**, 1874—1891).—The author's previous work on this subject (*Abstr.*, 1886, 545) left the constitution of these compounds still somewhat in doubt. With the aim of settling this question, the author has examined the action of reducing agents on aromatic compounds of the formula

where the hydrogen of the acetylated nitrogen is replaced by an alkyl radicle. Such compounds on reduction should give rise to ortho-amido- or anhydro-compounds,  $\text{NH}_2\cdot\text{X}\cdot\text{NR}\cdot\text{CO}\cdot\text{C}_x\text{H}_y$ , or

If the latter were formed, it would show at once that in the condensation the oxygen-atom of the acid radicle removed the two hydrogen-atoms attached to the same nitrogen-atom. In the author's experiments, anhydro-compounds were formed, and he is therefore of opinion that the anhydro-compounds previously described are analogous in constitution and correspond with formula II given in that paper (*loc. cit.*).

But besides the anhydro-compounds the author obtained, during the reduction of the above-named substances, a new class of oxy-compounds to which he ascribes the formula

*Metanitroparamethylacetotoluide*,  $\text{NO}_2\cdot\text{C}_6\text{H}_3\text{Me}\cdot\text{NMe}\cdot\text{COMe}$ , was prepared by Gattermann's reaction (*Abstr.*, 1875, 975). It crystallises in small plates, melts at  $64^\circ$ , and boils at  $250\text{--}255^\circ$  under 270 mm. pressure. When reduced with tin and hydrochloric acid, it yields a mixture of *methylethenyldiamidotoluene*,  $\text{C}_6\text{H}_3\text{Me} < \overset{\text{N}}{\underset{\text{NMe}}{\text{C}}} > \text{CMe}$ , and

*oxymethylethenyldiamidotoluene*,  $\text{N} < \overset{\text{O}}{\underset{\text{C}_6\text{H}_3\text{Me}\cdot\text{NMe}}{\text{C}}} > \text{CMe}$ . The former

crystallises in white needles, which are easily soluble in benzene, ether, &c., and in boiling water. It sublimes at  $110^\circ$ , forming thin cubic crystals, which melt at  $142^\circ$ ; the melting point is lower when the substance is crystallised in the ordinary way. Its aqueous solution gives a reddish coloration when heated with ferric chloride. It dissolves in ammonia with blue fluorescence. Concentrated hydrochloric acid does not decompose it even at  $250^\circ$ . The *hydrochloride* crystal-

lises with  $\frac{1}{2}$  mol.  $\text{H}_2\text{O}$  in needles, the *platinochloride* in yellow rhombic plates, melting with decomposition at  $234-244^\circ$ .

The oxy-compound crystallises in long needles containing  $2\text{H}_2\text{O}$ , which is given off at  $100^\circ$ . It is soluble in boiling water, alcohol, and chloroform, sparingly so in boiling benzene and ether. The anhydrous substance melts at  $63^\circ$ . It is not decomposed by concentrated hydrochloric acid even at  $180^\circ$ , nor by boiling alcoholic potash, nor is it reduced by long-continued boiling with tin and hydrochloric acid. The *hydrochloride* forms white, glistening needles soluble in water; the *platinochloride*, yellow scales melting with decomposition at  $220^\circ$ . When heated, this oxy-compound melts to a clear liquid, and at a slightly higher temperature explodes, leaving a thick brownish liquid, and a small quantity of methylethylenyldiamidotoluene. When heated with zinc-dust or with soda-lime, the decomposition takes place more quietly, methylethylenyldiamidotoluene being the chief product. Boiling acetic anhydride appears to act in a similar way, an aceto-derivative of the non-oxygenated base being formed. Concentrated sulphuric acid has no action on the oxy-compound at  $100^\circ$ .

*Metanitroparethylacetotoluide* resembles the methyl-compound, and volatilises with difficulty in a current of steam. Ethylethylenyldiamidotoluene (monethylanhydracetodiamidotoluene) has been already described by Hübner, Kronberg, and Tubbe (Abstr., 1882, 505). The *hydrochloride* forms a gummy mass; the *mercurochloride* crystallises in needles; the *picrate* forms crystals sparingly soluble in alcohol. The oxy-compound was not isolated, and if formed at all was only produced in very small quantities. When ethenyldiamidotoluene is heated with methyl iodide and methyl alcohol, it yields *methylethylenyldiamidotoluene methiodide*, soluble in alcohol and water, crystallising in needles, and melting at  $221^\circ$ . When heated with strong potash, the methiodide yields the corresponding *hydroxymethide*. This ammonium base crystallises in thin scales which soften at  $115^\circ$  and melt at  $135^\circ$ . It is a strong base, is insoluble in alkalis, and is not decomposed by heating with concentrated hydrochloric acid. The *hydrochloride*, *platinochloride*, and *picrate* are all crystalline. From the stability of the base, the author is inclined to consider its formula to be  $\text{C}_6\text{H}_3\text{Me} < \begin{smallmatrix} \text{NMe} \\ \text{NMe} \end{smallmatrix} > \text{CMe}\cdot\text{OH}$ .

*Tetramethyldiamidotoluene*,  $\text{C}_6\text{H}_3\text{Me}(\text{NMe}_2)_2$  [ $\text{Me} : \text{NMe}_2 : \text{NMe}_2 = 1 : 3 : 4$ ], is formed when toluenylenediamine is heated in closed tubes at  $120-130^\circ$ . It is a colourless, mobile liquid of strongly basic odour. It boils at  $225.5^\circ$  (uncorr.) under 717 mm. pressure. It is easily miscible with the usual solvents, sparingly soluble in water. The *platinochloride*, *picrate*, and *mercurochloride* are crystalline. *Nitrotetramethyldiamidotoluene*, formed by the action of nitrous acid on the base, crystallises in hexagonal prisms, is easily soluble in alcohol, ether, and benzene, and melts at  $63^\circ$ . It is still basic in properties. It is soluble in phenol, but sulphuric acid added to this solution only causes a slight lilac coloration, showing that no nitroso-group is present.

L. T. T.

**Nitrosalicylaldehydes.** By W. v. MILLER (*Ber.*, 20, 1927-1931). Mazzara has (this Journal, 1877, i, 597) described an  $\alpha$ - and a  $\beta$ -nitro-

salicaldehyde. The  $\alpha$ -aldehyde (true m. p.  $109^{\circ}$ ) when oxidised in acetic solution with chromic acid gives 1 : 2 : 3 nitrosalicylic acid, and is therefore 1 : 2 : 3 *nitrosalicaldehyde*,  $[\text{COH} : \text{OH} : \text{NO}_2 = 1 : 2 : 3]$ . The  $\beta$ -aldehyde (true m. p.  $126^{\circ}$ ) when similarly treated gives 1 : 2 : 5 nitrosalicylic acid, and is therefore 1 : 2 : 5 *nitrosalicylaldehyde*.  
L. T. T.

**Nitrocoumaraldehydes.** By W. v. MILLER and F. KINKELIN (*Ber.*, 20, 1931—1934).—Tiemann and Kees described (*Abstr.*, 1885, 1073) orthocoumaraldehyde, but were unable to obtain it by the condensation of salicylic and acetic aldehydes. The authors find that the introduction of a nitro-group into salicaldehyde renders the condensation possible.

1 : 2 : 5 *Nitrocoumaraldehyde*,  $[\text{C}_2\text{H}_2\text{COH} : \text{OH} : \text{NO}_2 = 1 : 2 : 5]$ , was obtained by dissolving 100 grams of the sodium salt of 1 : 2 : 5 nitrosalicylaldehyde (preceding Abstract) in  $2\frac{1}{2}$  litres of water, and adding 60 grams acetaldehyde, and 150 grams of 10 per cent. alcoholic potash. It is soluble in alcohol and acetic acid, very sparingly so in boiling water; it crystallises in yellow needles, and melts with decomposition at  $200^{\circ}$ . The *phenylhydrazone* crystallises in orange scales melting at  $235^{\circ}$ ; the *sodium-derivative* forms red plates easily soluble in water.

1 : 2 : 3 *Nitrocoumaraldehyde*, from 1 : 2 : 3 nitrosalicaldehyde, crystallises in glistening yellow needles, melts at  $133^{\circ}$ , and is easily soluble in alcohol and acetic acid, sparingly so in ether and boiling water. Its *phenylhydrazone* crystallises in red scales, and melts at  $157^{\circ}$ .  
L. T. T.

**Nitrosalicylaldehyde and Nitrocoumarin.** By C. TAEGER (*Ber.*, 20, 2109—2110).—A summary of the author's inaugural dissertation, which was published previously to the appearance of v. Miller's paper (preceding Abstract). Salicylaldehyde, when nitrated either with fuming nitric acid in a freezing mixture, or by boiling with dilute nitric acid, yields nitrosalicylic acid and two isomeric nitrosalicylaldehydes. The latter can be separated by means of their barium-derivatives, since on treatment with barium hydroxide the aldehyde melting at  $107^{\circ}$  crystallises first in orange crystals with 2 mols.  $\text{H}_2\text{O}$ , and that melting at  $125^{\circ}$  forms yellow spangles with 3 or 6 mols.  $\text{H}_2\text{O}$ , and separates from the second crystallisation. The sodium hydrogen sulphite compound of the former does not crystallise, that of the latter is solid, whilst the phenylhydrazides melt at  $165^{\circ}$  and  $186^{\circ}$  respectively.

The *nitrocoumarin* obtained by direct nitration with fuming nitric acid melts at  $183^{\circ}$ , and the corresponding *amido-derivative* formed by reduction with ferrous sulphate melts at  $161^{\circ}$ ; on oxidation with potassium permanganate in alkaline solution, it yields nitrosalicylic acid,  $[\text{COOH} : \text{OH} : \text{NO}_2 = 1 : 2 : 5]$  (m. p. =  $228^{\circ}$ ). A *dibromonitrocoumarin*, melting at  $271^{\circ}$ , is formed by the prolonged action of bromine-vapour.

When nitrosalicylaldehyde (m. p.  $125^{\circ}$ ) is boiled with acetic anhydride and sodium acetate, nitrocoumarin melting at  $183^{\circ}$  and iden-

tical with the preceding derivative is obtained; if, however, a lower temperature is employed in the reaction, an acetyl-derivative of nitrosalicylaldehyde results; this melts at  $112^{\circ}$ , and loses its acetyl-group on boiling with water. Under similar conditions, nitrosalicylaldehyde (m. p. =  $107^{\circ}$ ) yields a compound, probably a nitrocoumarin, from which a nitrosalicylic acid (m. p. =  $145^{\circ}$ ) was obtained on oxidation, and at a lower temperature forms an acetyl-derivative; this melts at  $110^{\circ}$ , and is also decomposed into nitrosalicylaldehyde on boiling with water.

W. P. W.

**Isophthalaldehyde.** By V. MEYER (*Ber.*, **20**, 2005).—Isophthalaldehyde,  $C_8H_6O_2$ , crystallises in long needles melting at  $89-90^{\circ}$ , has a very slightly aromatic odour, and reduces silver solution with difficulty; it can be distilled in small quantities without decomposition. The oxime crystallises from hot water in needles, which melt at  $180^{\circ}$ . When the latter is left in contact with twice its weight of acetic chloride for 12 hours, dicyanobenzene is formed (compare this vol., p. 482).

N. H. M.

**Benzoylaldehyde.** By L. CLAISEN and L. FISCHER (*Ber.*, **20**, 2191—2193).—*Benzoylaldehyde*,  $CH_2Bz\cdot COH$ , is obtained as a sodium-compound when a mixture of acetophenone and ethyl formate in molecular proportions is added to a dilute alcoholic solution of sodium ethoxide (1 mol.) cooled in ice, and separates as a colourless or pale-yellow oil, on treatment of the aqueous solution of the salt with acetic acid. Its alcoholic solution gives an intense red coloration with ferric chloride. The *copper* salt,  $(C_9H_7O_2)_2Cu$ , crystallises in dark-green, glistening, flat prisms. On adding a solution of a salt of the corresponding base to the aqueous solution of the sodium compound of benzoylaldehyde, the following derivatives are obtained: the *anilide*,  $CH_2Bz\cdot CH:NPh$ , crystallising in short, prismatic or scaly yellow forms melting at  $140-141^{\circ}$ ; the *paratoluidide*,  $CH_2Bz\cdot CH:NC_6H_7$ , crystallising in small, yellow forms melting at  $160-163^{\circ}$ , and the  *$\beta$ -naphthalide*,  $CH_2Bz\cdot CH:NC_{10}H_7$ , crystallising in small, bronze-coloured forms, melting at  $180-182^{\circ}$ . The anilide could not be converted into a quinoline-derivative either by heating alone or with concentrated sulphuric acid, and on dry distillation passes over for the most part unchanged.

W. P. W.

**Aromatic Ketones.** By K. ELBS (*J. pr. Chem.* [2], **35**, 465—509; compare *Abstr.*, 1886, 461).—Ditolyl ketone is prepared as follows: 50 grams of aluminium chloride, 60—70 c.c. of toluene, and 50 c.c. of carbon bisulphide are put into a strong half-litre flask; 10—12 c.c. of carbon bisulphide saturated with carbon oxychloride is added, and the flask closed with a cork provided with a glass tap drawn out to a fine capillary, which is fastened with wire. The whole is slightly warmed with steam for 15 to 30 minutes, allowed to cool, and the pressure relieved. It is then treated with more carbon oxychloride as before; this is repeated three or four times, and the product treated as previously described (*loc. cit.*). The yield is 40 to 50 per cent. of the theoretical.

*Orthoxylyl phenyl ketone*,  $C_6H_3Me_2 \cdot CPh$  [ $Me : Me = 1 : 2$ ], prepared from benzoic chloride and orthoxylene, crystallises from alcohol in groups of white, matted needles; it melts at  $47-48^\circ$ , boils at  $340.2^\circ$  under 744 mm. pressure, and is readily soluble in the usual solvents, except water.

*Orthoxylyl phenyl carbinol*,  $C_6H_3Me_2 \cdot CHPh \cdot OH$ , is readily obtained by reducing the ketone with zinc-dust and potash. It crystallises in groups of white needles, which dissolve readily in the usual solvents, except water; it melts at  $68^\circ$ , and boils at  $336^\circ$  under 744 mm. pressure with slow decomposition.

*Metaxylyl phenyl ketone*, forms a rather thick colourless oil boiling at  $321.2^\circ$  under 744 mm. pressure. In solubility, it resembles the ortho-compound. When boiled for 12 hours, a small amount of  $\beta$ -methylantraquinone melting at  $170-172^\circ$  is formed; when the ketone is boiled in presence of metaxylyl carbinol,  $\beta$ -methylanthracene is obtained.

*Metaxylyl phenyl carbinol*,  $C_{15}H_{16}O$ , is best purified by distillation. It melts at  $57^\circ$  and boils at  $330.8^\circ$ , under 744 mm. pressure.

*Paraxylyl phenyl ketone*, [ $Me : CO : Me = 1 : 2 : 4$ ], separates from its alcoholic solution in large, clear, well-formed prisms, very readily soluble in ether, alcohol, and acetone, sparingly in glacial acetic acid, more soluble in benzene; it melts at  $36^\circ$ , and boils at  $317.2^\circ$  under 744 mm. pressure. When boiled, it yields methylanthracene melting at  $199-200^\circ$ . The *disulphonic acid* is obtained by dissolving the ketone in pyrosulphuric acid; the *barium salt*, a yellow crystalline substance, is readily soluble in water. When the ketone is heated with nitric acid (sp. gr. 1.15) at  $170^\circ$  to  $180^\circ$  for six hours, it is oxidised to benzoyltetraphthalic acid.

*Paraxylyl phenyl carbinol* crystallises in prisms which melt at  $88^\circ$ , dissolve very sparingly in water, readily in alcohol, ether, acetone, and benzene.

*Diparaxylyl phenyl methane*,  $CHPh(C_6H_3Me_2)_2$ , is prepared by Hemilian's method (this Journ., 1875, 152, and *Ber.*, **16**, 2360); it crystallises from light petroleum in colourless prisms which melt at  $92.5^\circ$ , boils above  $360^\circ$ , and dissolves in the usual solvents except water. The solutions show a blue fluorescence.

*Diaxylyl phenyl  $\beta$ -pinacoline*,  $CPhBz(C_6H_3Me_2)_2$ , is obtained by Thömer and Zincke's method (*Ber.*, **11**, 65 and 1396). It forms almost colourless prisms, rather readily soluble in alcohol, ether, benzene, and light petroleum; it melts at  $146^\circ$ . When heated with soda-lime, diparaxylyl phenyl ketone is formed.

*Diparaxylyl ketone*,  $CO(C_6H_3Me_2)_2$  [ $CO : Me_2 = 2 : 1 : 4$  and  $5 : 1 : 4$ ], is prepared in a manner similar to diparaxylyl ketone. It is a thick, pale-yellow liquid, boiling at  $325-327^\circ$  (uncorr.). When boiled, it gives up the elements of water, and is converted into trimethyl-

anthracene,  $C_6H_2Me_2 \begin{array}{c} \diagup CH \\ | \\ CH \diagdown \end{array} C_6H_3Me$  [ $Me_2 = 1 : 4$  and  $Me = 2$ ]. The

latter crystallises in colourless plates, which show a blue fluorescence and melt at  $227^\circ$ . It sublimes below  $100^\circ$ , dissolves readily in ether and benzene, very sparingly in cold alcohol.

*Diparaxylyl carbinol*,  $\text{CH}(\text{C}_6\text{H}_3\text{Me}_2)_2\cdot\text{OH}$ , crystallises from alcohol in white needles melting at  $131^\circ$ . In solubility, it resembles its homologue.

*Triparaxylylmethane*,  $\text{CH}(\text{C}_6\text{H}_3\text{Me}_2)_3$ , is prepared by boiling a solution of diparaxylyl carbinol in paraxylene with phosphoric anhydride in a reflux apparatus for four hours. It crystallises from alcohol in colourless crystals which melt at  $188^\circ$ , and are moderately soluble in alcohol, readily in ether and benzene. It boils above  $360^\circ$ .

Mesityl phenyl ketone (Louise, Abstr., 1883, 577; 1884, 905) is best prepared by the general method previously described (*loc. cit.*); an excess of mesitylene need not be used. It melts at  $35^\circ$  and boils at  $318\text{--}319^\circ$ ; no anthracene-derivative could be obtained from it. The carbinol (Louise, *loc. cit.*) is best prepared by reducing the ketone with zinc-dust and potash. When the ketone is heated with strong sulphuric acid in a water-bath, mesitylenesulphonic acid and benzoic acid are formed; when the temperature does not rise above  $50^\circ$ , *mesitylphenylketonesulphonic acid* is formed; the *barium salt* is a yellow powder. When 2 grams of the ketone is dissolved in 30 c.c. of nitric acid (sp. gr. 1.45) and 10 c.c. of pyrosulphuric acid, two isomeric *trinitro-compounds* are formed; the one crystallises in slender, colourless needles which melt at  $188^\circ$ , almost insoluble in alcohol; the other crystallises from alcohol, in which it is rather readily soluble, in colourless needles melting at  $145^\circ$ . Nitric acid (sp. gr. 1.1) at  $200^\circ$  converts the ketone into a mixture of acids from which *benzoyl witic acid*,  $\text{COPh}\cdot\text{C}_6\text{H}_2\text{Me}\cdot\text{COOH}$  [ $\text{Me} : \text{CO} : (\text{COOH})_2 = 1 : 2 : 3 : 5$  or  $5 : 2 : 1 : 3$ ], was isolated; this crystallises from hot water in slender white needles melting at  $245^\circ$ .

*Pseudocumyl phenyl ketone*,  $\text{COPh}\cdot\text{C}_6\text{H}_2\text{Me}_3$ , boils at  $328\text{--}329^\circ$ ; when boiled, no dimethylantracene but dimethylantraquinone is formed; sulphuric acid converts it into benzoic and pseudocumenesulphonic acids. When nitrated, two isomeric *trinitropseudocumyl phenyl ketones* are obtained; both crystallise in slender needles; the one is sparingly soluble and melts at  $185^\circ$ , the other which is rather readily soluble melts at  $155^\circ$ . When oxidised with dilute nitric acid, *benzoyltrimellitic acid*,  $\text{C}_6\text{H}_2\text{Bz}(\text{COOH})_3$  [ $\text{Bz} : (\text{COOH})_3 = 5 : 1 : 2 : 4$ ] is formed together with other products.

Paracymyl phenyl ketone (Kollarits and Merz, *Ber.*, 6, 546 and 1264), prepared in a manner similar to the other ketones, is a readily soluble thick oil boiling at  $175^\circ$ . When boiled for eight days, a small amount of ordinary anthracene is formed.

*Paracymyl phenyl carbinol* forms a thick, pale-yellow oil.

*Paraxylylparacymylphenylmethane*,  $\text{C}_6\text{H}_3\text{Me}_2\cdot\text{CHPh}\cdot\text{C}_6\text{H}_3\text{MePr}$ , is prepared by adding 20 grams of phosphoric anhydride to a solution of 30 grams of paracymyl phenyl carbinol in 30 grams of paraxylene, and boiling the whole for five hours. It is a thick, reddish-yellow oil which boils above  $360^\circ$ .

*Dinitroparacymyl phenyl ketone*,  $\text{C}_{17}\text{H}_{16}\text{O}(\text{NO}_2)_2$ , is obtained by adding potassium nitrate to a solution of the ketone dissolved in 10 parts of sulphuric acid; it forms white flakes rather readily soluble in ether, acetone, and benzene, &c., and could not be crystallised.

When the ketone is heated with nitric acid (sp. gr. = 1.1) at 250° benzoylterephthalic acid is formed. The *sulphonic acid* of the ketone is obtained by the action of pyrosulphuric acid at 60°; the *barium salt* is a yellow powder.

$\alpha$ -Naphthyl phenyl ketone,  $\text{COPh}\cdot\text{C}_{10}\text{H}_7$  (Kollarits and Merz, *Ber.*, 13, 360), is prepared from naphthalene and benzoic chloride.  $\alpha$ -Naphthylphenyl- $\beta$ -pinacoline,  $\text{C}_{34}\text{H}_{24}\text{O}$ , is a greenish-yellow substance which melts at 130°; it is readily soluble in acetone and ether.

*Di- $\alpha$ -naphthyl phenyl carbinol*,  $\text{CPh}(\text{C}_{10}\text{H}_7)_2\cdot\text{OH}$ , is obtained together with benzaldehyde by boiling the  $\beta$ -pinacoline with alcoholic potash; it is a crystalline substance, readily soluble in ether and acetone, less soluble in alcohol and benzene, and melts at 160° to 170°. When distilled with two or three parts of zinc-dust,  $\alpha$ -naphthylphenylmethane (m. p. 58.5°) and *dinaphthylphenylmethane* are formed. The latter resembles the carbinol in solubility and melts at about 180°. It is best prepared by distilling the  $\beta$ -pinacoline with zinc-dust. *Dinitromonobromo- $\alpha$ -naphthyl phenyl ketone*,  $\text{C}_{17}\text{H}_9\text{OBr}(\text{NO}_2)_2$ , is obtained by dissolving as much of the bromo-ketone as possible in 10 c.c. of nitric acid (sp. gr. 1.48); it crystallises from a mixture of ether and alcohol in small, lustrous, deep-yellow crystals which melt with evolution of gas at 90°.

N. H. M.

**Introduction of Acid Radicles into Ketones.** By C. BEYER and L. CLAISEN (*Ber.*, 20, 2178—2188).—Acetylacetophenone is obtained by adding acetophenone (1 mol.) to a mixture of sodium ethoxide free from alcohol (1 mol.) and ethyl acetate (2 mols.), cooled in ice, and subsequently decomposing the sodium-compound (which separates in slender, bright yellow crystals) with acetic acid; the yield amounts to 80—90 per cent. of the acetophenone employed, and the product is identical with benzoylacetone prepared in like manner from acetone and ethyl benzoate, and with that obtained from ethyl benzoylacetate (Abstract, 1885, 1237). The amido- or imido-derivative,  $\text{C}_{10}\text{H}_{10}\text{O}:\text{NH}$ , forms colourless, glistening rhombic crystals;  $a : b : c = 0.99275 : 1 : 0.88205$ ; and the *copper*-derivative,  $(\text{C}_{10}\text{H}_9\text{O}_2)_2\text{Cu}$ , crystallises from benzene or alcohol in bright green needles. By employing the corresponding homologues of ethyl acetate in the above reaction, the following derivatives have been prepared: *propionylacetophenone*, sp. gr. = 1.081 at 15°, boiling point = 276—277° at the ordinary, and = 170—172° at 30—31 mm. pressure; *butyrylacetophenone*, sp. gr. = 1.061 at 15°, boiling point = 174° at 24 mm. pressure; *isobutyrylacetophenone*, boiling point = 170° at 26 mm. pressure; *valerylacetophenone*, boiling point = 183—184° at 30 mm. pressure.

*Ethyl benzoylpyruvate*,  $\text{CH}_2\text{Bz}\cdot\text{CO}\cdot\text{COOEt}$ , is obtained by dissolving 9.2 grams of sodium in 150 grams of alcohol, adding to the solution cooled in ice 48 grams of acetophenone and 58.4 grams of ethyl oxalate, and decomposing the crystalline sodium salt in aqueous solution by a current of carbonic anhydride; the yield amounts to 78 per cent. of that theoretically possible. It crystallises in long prisms, is readily soluble in the ordinary solvents, and yields a *copper salt*,  $(\text{C}_{12}\text{H}_{11}\text{O}_4)_2\text{Cu}$ , crystallising from benzene or alcohol in long, slender needles. The

ethyl salt, when heated with dilute aqueous soda, yields acetophenone, ethyl alcohol, and sodium oxalate, and on treatment with alcoholic ammonia in the cold is converted into acetophenone, ethyl alcohol, and oxamide. The *acid* is formed, together with a small quantity of a compound (oxalyldiacetophenone?) crystallising in yellow, benzil-like needles melting at  $179^{\circ}$ , when 2 mol. props. of acetophenone are employed in the foregoing reaction. It crystallises in yellowish-white prisms, melts at  $155\text{--}156^{\circ}$ , is soluble in alkalis, and alkaline carbonates and acetates, and evolves carbonic anhydride when heated above its melting point.

*Ethyl diphenylpyrazolecarboxylate*,  $C_3NHPh(NPh)\cdot COOEt$ , is formed when 10 grams of phenylhydrazine are added to 20 grams of ethyl benzoylpyruvate dissolved in 100 grams of acetic acid and the mixture boiled for two hours in a reflux apparatus. It crystallises in compact prisms, melts at  $90^{\circ}$ , is readily soluble in methyl and ethyl alcohol, ether, and chloroform, and distils at about  $400^{\circ}$  with partial decomposition. On saponification with concentrated aqueous soda and treatment in the cold with hydrochloric acid, *diphenylpyrazolecarboxylic acid* is obtained; this crystallises from alcohol in glistening forms of the composition  $C_{16}H_{12}N_2O_2 + EtOH$ , melts at  $185^{\circ}$ , and is readily soluble in acetone, chloroform, and acetic acid, soluble in methyl alcohol and benzene, very sparingly soluble in water. When heated to  $250^{\circ}$ , the acid evolves carbonic anhydride and is converted into *diphenylpyrazole*; this is a thick pale-yellow oil which boils at  $335\text{--}336^{\circ}$ , and on the addition of a particle of its crystalline hydrochloride solidifies to a silky, brittle mass melting at  $56^{\circ}$ .

The introduction of the acid radicle of an ethereal salt into a second ethereal salt or into a ketone by the action of sodium ethoxide, is regarded as due not to the direct withdrawal of the elements of ethyl alcohol by the ethoxide, but to the formation of an unstable double compound of the ethereal salt and sodium ethoxide,  $R\cdot C(ONa)(OEt)_2$ , which on the addition of the second ethereal salt or ketone undergoes decomposition as expressed by the equation  $R\cdot C(ONa)(OEt)_2 + CH_3\cdot COOEt = R\cdot C(ONa) : CH\cdot COOEt + 2EtOH$ . The fact that dilute alcoholic solutions of sodium ethoxide can be employed in these synthetical reactions in place of the pure compound affords evidence in favour of this view.

W. P. W.

**Nitrosoketones.** By L. CLAISEN and O. MANASSE (*Ber.*, 20, 2194—2198).—Nitrosoacetophenone (this vol., p. 575) crystallises from a chloroform solution, by slow evaporation, in colourless or pale-yellow, glistening, monoclinic prisms,  $a : b : c = 2.762 : 1 : 2.146$ ;  $\beta = 66^{\circ} 54'$ ; observed faces,  $0P$ ,  $\infty P\infty$ ,  $\infty P$ ,  $+P\infty$ ,  $+2P\infty$ , and a hemipyramid probably  $-P$ . The dry sodium salt decomposes very readily and explodes in a warm place or on contact with a trace of sulphuric acid, nitric acid, bromine, &c., with the formation of hydrogen cyanide and sodium benzoate; a similar decomposition is also effected by boiling the salt with dilute aqueous soda. When distilled, the ketone yields a mixture of hydrocyanic acid, benzoic acid, and benzoyl cyanide, and inasmuch as the compounds formed when it is treated with acetic anhydride and acetyl chloride give benzoyl

cyanide on distillation, it is probable that this is the first product of the change, and that it subsequently undergoes decomposition into hydrogen cyanide and benzoic acid. Nitrosoacetone when similarly treated also gives a good yield of acetyl cyanide. The readiness with which the nitroso-ketones undergo conversion into acid cyanides renders it evident that the colour reactions they give with sulphuric acid and benzene containing thiophen (Abstr., 1880, 67) and with sulphuric acid and phenol (Abstr., 1878, 659; this vol., p. 575) are due not to the ketones but to the cyanides formed by their decomposition, and this view is confirmed by the fact that benzoyl cyanide and acetyl cyanide yield with sulphuric acid and phenol colours identical in shade and intensity with those given by the corresponding nitroso-ketones. When an aqueous solution of the sodium salt of nitrosoacetophenone is treated with sulphurous anhydride, a compound,  $C_8H_{11}O_5NS$ , is obtained, which crystallises in white prisms or small needles, is sparingly soluble in water, and shows all the properties of a strong acid.

Benzoyl cyanide can readily be prepared, without the previous separation of nitrosoacetophenone, by gradually adding amyl nitrite (1 mol.) to a mixture of acetophenone (1 mol.) and acetyl chloride (3 mols.) heated at  $100^\circ$ , and distilling the product; the yield amounts to 65–70% per cent. of that theoretically possible. W. P. W.

**Derivatives of Orthotoluic Acid.** By S. RACINE (*Annalen*, 239, 71–78).—Orthotoluic acid is conveniently prepared by heating in a flask provided with a reflux condenser a mixture of phthalide, hydriodic acid (b. p.  $127^\circ$ ), and phosphorus. The crude acid is dissolved in sodium carbonate. The sodium salt,  $C_7H_7COONa + 2H_2O$ , forms glistening plates which effloresce and become anhydrous. The anhydride,  $(C_6H_4MeCO)_2O$ , is formed by the action of phosphorus oxychloride on the anhydrous sodium salt. It melts at  $36\text{--}38^\circ$  and boils at  $325^\circ$ . It is soluble in ether and benzene, and is slowly attacked by hot water.

Bromorthotoluic acid (m. p.  $167^\circ$ ) yields on oxidation with dilute nitric acid bromophthalic acid (m. p.  $156\text{--}158^\circ$ ). The anhydride of this bromophthalic acid melts at  $95^\circ$ .

A small quantity of bromophthalide is formed by the action of bromine on orthotoluic acid at  $130^\circ$ . It is soluble in alcohol and ether and melts at  $98\text{--}100^\circ$ . When oxidised, it yields  $\alpha$ -bromophthalic acid.

*Methyldinitrorthotoluate* is deposited from alcohol in colourless needles and melts at  $73\text{--}74^\circ$ . Dinitro-orthotoluic acid is converted by oxidation with dilute nitric acid into the dinitrophthalic acid melting at  $226^\circ$ , which Beilstein and Kurbatoff obtained from  $\beta$ -dinitronaphthalene. W. C. W.

**Chlorosalicylic Acids.** By L. VARNHOLT (*J. pr. Chem.* [2], 36, 16–31).—Chlorosalicylic acid [ $COOH : OH : Cl = 1 : 2 : 5$ ] is obtained by filling an autoclave with pure, dry sodium parachlorophenoxide and connecting it with a vessel containing liquid carbonic anhydride. The absorption of carbonic anhydride takes place with

considerable rise of temperature; after half an hour, the autoclave is heated for three to four hours at 140—150°. The product is an almost white powder.

An *isomeride* of the above acid having the constitution

is prepared from sodium orthochlorophenol. It crystallises in long needles melting at 178°, distils with steam, and sublimes with slight decomposition; it dissolves sparingly in water, readily in alcohol, chloroform, and glacial acetic acid, and gives an intense violet colour with ferric chloride. The *sodium salt* crystallises in plates, very readily soluble; the *barium salt* (with 3 mols.  $\text{H}_2\text{O}$ ) forms white needles readily soluble in alcohol, less soluble in water. The *silver* and *lead salts* are white, insoluble substances. The *methyl salt* crystallises from alcohol in needles melting at 83°; it boils at 259—260° with partial decomposition.

*Chlorosalicylic acid*  $[\text{COOH} : \text{OH} : \text{Cl} = 1 : 2 : 4]$ , prepared from sodium metachlorophenoxide, crystallises from water in small needles melting at 207°; it dissolves very readily in alcohol, benzene, chloroform, and glacial acetic acid, sparingly in water; it distils with steam, sublimes with slight decomposition, and gives an intense violet colour with ferric chloride. The acid was also prepared from nitrochlorotoluene  $[\text{Me} : \text{NO}_2 : \text{Cl} = 1 : 2 : 4]$  by oxidising it with nitric acid (sp. gr. 1.1) at 185° to nitrochlorobenzoic acid; this is then reduced, and the amido-acid diazotised. The *nitrochlorobenzoic acid*  $[\text{COOH} : \text{NO}_2 : \text{Cl} = 1 : 2 : 4]$ , obtained as intermediate product, crystallises in long needles melting at 138—139°.

Metachlorophenol is prepared as follows:—Chlorine is passed into 500 grams of nitrobenzene containing 10 grams of ferric chloride until the whole weighs 650 grams. It is purified by distillation, and reduced with tin and hydrochloric acid to metachloraniline; 10 grams of the latter is dissolved in 2 litres of water, treated with the calculated amount of sulphuric acid, cooled, and sodium nitrite added. After some time, it is heated on a water-bath; it is then extracted with ether and the metachlorophenol purified by distillation.

N. H. M.

**Action of Phosphorous Chloride on Salicylic Acid and Phenol.** By R. ANSCHÜTZ and W. EMERY (*Annalen*, 239, 301—313).—Phosphorus trichloride acts on salicylic acid at 70°, forming the compound  $\text{C}_7\text{H}_4\text{O}_3\text{PCl}$ , according to the equation  $\text{OH} \cdot \text{C}_6\text{H}_4 \cdot \text{COOH} + \text{PCl}_3 = \text{C}_7\text{H}_4\text{O}_3\text{PCl} + 2\text{HCl}$ . The authors regard the new substance as the monochloride of salicylphosphorous acid,  $\text{C}_6\text{H}_4 \langle \begin{smallmatrix} \text{CO} \cdot \text{O} \\ \text{O} \end{smallmatrix} \rangle \text{PCl}$ .

The chloride melts at 36—37°, and boils at 127° under 11 mm. pressure. It is soluble in alcohol, ether, and chloroform, and is decomposed by water into salicylic and phosphorous acids. Phosphoric chloride converts this substance into the compound  $\text{C}_7\text{H}_4\text{O}_3\text{PCl}_3$ . The new chloride is either identical with or closely resembles the product of the action of phosphoric chloride on salicylic acid.

The former boils at 167° under 11 mm. pressure, the latter at 168°. The sp. gr. of the substances are 1.55702 and 1.56207 respectively.

The chloride of salicylphosphorous acid unites directly with 2 atoms of bromine, forming a strongly refractive liquid,  $C_7H_4ClBr_2PO_3$ , which boils at  $185-138^\circ$  under 12 mm. pressure.

Noack (Abstr., 1883, 737) has shown that phenyl phosphoryldichloride,  $PhOPCl_2$ , diphenyl phosphoryldichloride,  $Ph_2O_2PCl$ , and triphenyl phosphite,  $Ph_3PO_3$ , are formed by the action of phosphorous chloride on phenol. They may be separated by distillation under reduced pressure, as they boil at  $90^\circ$ ,  $172^\circ$ , and  $220^\circ$  respectively under 11 mm. pressure.

Phenyl phosphoryldichloride is converted into the compound  $PhOPCl_4$ , by the action of phosphorus pentachloride. W. C. W.

**Action of Phosphoric Chloride on Salicylic Acid.** By R. ANSCHÜTZ and G. D. MOORE (*Annalen*, **239**, 314—333).—The compound  $C_7H_4Cl_3PO_3$ , which is formed by the action of phosphorus pentachloride ( $1\frac{1}{3}$  mols.) on dry salicylic acid (1 mol.) (Abstr., 1885, 1061), is converted into the chloride  $C_7H_4Cl_5PO_3$ , by the action of a second molecule of phosphoric chloride at  $170^\circ$ . On distillation under 11 mm. pressure, the new compound is obtained as a colourless liquid boiling at  $178-179^\circ$ ; sp. gr. = 1.62019 at  $20^\circ$  compared with water at  $4^\circ$ . It is decomposed by water, yielding phosphoric and salicylic acids, and is converted into orthobenzoyl trichloride by the action of a third molecule of phosphoric chloride at  $180^\circ$ .

The chloride,  $C_7H_4Cl_3PO_3$ , is decomposed by slow distillation under the ordinary atmospheric pressure, yielding phosphorus oxychloride, orthochlorobenzoylchloride, orthochlorobenzotrichloride, and the compound  $C_7H_4ClPO_4$ . W. C. W.

**Action of Phosphoric Chloride on Meta- and Para-hydroxybenzoic Acids.** By R. ANSCHÜTZ and G. D. MOORE (*Annalen*, **239**, 333—349).—*Metachlorocarbonylphenylphosphoric dichloride*,  $COCl \cdot C_6H_4 \cdot O \cdot POCl_2$  [ $1 : 3$ ], is formed by the action of phosphoric chloride ( $1\frac{1}{3}$  mols.) on metahydroxybenzoic acid (1 mol.). It boils at  $168-170^\circ$  under 11 mm. pressure, and is partially decomposed by distillation under atmospheric pressure. Its sp. gr. at  $20^\circ$  is 1.54844. It dissolves slowly in water, and the concentrated solution deposits crystals of *metacarboxylphenylorthophosphoric acid*,

The acid melts at  $200-201^\circ$ , and dissolves in water, alcohol, and ether. The aqueous solution is decomposed at  $150^\circ$ .

By the action of phosphoric chloride at  $150^\circ$ , the compound  $C_7H_4Cl_3PO_3$  is converted into  $C_7H_4Cl_5PO_3$ , probably  $COCl \cdot C_6H_4 \cdot O \cdot PCl_4$ . This substance boils at  $176-179^\circ$  under 11 mm. pressure. It is decomposed by water, yielding metacarboxylphenylphosphoric acid, and is converted into metachlorobenzotrichloride by the action of phosphoric chloride at  $180^\circ$ .

The following are the products of the action of 1 and 2 mols. of phosphoric chloride on anhydrous parahydroxybenzoic acid:—1. *Parachlorocarbonylphenylorthophosphoric dichloride*, and 2, *parachlorobenzoyl chloride*. The chloride,  $C_7H_4Cl_3PO_3$ , is a refractive liquid boiling at

176° under 13 mm. pressure, and partly decomposed by distillation under the ordinary pressure. It is converted into paracarboxylphenyl-phosphoric acid by the action of water.

W. C. W.

**Preparation of Mandelic Acid by its Derivatives.** By C. ENGLER and E. WÖHRLE (*Ber.*, 20, 2201—2204).—When dibromacetophenone is treated with dilute aqueous potash, it is converted into mandelic acid according to the equation  $\text{COPh}\cdot\text{CHBr}_2 + 2\text{KOH} = \text{OH}\cdot\text{CHPh}\cdot\text{COOH} + 2\text{KBr}$ , the dihydroxyacetophenone,

whose formation might be first expected, evidently being too unstable to exist, and so suffers change into the isomeric mandelic acid. Metanitromandelic acid was prepared in like manner from metanitracetophenone dibromide.

*Orthonitromandelic acid*,  $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CH}(\text{OH})\cdot\text{COOH}$ , prepared from orthonitracetophenone dibromide, forms small crystals, melts at 140°, but decomposes at a little above 100° when slowly heated. It dissolves readily in water, alcohol, ether, and chloroform. When reduced with tin and hydrochloric acid, it is converted into the hydrochloride of the corresponding amido-acid; this forms a crystalline mass, but owing to its instability could not be obtained in a pure state. There is little doubt that the product of its decomposition is dioxindole,  $\text{C}_6\text{H}_4\langle\begin{smallmatrix} \text{CH}(\text{OH}) \\ -\text{NH}- \end{smallmatrix}\rangle\text{CO}$ .

A. J. G.

**Reduction of Orthonitrophenylglycollic Acid.** By L. DUPARC (*Ber.*, 20, 1942—1945).—The author has examined the compound  $\text{C}_6\text{H}_7\text{NO}_2$ , which Fritsche obtained by the reduction of the above acid (*Abstr.*, 1880, 320) in order to determine whether its constitution is  $\text{C}_6\text{H}_4\langle\begin{smallmatrix} \text{O}\cdot\text{CH}_2 \\ \text{NH}\cdot\text{CO} \end{smallmatrix}\rangle$  or  $\text{C}_6\text{H}_4\langle\begin{smallmatrix} \text{O}\cdot\text{CH}_2 \\ \text{N}:\text{C}(\text{OH}) \end{smallmatrix}\rangle$ . This substance appears to be isomeric with that lately obtained by Aschan (this vol., p. 814) by the action of potash on chloracetoamidophenol, and to which that investigator has ascribed the first of the above formulæ.

Acetic anhydride had no action on the compound even at 180°. Attempts to replace one of the oxygen-atoms by the imide group proved unsuccessful. When heated with zinc-dust, a very small quantity of a base,  $\text{C}_6\text{H}_9\text{NO}$ , boiling at about 200°, was obtained. *Ethyl orthonitrophenylglycollate*,  $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{O}\cdot\text{CH}_2\cdot\text{COOEt}$ , forms colourless needles melting at 49°, and soluble in alcohol, ether, and benzene, insoluble in water. When reduced with tin and hydrochloric acid, the ethyl group is eliminated, and a base,  $\text{C}_6\text{H}_8\text{ClNO}_2$ , formed which appears to be a substitution derivative of Fritsche's compound. It crystallises in long needles, is soluble in alcohol, insoluble in water, and melts at 195°. It dissolves in alkalis and acids, but without forming salts. The investigation is being continued.

L. T. T.

**Paratolylglyoxylic, Paratolylhydroxyacetic, and Paratolylacetic Acids.** By A. CLAUS and K. KROSEBERG (*Ber.*, 20, 2048—2052).—Contrary to the statement made by Anschütz and Schönfeld (*Abstr.*, 1886, 786), the authors find that amyl chloroxalate is formed

when amyl oxalate is heated with phosphorus pentachloride, and have in consequence been able to compare Roser's paratolylcarboxylic acid (Abstr., 1883, 194) with the product obtained by them by the action of aluminium chloride on a mixture of toluene and ethyl chlor-oxalate. Paratolylglyoxylic acid seems to have no sharp melting point, inasmuch as it begins to soften at  $80^{\circ}$ , is partially fused at  $95^{\circ}$ , and is completely melted at  $100^{\circ}$ . It is not volatile with steam at ordinary pressure, but is completely decomposed by superheated steam. The *potassium*, *sodium* (with  $\frac{1}{2}$  mol. of  $\text{H}_2\text{O}$ ), *barium*, *calcium* (with 1 mol. of  $\text{H}_2\text{O}$ ), *copper*, *lead*, and *silver* salts are described. The *chloride* could not be isolated in the pure state, but the *amide*,  $\text{C}_6\text{H}_4\text{O}_2\cdot\text{NH}_2$ , obtained by saturating the benzene solution of the impure chloride with dry ammonia, crystallises in transparent, yellow, prismatic forms, melts at  $160^{\circ}$ , and is soluble in alcohol. The *ethyl* salt is a yellow oil, boils at  $260$ — $270^{\circ}$ , and has a fruity odour.

*Paratolylhydroxyacetic acid*,  $\text{C}_6\text{H}_4\text{Me}\cdot\text{CH}(\text{OH})\cdot\text{COOH}$ , is readily obtained by the reduction of paratolylglyoxylic acid with sodium amalgam or zinc-dust. It crystallises in large tables, melts at  $145$ — $146^{\circ}$ , and is soluble in alcohol, ether, chloroform, and benzene, sparingly soluble in cold water and insoluble in light petroleum. Its salts are not well characterised; the *ethyl* salt crystallises in colourless tufts of needles, melts at  $77^{\circ}$ , and is soluble in ether.

*Paratolylacetic acid*,  $\text{C}_6\text{H}_4\text{Me}\cdot\text{CH}_2\cdot\text{COOH}$ , is formed when paratolylglyoxylic acid is treated with warm water, red phosphorus, and iodine. It forms colourless crystals, melts at  $74^{\circ}$ , and is readily soluble in ordinary organic solvents and in hot water. The *sodium* (with 1 mol. of  $\text{H}_2\text{O}$ ), *barium* (with 2 mols. of  $\text{H}_2\text{O}$ ), and *calcium* (with 2 mols. of  $\text{H}_2\text{O}$ ) salts are readily soluble in water; the *ethyl* salt boils at  $240^{\circ}$ .

Steinicke, at the suggestion of Claus, has repeated the experiments of Buchka and Irish on the oxidation of paratolyl methyl ketone with potassium ferricyanide (this vol., p. 825), and also finds that an acid not volatile with steam is one of the products, but the yield is small and the acid has not been obtained free from nitrogen, whilst in addition its barium salt differs from that of paratolylglyoxylic acid. Inasmuch as paratolyl methyl ketone, when oxidised with potassium permanganate, does not yield paratolylglyoxylic acid, the law that aromatic ketones containing a side-chain in the ortho-position to the ketonic group are alone oxidised by potassium permanganate to  $\alpha$ -ketonecarboxylic acids (*Ber.*, 19, 234) still holds good.

W. P. W.

**Paratolylglyoxylic Acid.** By K. BUCHKA (*Ber.*, 20, 2213—2214).—A reply to Claus (preceding Abstract) in which the author asserts the accuracy of his results (this vol., p. 825) and the inaccuracy of the work brought forward in opposition.

**Behaviour of Ethyl Oxalate towards Resorcinol.** By A. MICHAEL (*J. pr. Chem.* [2], 35, 510—512).—Ethyl oxalate (1 mol.) is added to a solution of resorcinol (1 mol.) and sodium ethoxide (2 mols.) in absolute alcohol; after 4 or 5 days, water is added, and the yellow, crystalline precipitate so formed crystallised from alcohol.

It forms pale-yellow prisms melting at 253—256° with decomposition, insoluble in water, readily soluble in hot alcohol; it is also soluble in alkali. Analyses point to the formula  $C_{14}H_{10}O_6$ . The *acetyl-derivative*,  $C_{14}H_7Ac_3O_6$ , crystallises in white prisms melting at 125—127°; it is readily soluble in hot alcohol. The compound has probably the constitution

**Tannic Acid in Mountain Ash Berries.** By C. VINCENT and DELACHANAL (*Bull. Soc. Chim.*, **47**, 492—493). The juice of the ripe berries of *Sorbus aucuparia* contains a new tannin, *sorbitannic acid*, closely allied in its reactions to morintannic and caffetannic acids. To separate it, the juice is fermented to remove glucose, a small amount of lead acetate is added, the precipitate filtered off and excess of basic lead acetate added, the voluminous yellow precipitate formed is collected, well washed, and decomposed with hydrogen sulphide, and the clear solution evaporated to dryness in a vacuum. The residue is then extracted with absolute alcohol, and the alcoholic extract evaporated, when the tannic acid is obtained as a very thick, syrupy mass. It gives an intense yellow coloration with alkalis, which, however, disappears on the addition of an acid. No precipitate is formed with alum. It reduces silver salts and yields an olive-green precipitate with cupric acetate; with iron salts, it gives a very intense dark-green coloration which on the addition of alkalis turns to a reddish-brown; neutral lead acetate forms a yellow precipitate, and the basic acetate yields a citron-yellow precipitate; neither gelatin nor salts of quinine give any precipitate. When heated with dilute sulphuric acid, a reddish-yellow coloration appears, but no precipitate is formed; nitric acid gives rise to a deep yellow coloration. On distillation, a thick brown distillate is obtained containing much pyrocatechol, a voluminous coke being left; fused with potash, pyrocatechuic acid and phloroglucol are formed. A. P.

**Action of Arsenious Sulphide on the Acid Chlorides.** By B. RAYMAN (*Bull. Soc. Chim.*, **47**, 896—898).—*Benzoyl thioarsenite*,  $As(S \cdot COPh)_3$ , is obtained by gently heating benzoic chloride with arsenious sulphide, and extracting the result with alcohol, ether, or carbon bisulphide. It crystallises in large, rose-coloured needles, melts at 178—179°, dissolves in warm ammonia, and is precipitated unaltered on the addition of hydrochloric acid; if, however, the solution is left for some time, it is decomposed, arsenious sulphide being precipitated, and hydrogen sulphide being given off. On heating benzoyl thioarsenite with aniline, a similar reaction takes place, benzanilide being formed. A cold solution of benzoyl thioarsenite in ammonia is precipitated on the addition of solutions of the salts of the heavy metals; mercuric chloride yields a white precipitate of *mercury  $\alpha$ -thiobenzoate*,  $(PhCO \cdot S)_2Hg$ : this crystallises from boiling alcohol in slender colourless needles. Under similar circumstances salts of bismuth yield a white precipitate which becomes brown after

a white; salts of cadmium also yield a white precipitate, which when recrystallised from boiling alcohol is obtained as a yellow compound, containing cadmium, sulphur, and arsenic: the precipitate formed by salts of nickel is brick-red; the silver compound decomposes violently.

Phthalyl chloride acts on arsenious sulphide at elevated temperatures, arsenious chloride being formed and *thiophthalic anhydride*,  $C_6H_4<\overset{CS}{CO}>O$ ; the latter is a yellow substance, which melts at  $114^\circ$ , distils at  $278^\circ$ , and volatilises with aqueous vapour. When heated with resorcinol, it gives a fluorescent substance, whilst with aniline and toluidine, hydrogen sulphide is evolved, and the compound  $C_6H_4<\overset{(NPh)}{CO}>O$  is formed. A. P.

**Phthalaldehydic Acid.** By S. RACINE (*Annalen*, 239, 78—91).—The preparation and properties of  $\alpha$ -bromophthalide and of phthalaldehydic acid have been previously described by the author (Abstr., 1886, 549). The acid crystallises in monoclinic plates and melts at  $97^\circ$ . The *calcium* salt,  $Ca(C_8H_5O_3)_2 + 2H_2O$ , forms monoclinic prisms, sparingly soluble in cold water. The *silver* salt,  $AgC_8H_5O_3$ , is deposited from a hot aqueous solution in slender needles. The *ethyl* salt,  $EtC_8H_5O_3$ , crystallises in needles. It melts at  $66^\circ$  and, like the free acid, reduces ammoniacal silver solutions, and combines with hydroxylamine. The *methyl* salt,  $MeC_8H_5O_3$ , melts at  $44^\circ$ . The *acetyl* derivative melts at  $60$ — $63^\circ$ , and is soluble in alcohol, ether, and chloroform.

Phthalaldehydic acid unites with hydroxylamine, forming *benzaloximorthocarboxylic* acid, and with phenylhydrazine, forming a colourless crystalline compound,  $C_{14}H_{10}N_2O$ , melting at  $105^\circ$ . On reduction with tin and hydrochloric acid, phenylphthalimidine,  $C_{14}H_{11}NO$ , is obtained.

*Hydrobenzamidtricarboxylic acid*,  $N_2(CH \cdot C_6H_4 \cdot COOH)_3$ , precipitated when gaseous ammonia is passed into an alcoholic solution of phthalaldehydic acid. It melts at  $187^\circ$ . A condensation product, *orthobenzylidenecarboxylic acid*, is formed on mixing alcoholic solutions of aniline and phthalaldehydic acid. The acid is insoluble in water but sparingly soluble in alcohol. It melts at  $174^\circ$ , and unites directly with two atoms of bromine, forming a crystalline compound.

*Diphthalide ether*,  $<\overset{C_6H_4}{CO \cdot O}>CH \cdot O \cdot CH<\overset{C_6H_4}{O \cdot CO}>$ , formed as a by-product in the preparation of phthalaldehydic acid, is a colourless crystalline compound melting at  $221^\circ$ . It does not exhibit aldehydic reactions. *Amidophthalide*,  $C_6H_4<\overset{CH(NH_2)}{CO \cdot O}>$ , is precipitated when gaseous ammonia is passed into a solution of bromophthalide in benzene or ether. Amidophthalide melts at  $167^\circ$  and dissolves in alcohol, ether, benzene, chloroform, and in hot water and alkalis. It is reprecipitated from the alkaline solutions by acids. W. C. W.

**Benzyl and Benzoyl Compounds.** By C. A. BISCHOFF and H. SIEBERT (*Annalen*, 239, 92—110).—Conrad (Abstr., 1879, 707)

prepared ethyl benzylmalonate by the action of benzyl chloride on ethyl sodiomalonate, but he overlooked the formation of small quantities of ethyl dibenzylmalonate. *Benzylmalondiamide*,

is obtained by heating alcoholic ammonia and ethyl benzylmalonate at  $160^\circ$ . The mother-liquor contains the monamide of ethyl benzylmalonate,  $\text{NH}_2\cdot\text{CO}\cdot\text{CH}(\text{C}_7\text{H}_7)\cdot\text{COOEt}$ . The former compound melts at  $225^\circ$ , and the latter at  $98^\circ$ .

*Ethyl dibenzylmalonate*,  $\text{C}(\text{C}_7\text{H}_7)_2(\text{COOEt})_2$ , is a thick oil. On treatment with alcoholic ammonia, it yields a mixture of benzylmalondiamide and the monamide of ethyl benzylmalonate and other products. On hydrolysis with alcoholic potash, 40 grams of ethyl dibenzylmalonate yielded 20.5 grams of dibenzylmalonic acid and 5 grams of dibenzylacetic acid. *Dibenzylmalonic acid* melts at  $162^\circ$ , with evolution of carbonic anhydride. It is soluble in ether, alcohol, acetone, benzene, and is sparingly soluble in cold water and hot light petroleum. The acid crystallises from alcohol in thick prisms, from ether in plates, and from hot water in slender needles. The ammonium salt produces crystalline precipitates in solutions of lead acetate, calcium chloride, and barium chloride, and amorphous precipitates with mercuric chloride, zinc sulphate, and silver nitrate. Dibenzylacetic acid has been already described by Ehrlich (*Ber.*, 6, 1085; *Annalen*, 187, 21).

The chief product of the action of orthonitrobenzoic chloride on ethyl sodium benzylmalonate is ethyl orthonitrobenzoylbenzylmalonate, ethyl dibenzylmalonate, and ethyl benzylacetate. Ethylic orthonitrobenzoylbenzylmalonate,  $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CO}\cdot\text{C}(\text{C}_7\text{H}_7)(\text{COOEt})_2$ , is also formed by the action of benzyl chloride on the yellow sodium compound of ethyl mononitrobenzoylmalonate. It melts at  $94^\circ$ , and decomposes at a higher temperature with evolution of carbonic anhydride. It is freely soluble in ether, benzene, acetone, glacial acetic acid, and in hot alcohol. The production of this compound by these two reactions shows that in the yellow sodium compound of ethyl mononitrobenzoylmalonate described by Bischoff and Rach (*Abstr.*, 1885, 264) the sodium is directly attached to a carbon-atom, thus:  $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CO}\cdot\text{CNa}(\text{COOEt})_2$ .

Ethyl orthonitrobenzoylbenzylmalonate yields on saponification with potassium hydroxide, benzylmalonic and orthonitrobenzoic acids, and on treatment with alcoholic ammonia it is converted into orthonitrobenzamide.

W. C. W.

**Combination of Lactones with Ethereal Salts.** By W. WISLICENUS (*Ber.*, 20, 2061—2062).—Sodium is without action on a mixture of equimolecular proportions of phthalide and ethyl oxalate in ethereal solution, if these compounds are free from alcohol, but yields an intensely yellow-coloured precipitate when alcohol is present. This compound is best obtained by adding an ethereal solution of phthalide (1 mol.) to an ethereal solution of sodium ethoxide free from alcohol (1 mol.) and ethyl oxalate (1 mol.). The mixture is then allowed to remain for some hours. The yellow product is a sodium

compound, and on treatment with an acid yields a compound of the formula  $C_{12}H_{10}O_5$ . This crystallises from ether in small, slender needles and from alcohol in glistening scales, melts at  $121-122^\circ$ , and is insoluble in water. Its solution in alkalis very readily reduces Fehling's solution at the ordinary temperature, whilst the alcoholic solution is coloured a dark violet-red by ferric chloride.

The foregoing reaction is probably of general application, inasmuch as phthalide and ethyl benzoate yield a yellow compound which reduces Fehling's solution, and valerolactone and ethyl oxalate form a colourless sodium compound under similar conditions. W. P. W.

**Nitro- $\psi$ -cumidinesulphonic Acid.** By F. MAYER (*Ber.*, 20, 2066—2068).—Further investigation has shown that the acid obtained when trinitro- $\psi$ -cumene is reduced with hydrogen sulphide can be diazotised without displacement of the sulphonic group; the author, therefore, considers it to be a nitro- $\psi$ -cumidinesulphonic acid (compare this vol., p. 659).

*Diazonitro- $\psi$ -cumenesulphonic acid*,  $NO_2 \cdot C_6Me_3 < \begin{smallmatrix} N:N \\ -SO_3 \end{smallmatrix} >$ , obtained as a colourless precipitate on diazotising sodium nitro- $\psi$ -cumidine-sulphonate, is a comparatively stable compound which does not evolve nitrogen when boiled with alcohol under 250 mm. pressure, and decomposes extremely slowly when boiled with water. On treatment with  $\beta$ -naphthol dissolved in dilute aqueous potash, it yields  $\beta$ -naphtholazonitro- $\psi$ -cumenesulphonic acid,  $C_{19}H_{17}N_3SO_6 + 2H_2O$ , which crystallises in orange scales showing a metallic lustre, and sparingly soluble in water. The alkaline salts are dark-red in colour, and moderately soluble. The calcium salt crystallises in red scales showing a metallic lustre. W. P. W.

**Aromatic Thiosulphonates containing Bivalent Alkylradicles.** By R. OTTO and A. RÖSSING (*Ber.*, 20, 2079—2088).—*Ethylene thiobenzenesulphonate*,  $C_2H_4 : S_2(SO_2Ph)_2$ , is obtained when an alcoholic solution of potassium thiobenzenesulphonate (2 mols.) is heated with ethylene dibromide (1 mol.) at  $100^\circ$  for some hours in a reflux apparatus, until all odour of the dibromide has disappeared. It crystallises in small, slender, transparent, silky needles, is destitute of odour and taste, melts at  $84-85^\circ$ , and is readily soluble in benzene and hot alcohol, insoluble in water. On treatment in alcoholic solution with potassium hydroxide at  $100^\circ$ , until permanent alkalinity is produced, ethylene thiobenzenesulphonate yields a mixture of potassium benzenesulphinat, potassium ethylenedisulphinat, and diethylene tetrasulphide; and inasmuch as the addition of ethylene mercaptan to a warm alcoholic solution of ethylene thiobenzenesulphonate brings about the production of benzenesulphinic acid and diethylene tetrasulphide, the authors regard this reaction as taking place in two stages:—I.  $C_2H_4 : S_2(SO_2Ph)_2 + 4H_2O = 4PhSO_2H + C_2H_4(SO_2H)_2 + C_2H_4(SH)_2$ ; II.  $C_2H_4 : S_2(SO_2Ph)_2 + C_2H_4(SH)_2 = 2Ph \cdot SO_2H + (C_2H_4S_2)_2$ . The salt is also readily saponified by barium hydroxide, or when heated with aqueous ammonia at  $110^\circ$  in sealed tubes. If the hydrolysis is effected by means of potas-

sium sulphide, potassium thiobenzenesulphonate and potassium mercaptide are obtained, and the reaction corresponds with that occurring when monovalent alkyl salts are similarly treated (this vol., p. 226). When reduced with zinc and hydrochloric acid, ethylene thiobenzenesulphonate yields diethylene tetrasulphide and thiophenol, the latter doubtless resulting from the reduction of benzenesulphinic acid; if it is heated in alcoholic solution with zinc-dust at  $110^{\circ}$  for two hours, it is converted into zinc benzenesulphinate and zinc mercaptide.

*Ethylene thioparatoluenesulphonate* is obtained in like manner by heating equivalent quantities of ethylene bromide and potassium thioparatoluenesulphonate in alcoholic solution. It crystallises in colourless, transparent needles having pyramidal terminations, and showing a vitreous lustre, melts at  $76-77^{\circ}$ , has neither odour nor taste, and is readily soluble in benzene and hot alcohol, soluble in ether, insoluble in water. When saponified with potassium hydroxide, it yields diethylene tetrasulphide and potassium paratoluenesulphinate.

The following details are given in various footnotes:—Potassium thiobenzenesulphonate, with 2 mols.  $\text{H}_2\text{O}$ ; the sodium salt, with  $1\frac{1}{2}$  mols.  $\text{H}_2\text{O}$ ; potassium benzenesulphinate, with 2 mols.  $\text{H}_2\text{O}$ ; and the sodium salt, with 2 mols.  $\text{H}_2\text{O}$ , are described; and the optical properties of the crystals of the first and last salts are given. Ethylene mercaptan, when treated with ammonia and exposed to the air for some time, is converted into a compound melting between  $86^{\circ}$  and  $90^{\circ}$ .

Mixed alkyl tetrasulphides can be obtained from sulphinic acids and mercaptans containing bivalent radicles: thus, to judge from its decomposition products, ethylene diphenyltetrasulphide,

appears to be formed by the action of ethylene mercaptan (1 mol.) on benzenesulphinic acid (2 mols.) in alcoholic solution (compare this vol., p. 242).

Pure diethylene tetrasulphide melts at  $148-151^{\circ}$  without carbonisation (compare this vol., p. 463). W. P. W.

**Reduction of Aromatic Thiosulphonates containing Univalent and Bivalent Alkyl-radicles with Hydrogen Sulphide.** By R. OTTO and A. RÜSSING (*Ber.*, **20**, 2090—2092).—When phenyl thiobenzenesulphonate in dilute alcoholic solution is reduced with hydrogen sulphide, thiophenol and sodium benzenesulphonate are obtained, together with a viscous oil of unpleasant odour; this is a phenyl polysulphide, probably the tetrasulphide (compare preceding Abstract), inasmuch as it is reduced to phenyl bisulphide on treatment with colourless ammonium sulphide. Toly parathiotoluenesulphonate when similarly treated yields paratolyl bisulphide, tolyl tetrasulphide, and paratoluenesulphinic acid; thiocresol is probably formed in the reaction, but is not found among the products, owing to the readiness with which it reacts with toluenesulphinic acid to form tolyl bisulphide. Ethyl thiobenzenesulphonate under these conditions is converted into ethyl mercaptan, benzenesulphinic acid, and a phenyl polysulphide, which is reduced to phenyl bisulphide on

treatment with colourless ammonium sulphide. Ethylene thiobenzenesulphonate when suddenly reduced yields ethylene mercaptan, phenyl tetrasulphide, and a substance insoluble in hot alcohol, which most probably consists of the products obtained by the action of ethylene mercaptan on benzenesulphinic acid (see p. 954).

W. P. W.

**Halogen-derivatives of Phenylene Dichloracetylene Ketone.**  
By T. ZINCKE and C. FRÖLICH (*Ber.*, **20**, 2053—2057).—*Phenylene tetrachlorethylene ketone* (tetrachlorhydrindonaphthene ketone),

is formed when an acetic acid solution of phenylene dichloracetylene ketone is treated with chlorine until the yellow colour is no longer visible; the solution after remaining some time in a closed vessel is then allowed to evaporate at the ordinary temperature. It crystallises in large, colourless, transparent, monoclinic forms, or in thick, white, striated needles, melts at 107—108°, but sublimes at a lower temperature with an odour resembling that of hexachlorethane, and is soluble in alcohol and acetic acid. Sulphurous acid and potassium iodide are without action on the tetrachloro-ketone, but stannous chloride converts it into the dichloro-derivative, whilst hydroxylamine hydrochloride does not combine with it until the two compounds are heated at 120—160°, when the oxime of the dichloro-ketone is obtained.

*Orthotrichlorovinylbenzoic acid*,  $\text{CCl}_2:\text{CCl}\cdot\text{C}_6\text{H}_4\cdot\text{COOH}$ , is obtained if the tetrachloro-ketone is carefully heated with aqueous soda and a small quantity of alcohol, or if the warm alcoholic solution is added to cold aqueous soda. It crystallises in colourless needles or broad scales, melts at 163°, sublimes at higher temperatures without decomposition, and is soluble in alcohol and acetic acid. The *methyl* salt forms large, colourless, monoclinic (?) tables or prisms, and melts at 68°. Neither chlorine nor bromine additive compounds of the acid have been obtained, but 1 : 2 ethylbenzoic acid, melting at 68°, is formed on treating it with sodium amalgam in the presence of water.

*Phenylene dibromodichlorethylene ketone*,  $\text{C}_6\text{H}_4 \begin{array}{c} \text{CO} \\ \diagup \quad \diagdown \\ \text{CClBr} \end{array} \text{CClBr}$ , is prepared from the dichloro-ketone in a similar manner to the tetrachloro-ketone, bromine being used instead of chlorine, and is crystallised from acetic acid, inasmuch as partial decomposition into bromine and dichloro-ketone occurs if alcohol and ether are employed as solvents. It resembles the tetrachloro-ketone in crystalline form, melts at 125—128° when rapidly heated, but when cooled and reheated, or when heated slowly, the melting point is 113—114°. Sulphurous acid and stannous chloride convert it into the dichloro-ketone, hydroxylamine hydrochloride and aniline in alcoholic solution convert it on boiling into the oxime and anilide of the dichloro-ketone respectively, whilst iodine is liberated from alcoholic potassium iodide by its action.

*Orthodichlorobromovinylbenzoic acid*,  $\text{CClBr}:\text{CCl}\cdot\text{C}_6\text{H}_4\cdot\text{COOH}$ , prepared similarly to the trichloro-compound, forms colourless needles,

melts at 173—174°, and is readily soluble in alcohol. The *methyl* salt crystallises like the trichloro-salt, and melts at 82°. Neither chlorine nor bromine additive compounds of the acid have been obtained, but sodium amalgam readily reduces it to 1 : 2 ethylbenzoic acid. W. P. W.

**Indoles.** By A. PFÜLF (*Annalen*, **239**, 220—223).—Fischer and Hess (Abstr., 1884, 1181) have pointed out that phenylindolecarboxylic acid decomposes at 200° into phenylindole and carbonic anhydride. The indole is a pale-yellow oil boiling at 326—327°, soluble in alcohol, ether, and benzene. It does not form a compound with picric acid.

Sodium hypochlorite precipitates from a cold neutral solution of phenylindolecarboxylic acid,  $[\text{Ph} : \text{COOH} = 1' : 2']$ , a red, resinous mass which after a time becomes crystalline.

*Phenylpseudoisatin*,  $\text{C}_6\text{H}_4\langle\begin{smallmatrix} \text{CO}\cdot\text{CO} \\ \text{---NPh---} \end{smallmatrix}\rangle$ , is extracted from the alcoholic solution of this crude product by boiling it with alcoholic soda, removing the alcohol by evaporation, dissolving the residue in water, and precipitating the isatin by hydrochloric acid. Phenylpseudoisatin is deposited from ethereal solutions in red plates. It melts at 134°, and dissolves freely in alcohol, ether, and benzene.

Acetophenonephenylhydrazine melts at 97—98°, and is converted into diphenylindole  $[1' : 2']$  by the action of zinc chloride. This indole boils above 360°, and has not yet been obtained in the crystalline state. It is soluble in alcohol, ether, and benzene, and does not combine with picric acid. W. C. W.

**Indoles from Tolyhydrazines.** By J. RASCHEN (*Annalen*, **239**, 223—229).—*Paratolylhydrazinepyruvic acid* separates as a yellow, crystalline precipitate on adding an aqueous solution of paratolylhydrazine hydrochloride to pyruvic acid. The acid melts with decomposition at 158—160°. It is soluble in alcohol, chloroform, and acetic acid. The *ethylic* salt crystallises in needles of a pale-yellow colour. It is converted into the ethylic salt of methylindolecarboxylic acid by the action of zinc chloride at 220°. 3 : 2' *Methylindolecarboxylic acid* melts at 227—228° with evolution of carbonic anhydride and formation of methylindole  $[\text{Me} = 3]$  and other products. The acid is freely soluble in alcohol, ether, chloroform, and acetic acid. The *ethylic* salt forms colourless needles or plates melting at 158—160°. 3-*Methylindole* is soluble in alcohol, ether, benzene, light petroleum, and in hot water. It melts at 58·5°, and closely resembles indole in its reactions with pine-wood, and with nitrous and picric acids. The *picrate*,  $\text{C}_9\text{H}_9\text{N}\cdot\text{C}_6\text{H}_2(\text{NO}_2)_3\cdot\text{OH}$ , is deposited from a hot aqueous solution as it cools in red needles melting at 151°.

*Paratolylhydrazine-acetone* melts at 50—52°. On exposure to the air, it deliquesces and forms a resinous mass.

3 : 2'-*Dimethylindole* melts at 114—115°, and boils without decomposition. It is freely soluble in warm alcohol, benzene, ether, and glacial acetic acid. The *picrate*,  $\text{C}_{10}\text{H}_{11}\text{N}\cdot\text{C}_6\text{H}_2(\text{NO}_2)_3\cdot\text{OH}$ , is deposited from benzene in dark-red needles. This salt melts at 155°.

*Orthotolylhydrazinepyruvic acid* melts at 158—159° with decomposition. The *ethyl* salts melts at 61—62°, and is deposited from hot alcoholic solutions in slender needles of a pale-yellow colour. 1:2' Methylindolecarboxylic acid melts at 170—171° with decomposition, yielding a very small quantity of methylindole. The acid is soluble in alcohol, ether, acetic acid, and in hot water.

W. C. W.

**Methylindoles.** By M. WENZING (*Annalen*, **239**, 239—247).—The preparation of skatole from propyridenephnylhydrazine has been previously described by E. Fischer (Abstr., 1886, 806). The *hydrochloride*,  $(C_9H_9N)_2.HCl$ , is precipitated from its alcoholic solution by ether in white, needle-shaped crystals. It melts at 167—168°. The *picrate* contains picric acid and skatole in molecular proportion. *Benzylidenediskatole* is formed by the action of zinc chloride on benzaldehyde and skatole. It melts at 140—142°, and dissolves in hot alcohol, chloroform, ether, and acetic acid. It does not yield benzaldehyde when boiled with hydrochloric or sulphuric acids. *Hydro-skatole* formed by reducing an alcoholic solution of skatole with zinc-dust and hydrochloric acid, is a colourless oil resembling quinoline and piperidine in odour. It boils at 231—232° under 744 mm. pressure (thermometer immersed in vapour). It dissolves freely in alcohol, ether, and light petroleum, and the alcoholic solution stains pine-wood of an orange colour. The *hydrochloride* is soluble in water and alcohol, but insoluble in ether. The *oxalate* melts at 126° with decomposition, and is insoluble in ether. The *picrate* is deposited from benzene in yellow granular crystals melting at 149—150°. The *platinochloride*,  $(C_9H_{11}N)_2.H_2PtCl_6$ , forms yellow needles and is sparingly soluble in water. It is decomposed by hot water. Hydroskatole yields a nitroso-derivative. It is an oily liquid, and yields a hydrazine on reduction which forms a crystalline sulphate.

*Hydromethylketole* and the nitrosamine have been described by Jackson (Abstr., 1881, 734). Hydromethylketole boils at 227—228° under 742 mm. pressure. The *oxalate* and *picrate* are crystalline, and melt at 130° and 150° respectively. The *hydrazine* forms colourless prisms soluble in alcohol, ether, and light petroleum. It melts at 40—41°, and yields a crystalline sulphate and hydrochloride soluble in alcohol. Hydromethylketole forms a crystalline compound,  $C_{16}H_{16}N_2S$ , with phenyl thiocyanate. It is soluble in ether, and melts at 100—101°.

*Hydromethylindole* [ $Me = 1'$ ] boils at 216° under 728 mm. pressure, and is volatile in a current of steam. It is soluble in alcohol and ether. Most of its salts are soluble in alcohol and water. The *platinochloride*,  $(C_9H_{11}N)_2.H_2PtCl_6$ , is decomposed by boiling in water. The *oxalate* melts at 103—105°, and the *picrate* at 155°.

W. C. W.

**Condensation of Isobutaldehyde and Methylal with Aniline.** By W. v. MILLER and F. KINKELIN (*Ber.*, **20**, 1934—1942).—The author investigated this reaction in the hope of obtaining an indole according to the reactions:  $CHMe_2.COH + CH_2O = CHMe_2.CH(OH).COH$  and  $CHMe_2.CH(OH).COH + C_6H_5.NH_2 =$

The product of the reaction had no odour of indole, but yielded a base which, when heated with zinc chloride, gave small quantities of an indole, probably of the above formula. Besides this indole, the author obtained from the zinc chloride melt two isomeric bases,  $\text{C}_{11}\text{H}_{11}\text{N}$ , and a base,  $\text{C}_{13}\text{H}_{15}\text{N}$ . The bases,  $\text{C}_{11}\text{H}_{11}\text{N}$ , the author believes to be dimethylquinolines. The one is solid, melts at  $63\text{--}65^\circ$ , and boils at  $274\text{--}275^\circ$ ; the other is liquid, and boils about  $265\text{--}275^\circ$ . The base,  $\text{C}_{13}\text{H}_{15}\text{N}$ , boils about  $300^\circ$ . All are being investigated.

L. T. T.

**Diphenylenedihydrazine.** By R. ARHEIDT (*Annalen*, **239**, 206—215).—*Diphenylenedihydrazine*,  $\text{C}_{12}\text{H}_8(\text{N}_2\text{H}_3)_2$ , is prepared by reducing the diazo-compound of diamidodiphenyl with sodium sulphite or stannous chloride. The salts of the base are crystalline; the nitrate is freely soluble in hot water; the sulphate and hydrochloride are sparingly soluble. The base is precipitated from solutions of its salts by alkalis and also by sodium acetate. It melts with decomposition at  $165\text{--}167^\circ$ , and dissolves sparingly in alcohol, ether, and chloroform. The addition of the theoretical quantity of an aqueous solution of potassium cyanate converts diphenylenedihydrazine hydrochloride into *diphenylenedisemicarbazide*,  $\text{C}_{12}\text{H}_8(\text{NH} \cdot \text{NH} \cdot \text{CONH}_2)_2$ . This compound is soluble in glacial acetic acid. It melts with decomposition between  $306^\circ$  and  $308^\circ$ . The sulphate and hydrochloride are crystalline. *Diphenylenedinitrosohydrazine*,  $\text{C}_{12}\text{H}_8(\text{N}_2\text{H}_2\text{NO})_2$ , melts with decomposition at  $112\text{--}113^\circ$ . It is soluble in acetone, chloroform, and acetic acid, but the solutions are unstable. *Diphenylenedihydrazine-pyruvic acid*,  $\text{C}_{12}\text{H}_8(\text{N}_2\text{H} : \text{CMe} \cdot \text{COOH})_2$ , is freely soluble in acetone and in alkalis. It melts at  $197\text{--}198^\circ$  with decomposition. *Diphenylenediacetonehydrazine*,  $\text{C}_{12}\text{H}_8(\text{N}_2\text{H} : \text{CMe}_2)_2$ , is very unstable. It is freely soluble in alcohol, chloroform, and acetic acid, and melts with decomposition at  $197\text{--}199^\circ$ . It is converted into *diphenyldimethylindole*,  $\text{C}_6\text{H}_5 \cdot \text{C}_6\text{H}_3 \left\langle \begin{array}{c} \text{CH} \\ \text{—NH} \end{array} \right\rangle \text{CMe}$ , and diphenyl by the action of zinc chloride at  $215^\circ$ . Diphenyldimethylindole melts at  $270^\circ$ , and boils without decomposition. It is freely soluble in alcohol and acetic acid and exhibits the characteristic indole reaction.

W. C. W.

**Orthodibenzylidicarboxylic Acid.** By N. DOBREFF (*Annalen*, **239**, 65—71).—In addition to the salts of orthodibenzylidicarboxylic acid, which have been previously described by Graebe, the author has prepared the following salts:—The ammonium salt,  $\text{C}_{16}\text{H}_{12}\text{O}_4(\text{NH}_4)_2$ , is very soluble in water; the calcium and barium salts are also very soluble, and crystallise with difficulty. The ammonium salt precipitates basic salts from solutions of lead, copper, and zinc acetates. The methyl salt,  $\text{C}_{16}\text{H}_{12}\text{O}_4\text{Me}_2$ , melts at  $100\text{--}101^\circ$  and is freely soluble in methyl alcohol, alcohol, chloroform, and carbon bisulphide. The ethyl salt,  $\text{C}_{16}\text{H}_{12}\text{O}_4\text{Et}_2$ , crystallises in needles or prisms and melts at  $69\text{--}71^\circ$ . It is best recrystallised from hot amyl alcohol. On saturating the alcoholic solution with ammonia gas, crystals of ethyl dibenzylidicarboxylic acid are obtained.

oxylamine,  $\text{COOEt} \cdot \text{C}_6\text{H}_4 \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{CONH}_2$ , are slowly deposited. The compound melts between  $65^\circ$  and  $68^\circ$ .

Dibenzoyldicarboxylic acid yields diphtalylic acid when oxidised with potassium permanganate, and stilbene when distilled with soda-lime. Fuming nitric acid converts diphenyldicarboxylic acid into a dinitro-product which is soluble in hot water and in hot alcohol. The calcium and barium salts are amorphous, and explode when heated. The ethyl salt,  $\text{C}_{16}\text{H}_{11}(\text{NO}_2)_2\text{O}_4\text{Et}$ , melts at  $60^\circ$ .

On oxidation with potassium permanganate, dinitrobenzoyldicarboxylic acid yields  $\beta$ -nitrophthalic acid. W. C. W.

**So-called Carbonylcarbazole (Carbazole-blue).** By E. BAMBERGER and R. MÜLLER (*Ber.*, 20, 1903—1907).—Suida first described this compound (Abstr., 1880, 245) as an anhydride of orthamidophenylbenzoic acid, giving it the formula  $\langle \text{C}_6\text{H}_4 \cdot \text{NH} \rangle_{\text{C}_6\text{H}_4 \cdot \text{CO}}$ . The authors have re-examined it, and find it to belong to the class of triphenylmethane colouring matters, and to have the constitution

The authors consider the blue colour of the free base to be only superficial and due to impurities, and on the addition of strong hydrochloric acid it is very much intensified owing to the formation of the true dehydrated colouring matter. When treated with acetic acid and zinc, the *leuco-base* is obtained, which crystallises in microscopic needles, dissolves in ether to a bluish-violet fluorescent liquid, and is reconverted into the colour-base by oxidation. When heated alone or with zinc-dust, the colouring matter yields carbazole. A very similar substance was also prepared by fusing carbon hexachloride with carbazole. The authors therefore propose the name *carbazole-blue* for this substance. L. T. T.

**The Hydrocarbon  $\text{C}_{16}\text{H}_{12}$  from Styrolene Alcohol.** By T. ZINCKE (*Annalen*, 240, 137—147).—In the light of the formation of naphthalene-derivatives by condensation lately observed, and especially of the formation of  $\alpha$ -naphthol from phenylisocrotonic acid (Fittig and Erdmann, Abstr., 1885, 545), the author believes the hydrocarbon obtained from styrolene alcohol (phenylglycol) to be  $\beta$ -phenylnaphthalene [ $\text{Ph} = 2$ ], and not to have the formula  $\langle \text{CPh} : \text{CH} \rangle_{\text{CH} : \text{CPh}}$  previously (Abstr., 1885, 269) ascribed to it. The derivatives will thus be  $\beta$ -phenylnaphthaquinone,  $\beta$ -phenylamidonaphthaquinone, &c., the constitution of the last-named, for instance, being  $[\text{O} : \text{Ph} : \text{NH}_2 : \text{O} = 1 : 2 : 3 : 4]$ . This constitution will more fully explain the reactions of this hydrocarbon than the one previously given. The one piece of evidence that seems to be antagonistic to the naphthalene formula—that is, the formation of 0.9 gram of benzoic acid from 1 gram of the hydrocarbon—is probably due to an error in weighing, 2 grams having most likely been really taken. A repetition of the experiment yielded the lower percentage of benzoic acid. The formation (*loc. cit.*) of

phthalic acid and the acid  $C_9H_6O_5$  (probably  $COOH \cdot C_6H_4 \cdot CO \cdot COOH$ ) points to the correctness of the naphthalene formula.

All attempts to synthesise  $\beta$ -phenylnaphthalene by other methods for comparison with the above hydrocarbon gave negative results. Graebe has described (*Ber.*, 7, 792) a phenylnaphthalene which is probably the  $\alpha$ -naphthalene. Watson Smith has described a  $\beta$ -phenylnaphthalene obtained by the action of bromobenzene on naphthalene (*Abstr.*, 1880, 125, 261; see also Smith and Takamatsu, *Trans.*, 1881, 546). The author questions the correctness of Smith's view and believes the compound rather to be the (perhaps impure)  $\alpha$ -derivative.

L. T. T.

**Action of Chlorine on Phenols.** By T. ZINCKE (*Ber.*, 20, 2058—2061).—In certain cases, chlorinated ketones are formed when phenols dissolved in acetic acid are treated with chlorine. Definite results have been obtained with the two naphthols, but so far the attempts made to isolate the products of the action of chlorine on hydroxyquinoline, thymoquinone, catechol, and resorcinol have not met with success.

When  $\alpha$ -naphthol is treated with chlorine in acetic acid solution, a compound is obtained, which appears to be a chloride of dichloro- $\beta$ -naphthaquinone,  $C_6H_4 \begin{smallmatrix} \text{CO} \cdot \text{CCl}_2 \\ \text{CCl} \cdot \text{CCl} \end{smallmatrix}$ . It crystallises in large, colourless, rectangular tables, melts at  $156$ — $157^\circ$ , is not decomposed on heating, and is sparingly soluble in ether and light petroleum, readily soluble in benzene and hot alcohol. Although insoluble in dilute alkali it dissolves slowly in concentrated alkali on addition of alcohol, and is converted into phenylenedichloroacetyleneglycollic acid (this vol., pp. 54, 728). When the ketone chloride is dissolved in hot alcohol and treated with dilute aqueous soda until the reaction is feebly alkaline, a compound is formed which, on the addition of an acid, separates in slender, orange needles melting at  $146^\circ$ . This is probably a hydroxy-derivative obtained by the substitution of hydroxyl for chlorine in the ketone chloride; it dissolves without decomposition in cold dilute alkali with a yellow colour, but on heating the solution it becomes dark red, and yields chlorhydroxy- $\alpha$ -naphthaquinone (m. p. =  $215^\circ$ ) when treated with an acid. Dichloro- $\beta$ -naphthaquinone and its chloride, therefore, exhibit a similar series of reactions, inasmuch as it is converted into chlorhydroxy- $\alpha$ -naphthaquinone by prolonged treatment with sodium carbonate, or by heating with concentrated hydrochloric acid.

The ketone chloride obtained from  $\beta$ -naphthol under similar conditions crystallises from the acetic acid solution in broad lustrous laminae, melts at  $85^\circ$ , and is readily soluble in alcohol and acetic acid, but quickly resinifies in these solutions. From benzene and light petroleum, however, it crystallises in small, glistening scales, which melt at  $100^\circ$  to a turbid liquid which becomes clear at  $140^\circ$ . Dilute alkali converts the ketone chloride into black resinous products, but on treating its solution in aqueous alcohol with sodium carbonate, it yields a compound which crystallises in thick, glistening, red needles, melts at  $174^\circ$ , and is soluble in benzene and acetic acid. The investigation will be continued.

W. P. W.

**Action of Chlorine on Aceto- $\beta$ -Naphthylamine.** By P. T. CLEVE (*Ber.*, **20**, 1989—1992).—*Acetochloro- $\beta$ -naphthylamine*,  $C_{10}H_6Cl \cdot NHAc$ , is prepared by passing chlorine (1 mol.) into a solution of aceto- $\beta$ -naphthylamine in dilute acetic acid, and precipitating with water. It crystallises from alcohol in very slender colourless needles, which melt at  $147^\circ$ ; it is sparingly soluble in boiling water, readily in alcohol.

*Chloro- $\beta$ -naphthylamine*,  $C_{10}H_6Cl_2 \cdot NH_2$ , is obtained by treating an alcoholic solution of the above acetyl-derivative with hydrochloric acid. It crystallises from dilute alcohol in slender colourless needles, melting at  $59^\circ$ . The *hydrochloride* crystallises (with 1 mol.  $H_2O$ ) in lustrous colourless needles, rather soluble in boiling water containing hydrochloric acid. When the base is treated with nitrogen trioxide in presence of sulphuric acid,  $\alpha$ -chloronaphthalene is formed; when boiled with nitric acid, it is oxidised to phthalic acid.

*Dichloronaphthalene*,  $C_{10}H_6Cl_2$ , is formed when 10 grams of chloro- $\beta$ -naphthylamine hydrochloride dissolved in boiling hydrochloric acid is treated with 5 grams of cuprous chloride, and 4 grams of potassium nitrate dissolved in 20 c.c. of water added by drops. The product is steam distilled, and the yellow oil so obtained, which solidifies in a few days, crystallised from alcohol; it separates in tabular monoclinic crystals;  $a : b : c = 1.5196 : 1 : ?$ ;  $\beta = 76^\circ 46'$ ; it melts at  $34\text{--}35^\circ$ ; Widman's  $\alpha$ -dichloronaphthalene melts at  $38^\circ$ , and crystallises in pointed needles.

When monochloronaphthylamine is heated with soda-lime,  $\alpha$ - $\beta$ -naphthazine (Witt, *Ber.*, **19**, 2791) is formed. The dichloronaphthalene described above is therefore an  $\alpha$ - $\beta$ -derivative. N. H. M.

**Orthoamidated Aromatic Mercaptans.** By P. JACOBSON (*Ber.*, **20**, 1895—1903).—The author has previously shown (*Abstr.*, 1886, 700 and 876) that the anhydro-compounds of orthamidophenyl mercaptan are easily formed by the oxidation of thioanilides. He has now extended this reaction to the naphthalene series.

$\alpha$ -Thioacetophthalide described by Bernthsen and Trompeter (*Abstr.*, 1879, 146) is best obtained by acting on acetophthalide with phosphoric sulphide; it melts at  $110\text{--}111^\circ$  (Bernthsen and Trompeter give  $95\text{--}96^\circ$ ). When oxidised with potassium ferri-

cyanide, this yields ethenylamidonaphthyl mercaptan,  $C_{10}H_6 < \begin{smallmatrix} N \\ S \end{smallmatrix} > CMe$ , probably identical with that recently obtained by Hofmann (this vol., p. 839). The *hydrochloride* crystallises in needles. Benzenylamidonaphthyl mercaptan, also described by Hofmann (*loc. cit.*), was similarly obtained from  $\alpha$ -thiobenzophthalide. The *picrate* yields characteristic orange needles, melting at  $130\text{--}131^\circ$ . Attempts to prepare amidonaphthyl mercaptan by heating the benzyl base with alcoholic potash were unsuccessful, but a slightly basic oxidation derivative crystallising in yellow scales and melting at  $131\text{--}132^\circ$  was obtained. The author is unable at present to decide whether this is a diamidodinaphthyl bisulphide,  $S_2(C_{10}H_6 \cdot NH_2)_2$ , or a thionaphthoquinonimide,  $C_{10}H_6 < \begin{smallmatrix} NH \\ S \end{smallmatrix} >$ , the percentage composition of which are very similar. When treated

with acetic anhydride, this substance yields *diacetylamidonaphthyl mercaptan*,  $\text{NHAc} \cdot \text{C}_{10}\text{H}_6\text{S} \cdot \text{Ac}$ , crystallising in long needles, and melting at  $173.5-175^\circ$ . When heated with hydrochloric acid at  $200-220^\circ$ , this acetyl-derivative is decomposed, ethenylamidonaphthyl mercaptan being formed.

Orthamidophenyl mercaptan bisulphide, when heated with acetic anhydride, yields *diacetylamidophenyl mercaptan*,  $\text{NHAc} \cdot \text{C}_6\text{H}_4\text{S} \cdot \text{Ac}$ , crystallising in prisms melting at  $135^\circ$ . Phenyl bisulphide and benzyl bisulphide are, however, not attacked by acetic chloride, so that this is not a general reaction for bisulphides, and does not decide which of the two formulæ proposed for the new compound is the correct one.

L. T. T.

**Action of Aldehydes on Amidosulphonic Acids.** By E. CAHN and M. LANGE (*Ber.*, **20**, 2001—2002).—When sodium naphthionate (1 mol.) dissolved in a little water is treated with benzaldehyde (1 mol.) and shaken, the *condensation product*  $\text{SO}_3\text{Na} \cdot \text{C}_{10}\text{H}_6\text{N} : \text{CHPh}$  separates in straw-coloured plates. This is decomposed into its original constituents by prolonged boiling with water. The corresponding condensation product from  $\alpha$ -naphthylaminesulphonic acid and benzaldehyde is prepared by adding the aldehyde to an alcoholic solution of the sodium salt of the sulphonic acid, and crystallises in concentrically grouped needles. The analogous compound from  $\beta\beta$ -naphthylaminesulphonic acid and benzaldehyde crystallises in well-formed, long, pale-yellow prisms.

Benzidinesulphonic acid and the sulphonic acid of amido-azo-compounds yield analogous compounds.

N. H. M.

**$\beta$ -Naphthylaminesulphonic Acids.** By S. FORSLING (*Ber.*, **20**, 2099—2106).—Further examination has shown that the  $\beta$ -naphthylaminesulphonic acid obtained by heating  $\beta$ -naphthylamine with sulphuric acid at  $140^\circ$  (Abstr., 1886, 890), is not pure, but contains three isomerides, of which one is identical with Brönner's acid (this vol., p. 375), and a second, produced in small quantity only, is perhaps identical with the  $\delta$ -acid (*loc. cit.*, p. 732), whilst the remaining two, designated as 1 and 2, are respectively identical with the acids termed  $\alpha$  and  $\gamma$  in a patent specification of Dahl's. A separation of the acids was effected by fractional crystallisation of the calcium salts.

*$\beta$ -Naphthylaminesulphonic acid*, 1, dissolves in about 1700 parts of cold water, and is almost insoluble in alcohol. Its salts generally are readily soluble in water, yielding solutions fluorescing blue, and, with the exception of the silver and copper salts, can be heated at  $180^\circ$  without decomposition. The *potassium* salt with  $\frac{1}{2}$  mol.  $\text{H}_2\text{O}$ , forms six-sided tables; the *sodium* salt is anhydrous, and crystallises in thin four-sided scales; the *barium* salt, with 4 mols.  $\text{H}_2\text{O}$ , forms long prisms, and dissolves in about 23 parts of cold water; the *calcium* salt, with 6 mols.  $\text{H}_2\text{O}$ , forms large, thick tables, which become coloured red on crystallisation from an aqueous solution, and dissolve in about 11 parts of cold water; the *magnesium* salt, with  $3\frac{1}{2}$  mols.  $\text{H}_2\text{O}$ , forms small crystalline aggregates; the *zinc* salt, with 6 mols.  $\text{H}_2\text{O}$ , crystallises in prisms; and the *lead* salt crystallises in small needles, and is anhydrous. The corresponding diazonaphtha-

lenesulphonic acid,  $C_{10}H_6N_2SO_3$ , a greenish-yellow, indistinctly crystalline powder, yields, when boiled with water, Bayer's  $\beta$ -naphtholsulphonic acid, from which *o*-dichloronaphthalene (m. p.  $61.5^\circ$ ) is obtained on treating its potassium salt with phosphorus pentachloride.

*$\beta$ -Naphthylaminesulphonic acid*, 2, dissolves in about 1300 parts of cold water, and is almost insoluble in alcohol. Its salts dissolve readily in water, yielding solutions fluorescing blue, and show great similarity in properties to the corresponding salts of the No. 1 acid. The *potassium* salt, with 1 mol.  $H_2O$ , crystallises in small rhombohedra; the *sodium* salt, with 5 mols.  $H_2O$ , crystallises in large tables; the *barium* salt, with  $2\frac{1}{2}$  mols.  $H_2O$ , forms small aggregates; the *calcium* salt, with 11 mols.  $H_2O$ , crystallises in long, yellowish needles, and dissolves in about 11 parts of cold water: the amount of water of crystallisation in this salt varies with the temperature at which crystallisation takes place, and at about  $10^\circ$  crystals are obtained which at once effloresce when separated from the mother-liquor; the *magnesium* salt, with 8 mols.  $H_2O$ , forms small, well-formed crystals; and the *lead* salt is anhydrous. The *diazonaphthalenesulphonic acid* is obtained as a green microcrystalline powder, and when boiled with concentrated hydrochloric acid yields a chloronaphthalenesulphonic acid, from which, on treatment of its potassium salt with phosphorus pentachloride, a dichloronaphthalene (probably 1' : 2) is obtained, melting at  $48^\circ$ .

W. P. W.

**Action of Phosphorus Pentachloride on  $\alpha$ -Hydroxynaphthoic Acid.** By R. WOLFFENSTEIN (*Ber.*, 20, 1966—1967).— *$\alpha$ -Chlorocarboxynaphthylorthophosphoric dichloride*,  $POCl_2 \cdot O \cdot C_{10}H_6 \cdot CCl_3$ , is obtained by warming  $\alpha$ -hydroxynaphthoic acid with phosphorus pentachloride (rather more than 2 mols.) in presence of a little phosphoric chloride, until the mixture is homogeneous. The product, when cold, is poured on to ice. It crystallises from light petroleum in transparent, colourless prisms melting at  $115^\circ$ . The compound is analogous to that obtained by Anschütz and More (*Annalen*, 239, 314) from salicylic acid and phosphorus pentachloride.

N. H. M.

**Indoles from  $\alpha$ -Naphthylhydrazine.** By A. SCHLIEPER (*Annalen*, 239, 229—239).—The indoles from  $\alpha$ -naphthylhydrazine are prepared by the same methods which the author employed in the preparation of the  $\beta$ -naphthindoles (this vol., p. 554).

*$\alpha$ -Naphthylhydrazinepyruvic acid* has been previously described by E. Fischer (*Abstr.*, 1886, 554). The *ethyl* salt forms yellow prisms, and is freely soluble in benzene, chloroform, ether, acetic acid, and hot alcohol. It melts at  $100^\circ$ , and on fusion with zinc chloride yields ethyl  $\alpha$ -naphthindolecarboxylate and small quantities of indole and  $\alpha$ -naphthindolecarboxylic acid. *Ethyl  $\alpha$ -naphthindolecarboxylate* can be distilled in a current of superheated steam. It melts at  $170^\circ$ , and dissolves freely in benzene, hot alcohol, and glacial acetic acid.

*$\alpha$ -Naphthindolecarboxylic acid*,  $C_{10}H_6 \langle \begin{smallmatrix} NH \\ CH \end{smallmatrix} \rangle C \cdot COOH$ , melts at  $202^\circ$ , and decomposes at  $210$ — $220^\circ$ , yielding  $\alpha$ -naphthindole; it is soluble in alcohol, ether, and acetic acid, and in alkalis. It is reprecipitated from the alkaline solution on the addition of an acid, and from the

ammoniacal solution on boiling. The nickel, cadmium, barium, and sodium salts are crystalline.

$\alpha$ -Naphthindole melts at  $175^{\circ}$ , and dissolves freely in alcohol, ether, and benzene. It is less soluble in hot water, dilute acetic acid, and light petroleum, and it is deposited from these solutions in colourless plates. The *picrate* crystallises in needles. The solution of the indole in acetic acid gives a red coloration with strong nitric acid, a colourless precipitate with hydrochloric acid, probably  $(C_{12}H_9N)_3.HCl$ , and a bluish-green precipitate on boiling with hydrogen peroxide.

$\alpha$ -Hydronaphthindole is obtained as a crystallisable oil on boiling the alcoholic solution of the indole with zinc-dust and hydrochloric acid. The alcoholic solution gives a red-violet coloration with silver nitrate, ferric chloride, and nitrous acid. The salts of the mineral acids are soluble in water. The oxalate is deposited from hot alcoholic solution in colourless needles melting at  $166^{\circ}$ . It is precipitated on adding oxalic acid to a solution of the base.

Methyl- $\alpha$ -naphthindole,  $C_{10}H_6<\begin{smallmatrix} NH \\ CH \end{smallmatrix}>CMe$ , obtained from acetone- $\alpha$ -naphthylhydrazine (Abstr., 1886, 555), is soluble in alcohol, ether, benzene, acetic acid, and in hot water. It melts at  $132^{\circ}$ . The *picrate* is deposited from hot benzene in dark red needles, and melts at  $167$ – $168^{\circ}$ . The acetic acid solution of the indole gives a cherry-red coloration with ferric chloride, and on the addition of water a coloured precipitate is formed. W. C. W.

**Nitroacenaphthene.** By E. JANDRIER (*Compt. rend.*, **104**, 1858).—Nitric acid of sp. gr. 1.34 is added drop by drop to a warm saturated solution of acenaphthene in glacial acetic acid, and the product crystallised from alcohol, ether, or acetic acid. It forms white, silky needles which melt at  $155^{\circ}$ , and sublime at a low temperature, condensing in pale-yellow needles. The nitro-derivative is easily reduced by zinc and hydrochloric acid or iron and acetic acid, and the amido-derivative yields a blue-violet product when carefully oxidised. With potassium dichromate and sulphuric acid, or with calcium hypochlorite, it yields a green solution and a green precipitate. The diazo-derivative forms a yellow colouring matter with phenol, and scarlet and ponceaus with  $\beta$ -naphthol or its disulphonic acid. C. H. B.

**Methylethyrohydroxyanthraquinone.** By W. BIRUKOFF (*Ber.*, **20**, 2068—2071).—Baeyer and Drewsen (Abstr., 1882, 1099) prepared methylethyrohydroxyanthraquinone [ $Me : OH = 1 : 4$ ] in very small quantity by the condensation of phthalic anhydride and paracresol with sulphuric acid. A yield of 5 per cent. of the paracresol employed can be obtained if phthalic anhydride (5 parts) is heated with paracresol (2 parts) and sulphuric acid (15 parts) for 10 minutes at  $160^{\circ}$ . The compound crystallises in yellowish-red, or from acetic acid in dark-brown, glistening needles, melts at  $169$ – $170^{\circ}$ , and readily sublimes. In alkalis, it dissolves with a red colour; ammonia and soda do not dissolve it in the cold, and only sparingly on boiling; and with barium oxide and lime it yields insoluble brick-red lakes. Fusion with potassium hydroxide converts it with difficulty into a

coloured hydroxyanthraquinone, whilst sulphuric acid dissolves it with an orange-yellow colour, and the solution gives a spectrum corresponding entirely with that of erythrohydroxyanthraquinone. The *acetyl*-derivative crystallises in yellow needles and melts at 179—180°.

$\alpha$ -Methylanthracene [Me = 1] is obtained on distilling methyl-erythrohydroxyanthraquinone with zinc-dust. It crystallises in white laminae, melts at 199—200°, and is soluble in alcohol, yielding a solution fluorescing a pale blue. The *picrate* crystallises in red needles. When oxidised with chromic acid in acetic acid solution, it is converted into  $\alpha$ -methylantraquinone, together with the corresponding carboxylic acid if the reaction is allowed to become violent. The quinone crystallises in small, white needles, which speedily become pale-red on exposure to light; it melts at 166—167°, and is readily soluble in benzene and alcohol. W. P. W.

**Preparation of Anthranol and Dianthryl.** By C. LIEBERMANN and A. GIMBEL (*Ber.*, 20, 1854—1855).—These two compounds can easily be prepared by the reduction of anthraquinone by tin and acetic acid. If 10 grams of anthraquinone is dissolved in 500 grams of boiling glacial acetic acid, 25 grams of zinc added, and then a few c.c. of fuming hydrochloric acid added from time to time, almost all the

quinone is reduced to anthranol,  $C_6H_4 \begin{array}{c} \text{CH} \\ \diagup \quad \diagdown \\ | \quad \quad | \\ \text{C}(\text{OH}) \end{array} C_6H_4$ , which is then

precipitated by pouring the solution into acidulated water. If, however, 10 grams of anthraquinone are added to just enough glacial acetic acid to form a thin paste, this then heated to boiling, 40 grams of tin added in two or three portions, and finally about half as much fuming hydrochloric acid as there was acetic acid, the reduction takes place almost entirely to dianthryl (dianthranyl),  $C_{28}H_{18}$ , a small quantity of anthracene being formed at the same time. *Dibromodianthryl* is obtained by the action of bromine on a carbon bisulphide solution of dianthryl. It forms pale yellow prisms which melt considerably above 300°. L. T. T.

**Terpenes and Ethereal Oils. Part V.** By O. WALLACH (*Annalen*, 239, 1—54). The eight isomeric terpenes may be distinguished from each other by comparing the properties of their compounds with HCl, HBr, HI, &c., as shown in the following table (p. 966.)

The compounds of the terpenes with 2 mols. HBr, HI, &c., may be conveniently prepared on the small scale by saturating glacial acetic acid with hydrogen chloride, and adding this solution to the terpene dissolved in acetic acid. When the product is poured into ice-cold water, the compound separates in the pure state.

The bromides are prepared by adding bromine to the terpene diluted with ten times its volume of glacial acetic acid. They are purified by recrystallisation from warm ethyl acetate. The hydrochlorides are easily decomposed by boiling with glacial acetic acid and anhydrous sodium acetate, the chief product being the original

terpene. If pinene monohydrochloride is treated in this manner at 200° for four hours, it yields camphene. The conversion of pinene into dipentene, terpinolene, and terpinene, has been previously described (Abstr., 1885, 550, and 1886, 70). Pure pentene and all its derivatives are optically inactive. The dihydriodide,  $C_{10}H_{16}, 2HI$ , is deposited from light petroleum in two distinct forms, namely, in rhombic crystals [ $a : b : c = 0.6644 : 1$ ], melting at 77°, and in monoclinic crystals [ $a : b : c = 1.0269 : 1 : 0.92619$ ;  $\beta = 49^\circ 54'$ ], melting at 78—79°. Pure dipentene is converted into terpinene by treatment with alcoholic sulphuric, or hydrochloric acid.

Cineol, cajuputol, and eucalyptol are identical. This substance crystallises when it is cooled in a freezing mixture.

*Terpinolene* is obtained by boiling terpene hydrate, terpineol, or cineol, with dilute sulphuric or phosphoric acid. The melting point of the freshly prepared tetrabromide is 116°, but old specimens melt at about 112°. At the moment of fusion, a slight evolution of gas is perceptible. Solutions of the tetrabromide are optically inactive.

\* Identical with the corresponding dipentene compounds.

† Probably identical with the corresponding dipentene compounds.

By the action of hydrochloric, hydrobromic, or hydriodic acids on terpinolene, the hydrochloride, hydrobromide, &c., of dipentene are formed. Pure sylvestrene hydrochloride is obtained by saturating Swedish oil of turpentine (b. p. 174—178°) diluted with ether with dry hydrogen chloride. After an interval of two days, the ether is distilled off, and the residue is poured into shallow dishes, when the hydrochloride slowly crystallises out. The operation should be carried out in winter. After recrystallisation from warm alcohol, the hydrochloride melts at 72°. It is less soluble in ether and in light petroleum than dipentene hydrochloride. The ethereal solution is powerfully dextrogyrate. Sylvestrene boils at 175—178°; an intense blue coloration is produced by adding a drop of strong sulphuric or nitric acid to a solution of the hydrocarbon in acetic anhydride. Sylvestrene regenerated from the hydrochloride is identical with the hydrocarbon present in Swedish oil of turpentine. It is dextrogyrate.

The hydrochloride, hydrobromide, and tetrabromide crystallise in the monoclinic system.

The hydrochloride forms plates,  $a : b : c = 2.0199 : 1 : 2.7641$ ;  $\beta = 76^\circ 32\frac{1}{2}'$ .

The hydrobromide also forms plates,  $a : b : c = 1.8887 : 1 : 2.6937$ ;  $\beta = 73^\circ 14'$ .

For the tetrabromide,  $a : b : c = 1.2166 : 1 : 1.6581$ ;  $\beta = 46^\circ 9'$ .

*Terpinene* is obtained by gradually adding 70 c.c. of strong sulphuric acid to two litres of oil of turpentine. The mixture is kept cool and is well shaken. After an interval of two days the acid is neutralised with soda, and the terpinene distilled over in a current of steam. Dipentene, phellandrene, and cineol also yield the same hydrocarbon.

*Terpinene nitrite*,  $C_{10}H_{16} \cdot N_2O_3$ , is obtained in crystals by adding sodium nitrite in small quantities to a mixture of terpinene, acetic acid, and water. The compound is deposited in the course of two days at the ordinary temperature, or immediately in working on the small scale if the vessel containing the mixture is dipped for an instant into hot water.

The nitrite melts at 155°. It is insoluble in water and light petroleum, but dissolves freely in alcohol, ether, and ethyl acetate.

The solutions are optically inactive. The nitrite dissolves in strong hydrochloric, sulphuric, and acetic acids, and is reprecipitated unaltered on diluting the acid solutions. On reduction with stannous chloride, the nitrite is converted into a base which has not yet been properly investigated. Terpinine is not converted into camphene or any other terpene by treatment with alcoholic sulphuric acid, or strong sulphuric acid.

The properties of *phellandrene* have been recently described by Pesci (Abstr., 1886, 1038). The aqueous solution is dextrogyrate, but the nitrite is lævogyrate. The nitrite behaves like a saturated compound, and does not destroy the colour of bromine-water. Phellandrene has not been obtained in a pure state. It easily changes into dipentene- or terpinene-derivatives.

The author proposes the following formulæ for the terpenes—

Pinene.

Pinene hydrochloride.

Limonene.

Dipentene.

Phellandrene.

W. C. W.

**Conversion of Dextrorotatory Terpene from Russian Turpentine by means of Hydration and Dehydration.** By F. FLAWITZKY (*Ber.*, 20, 1956—1965).—The dextrorotatory terpene employed was prepared from steam-distilled Russian turpentine by fractional distillation and treatment with dry potash; it was then warmed with sodium. It boils at 155·5—156·5° (corr.), sp. gr. = 0·8764 at 0° and 0·8600 at 20° (water at 4° = 1). Coefficient of expansion between 0° and 20° = 0·00095. At 20° (with 100 mm.)  $[\alpha]_D = +27·5$ .  $[\alpha]_D = \frac{+27·5}{0·8600} = +32·0°$ . Molecular refraction = 71·24. The terpene was treated with twice its weight of a mixture of 3 parts 90 per cent. alcohol and 1 part sulphuric acid of sp. gr. = 1·64. After six days, the solution was separated from the unchanged terpene, decomposed by water (kept cool with ice), and the portion which separated washed first with water, then with alkali. The product, when dried over potash, showed rotation (with 100 mm.)  $[\alpha]_D = +35·6°$ ; that is 8·1° more than in the case of the original terpene. The product precipitated from the solution dissolved in alcoholic sulphuric acid only to the extent of one half; when steam distilled, it gave three distillates having different rotatory powers. A substance boiling at 213·7° to 217·7° was obtained.  $[\alpha]_D = +44·5$  at 19·5° (with 100 mm.). Analysis showed it to be a hydrate,  $\text{C}_{10}\text{H}_{16}\cdot\text{H}_2\text{O}$ . It forms a thick liquid, insoluble in water, miscible with alcoholic sulphuric acid, and has a peculiar odour and a bitter burning taste. Sp. gr. = 0·9335 at 0° and 0·9189 at 19·5°.

Coefficient of expansion = 0.00081.  $[\alpha]_D = +48.4$ . Molecular refractive power = 77.28. A table is given showing the similarity between the dextro- and lævo-terpene hydrates. When the hydrate is saturated with hydrogen chloride, the *hydrochloride*  $C_{10}H_{16}(HCl)_2$  is formed; this crystallises from alcohol in tabular crystals melting at  $49.5^\circ$ .

The fraction of the substance of the rotatory power  $[\alpha]_D = +35.6^\circ$ , which boiled below  $210^\circ$ , gave  $[\alpha]_D = +40.0^\circ$ . When purified by repeated distillation over sodium, it boiled at  $173\text{--}176^\circ$ , and crystals separate on cooling it to  $-25^\circ$ . After being again distilled, it was pure.  $[\alpha]_D = +49.1$  at  $15^\circ$ . Sp. gr. = 0.8627 at  $6^\circ$  and 0.8480 at  $20^\circ$ . Coefficient of expansion = 0.00089.  $[\alpha]_D = +57.6$ . It differs, therefore, distinctly from the original terpene, but resembles lævo-isoterpene, and is, therefore, described as *dextro-isoterpene*.

The new dextro-isoterpene resembles the dextro-isoterpene from oil of lemon in its molecular refraction and other physical properties. When the new isoterpene is saturated with hydrogen chloride, it becomes heated, but no crystalline hydrochloride separates. The *dihydrochloride*,  $C_{10}H_{16}(HCl)_2$ , is obtained by saturating the solution of the terpene in glacial acetic acid with hydrochloric acid, and adding water; it separates from alcohol in crystals melting at  $49^\circ$ .

N. H. M.

**Action of Glacial Acetic Acid on Lævogyrate Camphene.** By J. LAFONT (*Compt. rend.*, 104, 1717—1719).—Lævogyrate camphene, obtained by the action of alcoholic potassium acetate at  $150^\circ$  on terebenthene hydrochloride, was heated with 1.5 parts of glacial acetic acid in sealed tubes at  $100^\circ$  for about 60 hours. The product was then distilled in a vacuum, and the portion boiling above  $100^\circ$  was again treated in the same way, this process being repeated six times. The final product was washed with water and fractionated in a vacuum. The fraction boiling at  $155\text{--}158^\circ$  under normal pressure consists of non-combined camphene, the rotatory power of which has diminished to  $[\alpha]_D = -19^\circ 53'$ . It yields a hydrochloride with a rotatory power  $[\alpha]_D = +9^\circ 32'$ .

The fraction boiling at  $125\text{--}127^\circ$  under a pressure of 35 mm. consists of a dextrogyrate acetate, which is liquid at the ordinary temperature, but becomes pasty at  $-50^\circ$ ; sp. gr. at  $0^\circ = 1.002$ ; rotatory power  $[\alpha]_D = +19^\circ 41'$ . If heated with alcoholic potash in sealed tubes, it yields borneol, which when purified by sublimation melts at  $211^\circ$ . Its rotatory power is  $[\alpha]_D = +14^\circ 51'$ ; when treated with nitric acid, it yields a camphor which melts at  $175^\circ$ , and has a rotatory power  $[\alpha]_D = -20^\circ 2'$ .

The action of acetic acid on lævogyrate camphene yields only one acetate, which is dextrogyrate, and when this is treated with alcoholic potash it yields potassium acetate and camphenol only.

C. H. B.

**Black Pepper Oil.** By L. A. EBERHARDT (*Arch. Pharm.* [3], 25, 515—519).—The oil had a specific gravity of 0.87352 at  $15^\circ$ , and showed a greenish colour, due neither to chlorophyll nor to copper. At  $22^\circ$ , the oil had a lævorotatory power of  $3.2^\circ$  in a column 100 mm. long. On rectification, a very small quantity passed over at  $160^\circ$ . Fractions obtained at  $170^\circ$ ,  $176^\circ$ , and  $180^\circ$  were colourless;  $190^\circ$  faint

green; 250° green; 310° brown-green. Above 310°, a brown tenacious residue was obtained in which phenol could not be detected.

The 170° fraction, when rectified under reduced pressure, gave a terpene boiling at 164—165°, and showed a left-handed rotation of 7·6° in 100 mm.; it gave numbers agreeing with the formula  $C_{10}H_{16}$ , and a vapour-density of 480° by Hofmann's method. The composition of the other fractions was much the same as this. The terpene hydrate was obtained by Tilden's method (this Journ., 1878, 247). The tetrabromide was also obtained in well-crystallised forms. The oil consists of a lævorotatory terpene and isomeric compounds of higher boiling points. J. T.

**$\beta$ -Chloronitro-camphor.** By P. CAZENEUVE (*Bull. Soc. Chim.*, 47, 926—927).—The  $\beta$ -chloronitro-camphor previously described (Abstr., 1884, 1041) is more readily soluble in alcohol than the  $\alpha$ -compound, and may, therefore, be separated from its isomeride by washing the mixture with 80 per cent. alcohol. On spontaneous evaporation, the solution obtained deposits microscopic crystals which may be purified by repeated recrystallisation from 93 per cent. alcohol. Thus obtained it is a soft camphor-like substance, crystallising in microscopic arborescent forms; it softens at 91°, and melts at 98°; it is dextrorotatory, an examination of its alcoholic solution showing it to have the rotatory power  $[\alpha]_D = +10\cdot5^\circ$ . The chlorine in this compound is much less stable than in its isomeride, as alkalis decompose it at the normal temperature, metallic chlorides and nitro-camphors being formed. Sodium ethoxide also attacks it, sodium chloride, and what appears to be an ethyl ether of a nitro-camphor, being formed. A copper-zinc couple also decomposes it, nitro-camphor being produced. The  $\alpha$ -compound yields the same reactions, but only on prolonged boiling; the nitro-camphors formed are, however, the same in each case. A. P.

**Strophanthus and Strophanthin.** By A. W. GERRARD (*Pharm. J. Trans.* [3], 17, 923; comp. this vol., p. 991).—Boiling alcohol completely removes both oil and extract from *Strophanthus* seed at one operation; the oil can then be easily poured from the extract, and adhering traces washed away with a little ether. The author was, like Elborne, unable to obtain any alkaloid from the hairs of *Strophanthus* seeds.

*Strophanthin* was prepared by dissolving the alcoholic extract, filtering, adding tannic acid in excess, and then collecting the precipitate, which after washing was mixed with basic lead acetate. The mixture was then dried, exhausted with warm alcohol, and filtered. Traces of lead were removed by hydrogen sulphide, and on evaporation *strophanthin* was obtained as a scaly residue, which was finally purified by solution in water and treatment with animal charcoal.

*Strophanthin* has well-marked glucosidal characters. The author was unable to obtain *strophanthin* in crystals as described by Fraser.

R. R.

**Cubebin.** By E. SCHÄR (*Arch. Pharm.* [3], 25, 531—539).—Cubeb powder when extracted with ether yields a compound which

closely resembles aconitine and digitalin in its reactions, and also shows some resemblance to veratrine and morphine. This is probably cubebin, a non-nitrogenous, indifferent substance occurring crystallised in cubebs. Comparing cubebin and veratrine, the sulphuric acid test is most characteristic when the substances are dissolved in chloroform. On contact with concentrated sulphuric acid, cubebin gives at once an intense purple-red colour at the surface of contact, whilst veratrine passes through orange-yellow, yellowish-red, and blood-red to purple-red; also a characteristic fluorescence appears in the latter case. Cubebin, unlike veratrine, gives no purple-cherry-red colour with concentrated hydrochloric acid, neither do cane-sugar and slightly diluted sulphuric acid give the very characteristic colour reaction of veratrine. Sulphuric acid containing 10 to 15 per cent. of water gives with cubebin after a longer or shorter time, according to the strength of the acid and the temperature, the beautiful red tint described by Grandeau as produced by digitalin with concentrated sulphuric acid. A little bromine added to the cubebin mixture produces sooner or later the strong blue-red coloration which has been considered as characteristic of digitalin. These two substances can be distinguished by their reactions with phosphomolybdic acid and with hydrochloric acid. The reactions of cubebin and aconitine are also compared and but slight differences were observed. The author hopes to investigate further. J. T.

#### **Pterocarpin and Homopterocarpin from Sandal Wood.**

By CAZENEUVE and HUGOUNENQ (*Compt. rend.*, **104**, 1722—1725).—Powdered sandal wood is mixed with an equal weight of calcium hydroxide, moistened with water, dried on a sand-bath, and extracted with ether. The colouring matter and resins unite with the lime and form compounds insoluble in ether. The yellow ethereal solution is distilled to dryness, the residue dissolved in alcohol of 93°, and afterwards recrystallised from alcohol and finally from ether. The product is a mixture of pterocarpin and homopterocarpin, and these can be separated by means of carbon bisulphide, which dissolves the homopterocarpin. 1 kilo. of sandal wood yields about 5 grams of homopterocarpin and 1 gram of pterocarpin.

*Pterocarpin*,  $C_{10}H_8O_3$ , forms white lamellar crystals insoluble in water and in cold alcohol, but somewhat more soluble in the hot liquid, slightly soluble in ether, from which it crystallises in lamellæ, insoluble in carbon bisulphide in the cold but slightly soluble on heating; readily soluble in chloroform, from which it crystallises in large monoclinic prisms with lævohemihedral faces. When dissolved in chloroform, it has a lævorotatory power  $[\alpha]_D = -211^\circ$ . When heated, it becomes pasty above 145°, and melts at 152° with slight decomposition. It has a neutral reaction, is insoluble in acids and in concentrated potash solution even when boiled, gives a green coloration with concentrated nitric acid, and is decomposed by fused potash with development of an odour of coumarin.

*Homopterocarpin*,  $C_{12}H_{12}O_3$ , has the same general properties as pterocarpin. It crystallises well in needles which are soluble in ether, chloroform, benzene, and carbon bisulphide. It is strongly lævogyrate, and when dissolved in chloroform has a rotatory power

$[\alpha]_D = -199^\circ$ . It softens at  $70^\circ$ , begins to melt at  $82^\circ$ , and is completely fused at  $86^\circ$ ; solidification takes place very slowly. Concentrated potash solution has no action even at  $200^\circ$ , but with fused potash it yields carbonic anhydride and phloroglucol, and an odour of coumarin is perceptible. When homopterocarpin is heated with twice its weight of concentrated hydrochloric acid at  $120^\circ$  for ten hours, it yields a red-brown, lustrous product which seems to be resorcinol ether,  $\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{O}\cdot\text{C}_6\text{H}_4\cdot\text{OH}$ . The supernatant acid has a yellow colour, and when the acid is expelled and the liquid mixed with ammonia a very fluorescent substance is obtained. Methyl chloride is also formed in this reaction. This result indicates that homopterocarpin contains the resorcinol-group with one or several methyl-groups. In its stability and general properties, it resembles the internal anhydrides of the benzene series, especially coumarin.

The compound now described as homopterocarpin was formerly called pterocarpin (*Bull. Soc. Chim.*, 1874). C. H. B.

**Bitter Principle of Calamus Root.** By A. GEUTHER (*Annalen*, 240, 92—110).—The author has repeated the experiments of Thoms (Abstr., 1886, 895), and obtained the following results: (1) the acorin prepared by Thoms' method contains nitrogen; it is a mixture of ethereal oil, acid, and bitter principle. No sugar is formed when it is boiled with dilute alkali. (2) Thoms' acoretin is not a product of acorin but forms the bitter principle contained in that substance. Acoretin is not reduced by nascent hydrogen but remains unaltered. When calamus root is steam distilled, a distillate containing methyl alcohol is obtained. N. H. M.

**Chlorophyll.** By E. SCHUNCK (*Proc. Roy. Soc.*, 42, 184—188).—The author prepares compounds of phyllocyanin and carbonic anhydride. Carbonic anhydride passed through alcoholic phyllocyanin in the presence of ferrous hydrate gave no result. With copper oxide, a slight action took place. With zinc oxide, the colour of the phyllocyanin changes to bluish-green, exhibiting absorption-bands similar to those of phyllocyanin zinc acetate. On adding acid, it is decomposed into phyllocyanin and carbonic anhydride. The absorption-bands and general properties of phyllocyanin zinc-compounds resemble those of chlorophyll. In order to determine their relative stability, compounds of phyllocyanin with zinc, ferrous, and cupric acetates together with uncombined phyllocyanin and chlorophyll were exposed to air and daylight. The cupric compound was very stable, whilst the zinc-compound decomposed almost as easily as chlorophyll itself, the ferrous compound holding a position between the zinc-compound and uncombined phyllocyanin. On boiling phyllocyanin with aqueous potash and zinc-dust, and acidifying with acetic acid, a precipitate is obtained which dissolves in ether, giving absorption-bands similar to those of phyllocyanin zinc acetate, but moved further away from the red. Compounds having characteristic absorption-bands are also obtained by the action of hydrochloric acid and tin on phyllocyanin.

H. K. T.

**Derivatives from  $\alpha$ -Quinolinedisulphonic Acid.** By W. LA COSTE and F. VALEUR (*Ber.*, 20, 1820—1827).—The author has already described (*Abstr.*, 1886, 629)  $\alpha$ -dihydroxyquinoline obtained from the above acid. The *hydrochloride*,  $C_9NH_5(OH)_2.HCl + H_2O$ , crystallises in plates, is soluble in water, and melts at 254—256°. The *platinochloride* form a yellow, crystalline precipitate; the *picrate* yellow needles, soluble in warm water and alcohol, and melting at 227—237°. The *dibenzoate*,  $C_9NH_5(OBz)_2$ , yields white needles which dissolve in alcohol, ether, &c., but not in water or alkalis; it melts at 130—134°.

The *monacetate* crystallises in white needles, soluble in alcohol, ether, and boiling water, and melting at 115—117°; no diaceto-compound could be obtained. *Methoxy-hydroxyquinoline*,  $OH.C_9NH_5.OMe$ , is formed by the action of methyl iodide on dihydroxyquinoline dissolved in alcoholic potash. It forms an unstable oil soluble in boiling water. The *hydrochloride* crystallises in anhydrous needles, which under water become converted into prisms containing 1 mol.  $H_2O$ ; it is soluble in hot water, and melts at 255—259°. The *platinochloride* forms insoluble needles which decompose when heated with water. The *picrate* yields yellow needles soluble in boiling water, and melting at 221—226°. *Dimethoxyquinoline*,  $C_9NH_5(OMe)_2$ , is produced when methyl iodide is heated with a magma formed of dihydroxyquinoline, potash, and very little methyl alcohol. It forms an oil which is not volatile with steam. The *hydrochloride* is left as an oil on evaporating its aqueous solution, but may be obtained crystalline from ether; it melts at 262—266°. The *platinochloride* forms dark-red monoclinic crystals; the *picrate* broad, yellow needles melting at 102—104°; the *methiodide* pale-yellow crystals melting at 210—212°.

L. T. T.

**Existence of two Series of 4-(Ana)substituted Derivatives of Quinoline.** By E. LELLMANN (*Ber.*, 20, 2172—2177).—When quinoline (1 part) is sulphonated with fuming sulphuric acid (5 parts), containing 1 part of sulphuric anhydride dissolved in 2 parts of ordinary sulphuric acid, at temperatures rising by 20° intervals between 180° and 260°, the yield of anaquinolinesulphonic acid is found to gradually increase with the rise of temperature. After removal of the greater part of the orthoquinolinesulphonic acid by crystallisation, the ana-acid can readily be obtained by heating the mixed crystals of the later separations at 110°, when it effloresces and can be separated by means of a sieve from the crystals of the ortho-acid. The ana-acid prepared in this way is identical with that obtained by the author and Lange from metamidobenzenesulphonic acid by Skraup's reaction (this vol., p. 737), also with that obtained by La Coste and Valeur by sulphonating quinoline (this vol., p. 379), and erroneously described by them as anhydrous, but it differs from that prepared by Fischer and Riemerschmid by direct sulphonation (*Abstr.*, 1883, 91).

Fusion with a large excess of potassium hydroxide converts the author's anaquinolinesulphonic acid into a mixture of hydroxy- and dihydroxy-quinoline. *Dihydroxyquinoline*,  $C_9NH_5(OH)_2$ , crystallises in large, glistening, greenish-brown needles, becomes brown at 260°, melts above 320°, and is soluble in all the ordinary solvents. It yields

a hydrochloride which crystallises in lustrous, yellow needles, and is decomposed by water, but it does not form a platinochloride. Hydroxyquinoline,  $C_9NH_6 \cdot OH$ , forms small, silvery scales, becomes brown at  $210^\circ$ , melts at  $224^\circ$ , and on fusion with potassium hydroxide is partially converted into the foregoing dihydroxyquinoline; its *platinochloride*,  $(C_9NH_6O)_2 \cdot H_2PtCl_6 + 4H_2O$ , crystallises in long, broad, brittle needles. This hydroxyquinoline differs from those obtained by Skraup's reaction from ortho-, meta-, and para-amidophenol, but resembles, in its melting point and other properties, the so-called  $\beta$ -hydroxyquinoline prepared by Skraup from amidoquinoline (m. p. =  $109-110^\circ$ ), formed by the reduction of the nitroquinoline (m. p. =  $72^\circ$ ) isolated by Claus and Kramer from the product of the direct nitration of quinoline (Abstr., 1885, 908); it is probably identical also with Riemerschmid's hydroxyquinoline obtained by the fusion of his 4-quinolinesulphonic acid with soda (*Inaug. Dissert*; comp. Abstr., 1883, 91).

Rejecting the hypotheses (1) that the quinolinesulphonic acids prepared by Riemerschmid and himself differ only in the fact that the former is anhydrous and the latter hydrated, or (2) that Riemerschmid's acid contains the sulphonic group in some position other than 4, and that intramolecular change to the 4-position occurs during fusion, the author regards the two acids as isomeric 4-quinolinesulphonic acids, and ascribes their isomerism to a cause similar to that obtaining in the case of the 4-quinolinecarboxylic acids (this vol., p. 502). The formation of the same hydroxyquinoline from the two isomerides is accounted for by assuming that only one of the two (supposed) possible hydroxy-derivatives is stable at the high temperature, and that the unstable form undergoes changes into this during the fusion.

W. P. W.

**Action of Aniline on Mixtures of Alliphatic Aldehydes.** By W. v. MILLER (*Ber.*, 20, 1908—1911).—Extending his own and Doeberner's (Abstr., 1884, 1375) and C. Beyer's (Abstr., 1886, 629) work, the author has studied the action of aniline on a mixture of isobutaldehyde and acetaldehyde in the presence of hydrochloric acid. The product contained quinaldine and  $\alpha$ -isopropylquinoline, the latter corresponding with Doeberner's description (this vol., p. 504). The two bases were separated by means of their platinochlorides, that of quinaldine being the less soluble.

L. T. T.

**Action of Aniline on a Mixture of Acetaldehyde and Propionaldehyde.** By G. ROHDE (*Ber.*, 20, 1911—1915).—The author prepared  $\alpha$ - $\beta$ -dimethylquinoline by the action of aniline on tiglic aldehyde (Lieben and Zeisel, Abstr., 1886, 783). It crystallises in rhombic plates or prisms, melts at  $66^\circ$ , and boils at  $255-260^\circ$ . It is slightly soluble in water, readily in organic solvents. The platinochloride and picrate are both crystalline. Another quinoline base was formed in small quantity at the same time, but has not yet been identified. When a mixture of acetic and propionic aldehydes was used in place of tiglic aldehyde the same dimethylquinoline was formed, together with  $\alpha$ -ethyl- $\beta$ -methylquinoline and quinaldine.

When quinaldine is fused with benzil, an acridine base is formed.

It is crystalline, and melts at  $173^{\circ}$ . Dimethylquinoline under like treatment yields two other bases melting at  $120^{\circ}$  and  $240^{\circ}$  respectively, and now under investigation.

L. T. T.

**Action of Aniline on a Mixture of Propaldehyde and Methylal.** By W. v. MILLER and F. KINKELIN (*Ber.*, 20, 1916—1918).—In this reaction,  $\beta$ -methylquinoline and  $\alpha$ -ethyl- $\beta$ -methylquinoline are formed. When formaldehyde is substituted for methylal,  $\beta$ -methylquinoline and  $\gamma$ -ethyl- $\beta$ -methylquinoline are formed, but the yield is very small. Attempts to prepare quinoline by the action of aniline on a mixture of formic and acetic aldehydes were unsuccessful.

L. T. T.

**Condensation of Quinaldine with Aldehydes.** By W. v. MILLER (*Ber.*, 20, 2041).—A note calling attention to the point brought out in the researches of the author's pupils (see following Abstracts), that the first product of the condensation of quinaldines with an aldehyde is an aldol-like compound, which, however, cannot be isolated in every case, owing to the readiness with which it loses the elements of a molecule of water and is converted into an unsaturated compound.

W. P. W.

**Action of Isobutaldehyde on Quinaldine.** By J. C. A. BRUNNER (*Ber.*, 20, 2041—2042).—When equal weights of quinaldine and zinc chloride are heated at  $100^{\circ}$  with twice the theoretical quantity of isobutaldehyde, condensation occurs, and the product, after washing with hot water and aqueous soda yields, on extraction with ether and evaporation of the ethereal solution, a crystalline base, and a reddish-yellow, oily mother-liquor. The base,  $C_9NH_6 \cdot CH_2 \cdot CH(OH) \cdot CHMe_2$ , crystallises in snow-white, spherical aggregates of microscopic needles, melts at  $93^{\circ}$ , and is readily soluble in ether, benzene, and alcohol, soluble in light petroleum and hot water. The salts formed with mineral acids are syrups, which can only be crystallised with much difficulty, and are readily soluble in alcohol; the *picrate*,  $C_{20}H_{10}N_4O_8$ , forms small, prismatic crystals belonging to the triclinic system, melts at  $143$ — $145^{\circ}$ , and decomposes at  $150^{\circ}$ .

W. P. W.

**Action of Paraldehyde on Quinaldine.** By F. EISELE (*Ber.*, 20, 2043).— $\alpha$ -Allylquinoline,  $C_9NH_6 \cdot CH : CHMe$ , [ $C_2H_5Me = 2'$ ], is obtained when equimolecular proportions of quinaldine and paraldehyde are heated at  $210^{\circ}$  for four to five hours, and on distillation of the product after separation of the accompanying water is found in the fraction  $249$ — $253^{\circ}$ . During the distillation, water is formed, and this is considered to prove that the aldol-like compound,

is also one of the products of the reaction.  $\alpha$ -Allylquinoline yields a hydrochloride and sulphate crystallising in needles, and a *platinochloride*,  $(C_{12}H_{11}N)_2 \cdot H_2PtCl_6$ , which crystallises in small, yellow tablets, and is insoluble in alcohol.

W. P. W.

**Action of Furfuraldehyde on Quinaldine.** By J. O. SRPEK (*Ber.*, 20, 2044—2045).—When furfuraldehyde and quinaldine in molecular proportion are heated for two hours at 100° with a small quantity of zinc chloride, and after removal of the unaltered quinaldine the product is extracted with dilute hydrochloric acid, and the solution subsequently neutralised, a base,  $C_{15}H_{11}NO$ , is obtained, which crystallises from light petroleum at first in tufts of needles, afterwards in rhombic tables, and becomes black on exposure to light. The *hydrochloride*,  $C_{15}H_{11}NO \cdot HCl$ , crystallises in small, yellow needles, the *nitrate*,  $C_{15}H_{11}NO \cdot HNO_3$ , in small needles, and the *sulphate*,  $C_{15}H_{11}NO \cdot H_2SO_4 + H_2O$ , in small, reddish needles; the *platinochloride*,  $(C_{15}H_{11}NO)_2 \cdot H_2PtCl_6 + 2H_2O$ , is a yellow crystalline compound, sparingly soluble in water and alcohol, and the *picrate*,

crystallises in small yellow needles.

W. P. W.

**Action of Paranitrobenzaldehyde on Quinaldine.** By W. BULACH (*Ber.*, 20, 2046—2047).—An aldol-like base,

is obtained when paranitrobenzaldehyde and quinaldine in molecular proportion are heated at 120° for three hours. It crystallises from alcohol in white, silky needles, and melts at 160°. The *platinochloride*,  $(C_{17}H_{14}N_2O_3)_2 \cdot H_2PtCl_6$ , is a brick-red, crystalline precipitate; the *nitrate*,  $C_{17}H_{14}N_2O_3 \cdot HNO_3$ , forms white needles, and the *picrate* crystallises in yellow scales.

*Paranitrobenzylidenequinaldine*,  $C_9NH_6 \cdot CH : CH \cdot C_6H_4 \cdot NO_2$ , is formed when the preceding base is heated with acetic anhydride on a sand-bath for three hours; it crystallises in tufts of needles, melts at 164—165°, and is readily soluble in ether, chloroform, light petroleum, and hot alcohol.

W. P. W.

**Methylation of Indole.** By E. FISCHER and A. STECHE (*Ber.*, 20, 2199—2201).—In a previous communication (this vol., p. 588) the authors described a base,  $C_{11}H_{13}N$ , obtained by treating methylketole with methyl iodide; this base they considered probably might be a quinoline-derivative. In the present paper, this supposition is confirmed, as the base on treatment with tin and hydrochloric acid is converted into *dimethyltetrahydroquinoline*,  $C_9NH_6Me_2$  [Me : Me = 1' : 3']. This boils at 239°. When treated with methyl iodide, it yields the quarternary ammonium iodide,  $C_9NH_6Me_3I$ , melting with decomposition at 250—251°. The yellow, crystalline picrate melts at 161—162°.

When methylketone is heated in alcoholic solution with excess of ethyl iodide for 15 hours on the water-bath, it is converted into ethylmethylketole and a base boiling at 255—257°, most probably *dihydroethylmethylquinoline*,  $C_9NH_6Me_2Et$  [Et : Me : Me = 1' : 2' : 3']. Its methiodide melts at 189° (uncorr.).

*Ethylmethylketole*,  $C_8NH_5MeEt$  [Et : Me = 1' : 2'], boils at 287—288°

under 752 mm. pressure; it colours pinewood red, gives a dark-red picrate, and is insoluble in dilute acids.

Benzyl chloride also reacts with methylketole to form a quinoline base, but the yield is very small. Benzal chloride and benzotrichloride behave quite differently, the former acting like benzaldehyde (this vol., p. 265), the latter like benzoic chloride (this vol., p. 58).

1'-Methylindole is scarcely attacked by methyl iodide at 100°, but on heating the mixture for 12 hours at 120°, a good yield is obtained of a base, which probably is methyldihydroquinoline,  $C_9NH_8Me$  [Me = 1'].

A. J. G.

**Derivatives of Pseudocarbostyryl.** By P. FRIEDLÄNDER and F. MÜLLER (*Ber.*, **20**, 2009—2017; compare *Abstr.*, 1885, 989).—*Methylpseudocarbostyryl* is obtained when a solution of carbostyryl in 12 parts of alcohol and so much water that the hot solution remains clear is mixed with a slight excess of methyl iodide and the whole boiled in a reflux apparatus, a concentrated aqueous solution of sodium hydroxide (1 mol.) being gradually added. The alcohol is distilled off, the residue treated with soda and extracted with chloroform. It crystallises from light petroleum in slender, white needles melting at 71·5°, readily soluble in acetone, alcohol, and chloroform. The *platinochloride*,  $(C_{10}H_9NO)_2 \cdot H_2PtCl_6 + 2H_2O$ , is sparingly soluble; the *mercurichloride*,  $C_{10}H_9NO \cdot HgCl_2$ , crystallises from water in small, lustrous prisms melting at 189°. When methylcarbostyryl is reduced by means of sodium in alcoholic solution, methylhydroquinoline is formed. When oxidised with potassium permanganate, a compound is obtained, which yields methylamine and an acid when boiled with baryta-water. Sodium amalgam converts methylpseudocarbostyryl into a compound,  $C_{10}H_{10}NO$ , crystallising in small, lustrous plates which melt at 275—276°, and what is probably methylhydrocarbostyryl,  $C_{10}H_{11}NO$ . In like manner, carbostyryl is converted into hydrocarbostyryl and a sparingly soluble compound,  $C_9H_8NO$ , which melts above 300°. This behaviour is analogous to that of ethoxycarbostyryl (*Ber.*, **15**, 336 and 1424), which yielded on reduction two compounds, a lactim ether and a solid non-volatile compound, to which the formula of a dihydroethylcarbostyryl,  $C_{11}H_{13}NO$ , was ascribed. The analyses agree, however, better with the formula  $C_{11}H_{12}NO$ . When warmed with hydrochloric acid, it yields a compound identical with the product of reduction of carbostyryl. The sparing solubility, high melting point, and indifferent behaviour of these reduction products, make it probable that two or more molecules have united.

$\gamma$ -Chloromethylpseudocarbostyryl,  $C_7NH_5MeOCl$  [Me : O : Cl = 1' : 3' : 4'], is obtained from  $\gamma$ -chlorocarbostyryl in a manner similar to methylpseudocarbostyryl. It crystallises from methyl alcohol in hair-like needles which melt at 117·5°, dissolve readily in benzene, alcohol, acetone and chloroform, &c., sparingly in water and in light petroleum. It resembles methylpseudocarbostyryl. When treated with alcoholic soda solution, the chlorine is readily displaced by methoxyl or ethoxyl.

$\gamma$ -Methoxymethylpseudocarbostyryl,  $C_7NH_5MeON \cdot OMe$  [OMe = 4'], crystallises from dilute alcohol in slender, white needles which melt at 68°, and dissolve readily in alcohol, benzene, chloroform, and hot water;

it has stronger basic properties than methylpseudocarbostyryl, and yields a sparingly soluble *hydrochloride*; the *platinochloride*,

crystallises in long pyramids. The  $\gamma$ -ethoxy-compound crystallises from water in slender, white needles which melt at  $87.5^\circ$ . When heated with hydrochloric acid at  $120^\circ$ , both alkoxy-derivatives yield a compound,  $\text{C}_9\text{NH}_6\text{MeO}_2$ , which crystallises in white needles melting at  $259\text{--}260^\circ$ ; it is soluble in the usual solvents, and in caustic alkalis, from which it is precipitated by carbonic anhydride.

It has the constitution  $\text{C}_6\text{H}_4\langle \begin{smallmatrix} \text{C}(\text{OH}) : \text{CH} \\ \text{NMe} \cdot \text{CO} \end{smallmatrix} \rangle$ , or  $\text{C}_6\text{H}_4\langle \begin{smallmatrix} \text{CO} \cdot \text{CH}_2 \\ \text{NMe} \cdot \text{CO} \end{smallmatrix} \rangle$ .

When treated with nitrous acid, a sparingly soluble nitroso-derivative,  $\text{C}_{10}\text{H}_8\text{NO}_2 \cdot \text{NO}$ , is formed. This crystallises from acetic acid in red needles which decompose at about  $188^\circ$ , dissolve in alkaline carbonates with green coloration, and yield methylpseudoisatin when heated with hydrochloric acid at  $120^\circ$ . Stannous chloride reduces it to  $\beta$ - $\gamma$ -dihydroxymethylpseudocarbostyryl; this crystallises from alcohol in sparingly soluble needles which decompose at  $210^\circ$ . When a drop of soda is added to the alcoholic solution, a greenish-blue precipitate is formed which gradually dissolves with yellow colour; on adding ferric chloride, it acquires an emerald-green colour, which changes to reddish-yellow on warming, and it then contains a *pseudoquinisatin*,  $\text{C}_6\text{H}_4\langle \begin{smallmatrix} \text{CO} \cdot \text{CO} \\ \text{NMe} \cdot \text{CO} \end{smallmatrix} \rangle$ . The latter is very readily soluble in the usual solvents, dissolves in alkalis with yellow coloration, and melts at about  $120\text{--}122^\circ$ .  
N. H. M.

**$\alpha$ -Metanitrophenylparamethoxyquinoline and its Derivatives.** By W. v. MILLER and F. KINKELIN (*Ber.*, 20, 1919—1927). — $\alpha$ -Metanitrophenylparamethoxyquinoline,  $\text{C}_9\text{NH}_5(\text{OMe}) \cdot \text{C}_6\text{H}_4 \cdot \text{NO}_2$  [ $\text{C}_6\text{H}_4 \cdot \text{NO}_2 : \text{OMe} = 2' : 4'$ ], was prepared by treating a mixture of meta-nitrocinnamaldehyde and paranisidine with hydrochloric acid. It crystallises in glistening yellowish needles, melts at  $130^\circ$ , and is soluble in benzene, sparingly so in ether. Its salts are decomposed by water and their alcoholic solutions are not fluorescent. The *chloride* and *platinochloride* crystallise in needles. When the nitro-compound is reduced with stannous chloride, it yields  $\alpha$ -metamidophenylparamethoxyquinoline, which crystallises in colourless iridescent needles, melts at  $127^\circ$ , and is soluble in ether and benzene, sparingly so in alcohol and boiling water. It forms three series of salts, acid, normal, and basic. The *sulphate*,  $\text{C}_{16}\text{H}_{14}\text{N}_2\text{O} \cdot \text{H}_2\text{SO}_4 + 2\text{H}_2\text{O}$ , crystallises in concentrically grouped yellow needles; the *hydrochloride*,  $\text{C}_{16}\text{H}_{14}\text{N}_2\text{O} \cdot 2\text{HCl} + \text{H}_2\text{O}$  in yellow prisms, and the *platinochloride*,  $\text{C}_{16}\text{H}_{14}\text{N}_2\text{O} \cdot \text{H}_2\text{PtCl}_6 + \text{H}_2\text{O}$ , in thin, glistening prisms.  $\alpha$ -Metamidophenylparamethoxyhydroquinoline is obtained from the amido-derivative by the action of tin and hydrochloric acid. It forms crystals melting at  $87^\circ$ . The *hydrochloride* forms compact plates; the *platinochloride* a brown, amorphous precipitate.

$\alpha$ -Metahydroxyphenylparamethoxyquinoline is obtained by diazotising the amido-base. It crystallises in scales, is soluble in alcohol, melts

at  $188^{\circ}$ , and forms compounds with alkalis. The *hydrochloride* and *sulphate* form yellow crystals, and the acid solutions are not fluorescent. When a dilute sulphuric solution is treated with chlorine-water, the precipitate formed redissolved by the addition of soda. and ammonia added immediately, this base shows the green coloration hitherto considered characteristic of quinine, and this coloration becomes more marked on further dilution with water. The amido-base does not show this reaction, the nitro-base but very slightly.  $\alpha$ -*Meta-hydroxyphenylparamethoxyhydroquinoline* is formed from the hydroxy-base by the action of tin and hydrochloric acid. It crystallises in plates melting at  $110$ — $111^{\circ}$ , and is easily soluble in alcohol and ether. The *hydrochloride* forms small plates, and gives an intense green coloration with ferric chloride. The *sulphate* and *sodium-derivative* are both crystalline.

The  $\alpha$ - and  $\beta$ -*paramethoxydiquinolyl*,  $C_{19}N_2H_{14}O$ , were obtained by Skraup's reaction by heating the amido-base with glycerol, strong sulphuric acid, and nitro-phenol. The  $\alpha$ -base is soluble in alcohol (but much less so than the  $\beta$ -base), ether, and benzene, sparingly in boiling water; it melts at  $151^{\circ}$ , but cannot be distilled without decomposition. Its ethereal solution shows blue fluorescence. Its salts are yellow; the *methiodide* is a yellow, crystalline powder. The  $\beta$ -base is easily soluble in benzene and alcohol, sparingly so in ether, and the two latter solutions show blue fluorescence. Its melting point is not definite. The *hydrochloride* and *platinochloride* are crystalline. These bases only show the green colour reaction, mentioned above, to a very slight extent.

L. T. T.

**Oxidation-products of Diquinoline** [ $2' : 2'$ ]. By H. WEIDEL and J. WILHELM (*Monatsh. Chem.*, 8, 197—200; compare Abstr., 1886, 949 and 950).—In a former paper (Abstr., 1886, 950), the authors considered that all the evidence pointed to the constitutional formula of cyclothraustic acid being  $C_9NH_6 \cdot C(OH) : N \cdot C_6H_4 \cdot COOH$ . They find, however, that when a mixture of anthranilic acid and quinaldine is heated, a substance is obtained which agrees in all respects with cyclothraustic acid, the constitution of which must therefore be  $C_9NH_6 \cdot CO \cdot NH \cdot C_6H_4 \cdot COOH$ , and consequently that of pyridanthrilic acid,  $C_9NH_2(COOH)_2 \cdot CO \cdot NH \cdot C_6H_4 \cdot COOH$ .

G. H. M.

**Bases in Galician Petroleum.** By F. X. BANDROWSKI (*Monatsh. Chem.*, 8, 224—226).—The author has isolated a very small quantity of a base or series of bases from Galician petroleum. The substance gives all the reactions for and seems to belong to the group of alkaloids.

G. H. M.

**Occurrence of Alkaloid-like Bases in Paraffin Oil.** By A. WELLER (*Ber.*, 20, 2097—2099).—The so-called yellow oil of sp. gr. 0.850—0.860, obtained in the manufacture of Saxon petroleum, contains small quantities of basic substances, which can be separated by shaking with dilute sulphuric acid, precipitating with aqueous soda, and extracting with ether. A partial purification is then effected by redissolving and reprecipitating several times, and finally the dark-

brown product is subjected to steam-distillation to remove the non-volatile fluorescent impurities. The bases are thus obtained as a colourless oil, which is free from oxygen and sulphur, has an intensely unpleasant odour, and a sp. gr. = 0.98—0.99, does not solidify at  $-11^{\circ}$ , and is readily soluble in alcohol, ether, and chloroform, very sparingly soluble in water. Bromine and methyl iodide react with the mixture of bases, and form non-crystalline products, and treatment with concentrated aqueous potash causes the evolution of strongly alkaline but ammonia-free vapours. A separation of the bases cannot be effected by repeated fractional distillation, since the product obtained after many distillations boils, like the oil, between  $220^{\circ}$  and  $260^{\circ}$ , without the thermometer remaining constant at any one point. The most characteristic salt described is the oxalate, which crystallises in scales, and is soluble in alcohol, chloroform, benzene, and light petroleum, sparingly soluble in ether and water.

W. P. W.

**Normal Quinine Hydrochloride.** By A. CLERMONT (*J. Pharm.* [5], 15, 15).—A solution of the normal hydrochloride

is easily obtained, either by mixing equivalent solutions of normal quinine sulphate and barium chloride, or by adding an equivalent of hydrochloric acid to a solution of basic quinine hydrochloride. The solution obtained by either process, when completely evaporated below  $100^{\circ}$ , yields the normal hydrochloride. This salt dissolves easily in its own weight of water at the ordinary temperature, and appears to be suitable for hypodermic injections, as its solution is not caustic. Below  $5^{\circ}$ , it becomes a mass of crystals, which again liquefy at  $15^{\circ}$ .

J. T.

**Amorphous Cocaïne.** By R. STOCKMAN (*Pharm. J. Trans.* [3], 17, 861).—From the properties and reactions of amorphous cocaïne, it is concluded that the substance really consists of ordinary crystalline cocaïne retained in the amorphous state by *hygrine*, the liquid alkaloid which is also present in cocaïne leaves.

R. R.

**Emetine.** By H. KUNZ (*Arch. Pharm.* [3], 25, 461—479).—Ipecacuanha powder was extracted with ether until all soluble matter was removed. The dried powder was then treated with strong alcohol, and the tincture thus obtained freed from spirit by distillation. The dry residue was freed from tannic acid by the addition of 10 to 13 per cent. of ferric chloride in concentrated solution, and the addition of sodium carbonate to strong alkaline reaction, too much liquid being carefully avoided. The sodium carbonate sets free emetine, but not the tannic acid, and the former can be extracted by boiling with light petroleum. The author, however, finds it best to dry the mass on the water-bath, powder finely, and extract with hot alcohol. On distilling off the alcohol, the resulting impure emetine is dissolved in dilute sulphuric acid, fractionally precipitated by ammonia, and these precipitates are now dissolved in boiling light petroleum. From the saturated petroleum solution, the emetine separates

spontaneously on cooling or on passing a current of air, in the form of a snow-white amorphous powder. 10 kilos. of root gave 80 grams of pure emetine. The powder again dissolved in sulphuric acid, precipitated by ammonia, and taken up with light petroleum as above, gives a perfectly white, amorphous powder, highly electric, and quickly becoming yellow to brown in the light, soluble in alcohol to a wine-yellow solution. It is very sparingly soluble in cold water, but somewhat more soluble on heating. Light petroleum and ether dissolve only traces in the cold, but take up a large quantity when boiling. Methyl alcohol, chloroform, and benzene are also good solvents of emetine. The base has a decided alkaline reaction with litmus-paper. It fuses to a colourless liquid, which gradually passes through yellow to brown. The melting point appears to vary with the molecular condition and the state of dryness of the sample, from  $65^{\circ}$  to  $74^{\circ}$ . The formula seems to be  $C_{30}H_{40}N_2O_5$ . Emetine platinochloride,  $C_{30}H_{40}N_2O_5 \cdot H_2PtCl_6$ , is a whitish-yellow powder, unchanged in sunlight. Emetine appears to be, like quinine, a diatomic diamine. The chromate,

was also prepared. Emetine is insoluble in soda and potash, ammonia, and the corresponding carbonates. A methiodide,  $C_{30}H_{40}MeN_2O_5I$ , is readily formed, even in the cold.

*Methylemetonium hydroxide*,  $C_{30}H_{40}MeN_2O_5 \cdot OH$ , is obtained by treating the iodide with silver oxide; it is strongly alkaline. Various salts of this base are described by the author. He further shows that emetine, like quinine, is probably a quinoline-derivative, and that the *Radix ipecacuanhæ* contains bilineurin or choline. J. T.

**Alkaloids of Gelsemium Root.** By F. A. THOMPSON (*Pharm. J. Trans.* [3], 17, 805—808).—The author has isolated a second alkaloid, *gelseminine*, from the root of *Gelsemium sempervirens*.

Analyses of gelsemine and several of its salts point to the formula  $C_{54}H_{69}N_4O_{12}$  (Gerrad considered it to be  $C_{24}H_{28}N_2O_4$ ). It is tribasic. The following salts were analysed:—Hydrochloride,  $C_{54}H_{69}N_4O_{12} \cdot 3HCl$ ; aurochloride,  $C_{54}H_{69}N_4O_{12} \cdot 3HAuCl_4$ ; platinochloride,

The nitrate and sulphate are also described, as are further several colour reactions for the alkaloid.

*Gelseminine* could not be obtained in a state fit for analysis. It is a dark-brown resinous mass, permanent in air, sparingly soluble in water and light petroleum, readily so in alcohol, ether, and chloroform. It has strongly marked basic properties, but only amorphous salts have been obtained. Its reactions are described in detail.

A. J. G.

**Asiminine.** By J. U. LLOYD (*Arch. Pharm.* [3], 25, 503).—The alkaloid is obtained from the seed of *Asimina triloba* (Papaveraceæ) by extraction with alcohol, concentrating, and, to separate the fatty oil, diluting with water, acidifying with acetic acid, shaking well, and filtering after 24 hours. Ammonia is added to the filtrate until only a slight precipitate results, and the still moist precipitate is shaken

with ether. The residue from evaporation of the ethereal extract is taken up with a little alcohol, and a slight excess of hydrochloric acid is added. With a concentrated solution, the whole mass becomes crystalline, whilst a dilute solution requires concentration. The hydrochloride thus obtained can be purified by recrystallisation from hot alcohol. The pure alkaloid can be obtained by solution in water, precipitation by ammonia, and drying. It is white, amorphous, tasteless, and odourless; insoluble in water, easily soluble in alcohol and ether, less soluble in chloroform and benzene. Excepting the acetate and nitrate, its salts are easily crystallised. The hydrochloride is slightly soluble in water, the other salts are easily soluble, and have a bitter taste. Minute quantities give with nitric acid a carmine-red coloration, which quickly becomes purple-red, and can easily be mistaken for morphine. With sulphuric acid, asiminine effervesces and dissolves with a yellowish-green colour, gradually passing through yellowish-red to dark red. Hydrochloric acid after warming, and the addition of some sulphuric acid, produces a purple-red colour in the liquid. J. T.

**Cholic Acid.** By F. MYLIUS (*Ber.*, **20**, 1968—1989; compare this vol., p. 606).—Cholic acid is readily purified by recrystallisation from alcohol. The results of several analyses of the acid and of the silver salt point to the formula  $C_{24}H_{40}O_5$  (compare Latschinoff, this vol., p. 682). It readily forms stable compounds with alcohols. The compound  $C_{24}H_{40}O_5 + MeOH$  forms colourless tetrahedra; compounds with propyl and ethylene alcohols were also prepared. No double compound with acetone could be obtained. Cholamide (Hüfner, *Abstr.*, 1879, 949) crystallises from water with 3 mols.  $H_2O$ ; it melts at  $130-140^\circ$ , solidifies at  $180^\circ$ , and melts then at  $228^\circ$  without decomposition or loss of weight; when it is recrystallised from alcohol, it again has the low melting point. When cholic acid is heated, it appears to yield a mixture of different anhydrides. *Phenylmercaptan-dehydrocholic acid*,  $C_{36}H_{44}O_4S_2$ , is obtained by passing hydrogen chloride through a solution of dehydrocholic acid in phenyl mercaptan, and crystallises from alcohol in lustrous needles melting at  $220^\circ$ . It has acid properties; the sodium salt forms hair-like needles. *Phenylmercaptan-phenylhydrazine-dehydrocholic acid*,

melts at  $210-220^\circ$ ; it is almost insoluble in alcohol and glacial acetic acid.

Bilianic acid is prepared by adding 20 grams of cholic acid (free from alcohol) to a mixture of 60 grams of sulphuric acid, 160 c.c. of water, and 40 grams of potassium dichromate. It is purified by means of the potassium salt. It has the formula  $C_{24}H_{34}O_8$ . The silver salt,  $C_{24}H_{31}O_8Ag_3$ , was analysed. The *hydroxylamine compound*,  $C_{24}H_{36}N_2O_8$ , crystallises in lustrous plates soluble in dilute alcohol; the *phenylhydrazine-derivative*,  $C_{36}H_{46}N_4O_6$ , is sparingly soluble.

When crude bilianic acid is boiled with baryta-water, the barium salt of isobilianic acid is formed; the latter is readily soluble in cold, almost insoluble in hot water.

The above results point to the following three formulæ for cholic acid, dehydrocholic acid, and bilianic acid respectively :—

Cholic acid does not contain an aromatic nucleus, and the readiness with which it is destroyed by oxidation makes it improbable that any other closed-chain nucleus is present.

N. H. M.

**Myohæmatin.** By C. A. MACMUNN (*Journ. Physiol.*, **8**, 51—65).—Myohæmatin can be obtained in solution by extracting the muscles which contain it with ether. As a result of osmotic phenomena, a muscle juice exudes, and floating above it is the ether which, if the muscles of pigeons be used, contains in solution a yellow lipochrome. The muscle juice itself is of a red colour, and gives the spectrum of modified myohæmatin, which is not altered by a stream of either oxygen or carbonic acid. The juice is acid in reaction, and contains various proteïds, in addition to the myohæmatin, and also creatin, which crystallises out on evaporation.

W. D. H.

## Physiological Chemistry.

**Sensitiveness of the Sense of Smell.** By E. FISCHER and F. PENZOLDT (*Annalen*, **239**, 131—136).—The authors find that 1 vol. of mercaptan vapour in 50,000,000,000 vols. of air is clearly perceptible to the sense of smell, and 1 vol. of chlorophenol in 1,000,000,000 of air; or it is possible to detect by their odour  $\frac{1}{4,600,000}$  mgrm. chlorophenol and  $\frac{1}{460,000,000}$  mgrm. mercaptan.

W. C. W.

**New Constituent of Blood-serum.** By L. C. WOOLDRIDGE (*Proc. Roy. Soc.*, **42**, 230—232).—A very small quantity of a proteïd substance, serum-fibrinogen, can be obtained by rendering undiluted serum distinctly acid by means of dilute acetic or sulphuric (4 per 1000) acid. It is constantly present in the serum of dog's and sheep's blood, but absent from that of the horse and ox. In physical characters, it resembles fibrin, but is more readily soluble in dilute alkali than that substance. It is totally different from paraglobulin, and is interesting in view of Schmidt's theory that two proteïds are necessary for coagulation; it was perhaps an admixture of this substance with paraglobulin that led Schmidt to suppose that the latter substance is one of the two necessary proteïds. On adding a solution of serum fibrinogen to peptone plasma, coagulation is brought about in a few minutes. After injecting it into the circulation, the shed blood remains-uncoagulated for many hours. It has an extremely feeble influence on magnesium sulphate plasma, and hence contains but a trace of fibrin ferment.

W. D. H.

**Muscle Plasma.** By W. D. HALLIBURTON (*Proc. Roy. Soc.*, **42**, 400—401).—The facts described by Kühne relating to the properties of the muscle plasma of cold-blooded animals are true in great measure for that of mammals.

Admixture of muscle plasma with solutions of neutral salts prevents the coagulation of the latter. Dilution of such salted muscle plasma brings about coagulation; this occurs most readily at 37—40°. Saline extracts of rigid muscle differ from salted muscle plasma in being acid, but resemble it very closely in the way in which myosin can be made to separate from it; myosin in fact undergoes a recoagulation. This is not a simple precipitation; it is first a jellying through the liquid; the clot subsequently contracts, squeezing out a colourless fluid or salted muscle serum. This does not take place at 0°; it occurs most readily at the temperature of the body, and is hastened by the addition of a ferment prepared from muscle in the same way as Schmidt's ferment is prepared from blood. The ferment is not identical with fibrin ferment, as it does not hasten the coagulation of salted blood plasma; nor does the fibrin ferment hasten the coagulation of muscle plasma. The recoagulation of myosin is also accompanied by the formation of lactic acid.

The proteïds of muscle plasma are—1. Paramyosinogen, which is coagulated by heat at 47°. 2. Myosinogen, which is coagulated at 56°. It is on the presence of this proteïd that the power of fresh muscle juice to hasten the coagulation of blood plasma depends. 3. Myoglobulin, which differs chiefly from serum globulin in its coagulation temperature (63°). 4. Albumin, which is apparently identical with serum albumin  $\alpha$ , coagulating at 73°. 5. Myo-albumose; this has the properties of deutero-albumose, and is identical or closely connected with the myosin ferment. The first two proteïds in the above list go to form the clot of myosin; paramyosinogen is, however, not essential for coagulation; the three last remain in the muscle serum.

Paramyosinogen, myosinogen, and myoglobulin are proteïds of the globulin class. They are all completely precipitated by saturation with magnesium sulphate, or sodium chloride, or by dialysing out the salts from their solutions. They can be separated by fractional heat coagulation, or by fractional saturation with neutral salts.

When muscle turns acid, as it does during *rigor mortis*, the pepsin which it contains is enabled to act, and at a suitable temperature (35—40°) albumoses and peptones are formed by a process of self-digestion. It is possible that the passing off of *rigor mortis*, which is apparently due to the reconversion of myosin into myosinogen, may be the first stage in the self-digestion of muscle. W. D. H.

#### **Fermentation by Protoplasm from Recently Killed Animals.**

By FOKKER (*Compt. rend.*, **104**, 1730—1732).—If a small quantity of any organ of a recently killed animal is taken, with all precautions to prevent access of bacteria, and is placed in a sterilised fluid and gently heated, it can convert sugar into acid and starch into glucose: but careful examination by means of the microscope and by cultivation, fails to show the presence of any microbes.

When an acid is produced, the change ceases after a short time, because the acid formed arrests the action of the protoplasm. If, however, the liquid is carefully neutralised, the change recommences, and will continue for several months if the liquid is kept neutral. The quantity of acid produced by the protoplasm is smaller than would be formed under the same conditions by the action of microbes. The difference between protoplasm from a healthy animal and microbes lies mainly in the tendency of the latter to multiply. The only alteration which the tissues undergo during the fermentative changes which they produce, is the destruction of the nucleus.

C. H. B.

**Action of Caffeine and Theine on Voluntary Muscle.** By T. L. BRUNTON and J. T. CASH (*Proc. Roy. Soc.*, **42**, 238—239).—Both caffeine and theine cause rigor in the voluntary muscles of frogs; in the same frog, the stronger the solution used the more powerful is the action; although a large dose will often cause less action in one frog than a smaller one will cause in another. Theine is rather more powerful than caffeine; theine, moreover, tends to produce rhythmical contractions in the muscle. The addition of lactic acid or chloride of calcium aids, whilst potash diminishes the action of the alkaloids. W. D. H.

**Chemical Constitution and Physiological Action.** By T. L. BRUNTON and J. T. CASH (*Proc. Roy. Soc.*, **42**, 240).—The distinctive action of the lower members of the fatty series is their stimulant and anæsthetic action on the nerve centres. The members of the aromatic series also affect the nervous system—especially the motor centres, producing convulsions and paralysis. Benzene, chlorobenzene, bromobenzene, and iodobenzene are similar in their action on frogs, the halogen radicles not modifying the action of the benzene to any great extent. The introduction of hydroxyl into the benzene nucleus intensifies the convulsant action. W. D. H.

**Diabetes and Glycerols.** By W. B. RANSOM (*Journ. Physiol.*, **8**, 99—116).—The following conclusions are drawn from experiments on rabbits:—(1) That certain forms of glycosuria—for instance, that produced by puncture of the medulla oblongata, may be checked by glycerol; (2) that glycerol acts more efficiently when introduced into the alimentary canal than when injected subcutaneously; (3) that glycerol checks glycosuria by inhibiting the formation of sugar in the liver; (4) that in this way it may lead indirectly to an accumulation of glycogen in the liver. Viewing the formation both of glycogen and sugar as a process of cell metabolism, quite independent of ferment action, it is impossible to suppose that glycerol produces its effect by acting on a ferment in the blood, but more probably it exercises some direct influence on the protoplasm of the liver cells. The usual theory of a ferment which comes especially into play after death and changes the glycogen in the liver into sugar is considered untenable; and the *post-mortem* formation of sugar is regarded as being due to metabolism still going on in the cells of the liver which retain their vitality for some time after the heart has stopped.

W. D. H.

**Lævorotatory  $\beta$ -Hydroxybutyric Acid in the Blood of a Diabetic Patient.** By L. HUGOUNENQ (*Bull. Soc. Chim.*, **47**, 545—546).—Lævorotatory  $\beta$ -oxybutyric acid has been recognised in the urine of diabetic patients; the author has now detected its presence in the blood. The process used for its identification was as follows:—The blood was kept in contact with ether until the sugar present had been removed; it was then evaporated to dryness on the water-bath, and the solid coagulum exhausted with boiling water; the extract was precipitated with basic lead acetate and ammonia, and the filtered solution examined in the polariscope when the presence of the acid was indicated by its lævorotatory action. A second portion of the blood was then taken, evaporated, and extracted with water as in the first case, the aqueous solution evaporated almost to dryness, and the product treated with an equal volume of sulphuric acid and distilled; on fractioning the distillate, and treating the fractions with a freezing mixture, crystals separated which, after recrystallising from ether, were recognised as crotonic acid by the melting point ( $70$ — $71^{\circ}$ ), this acid having been formed by the dehydration of  $\beta$ -hydroxybutyric acid. According to the results obtained by Külz (who found the rotatory power of  $\beta$ -hydroxybutyric acid to be  $-25.4^{\circ}$ ), the author found the blood contained  $4.27$  grams of the acid per litre, the urine of the same patient containing  $4.48$  grams per litre. A. P.

**Does Human Urine contain Free Acid?** By E. BRÜCKE (*Monatsh. Chem.*, **8**, 95—100).—The theory generally accepted of the cause of the acidity of urine is that it is due to the presence of the acid phosphate of sodium or potassium in that secretion. E. Salkowski (*Lehre vom Harn*, Berlin, 1882, 15) leaves the question open as to whether hippuric acid which is present in small amount, is free or combined. The present research consists of experiments with congo-red, the colour of which is changed by acids. One part of hippuric acid dissolved in 55,000 of distilled water free from ammonia, causes a solution of congo-red to become violet or inky in colour. Hippuric acid does not appear however to be present in urine, and no urine hitherto examined produces any change on congo-red.

If to a solution of that pigment, a few drops of dilute sulphuric, phosphoric, or hydrochloric acid be added, the liquid assumes an inky tint. If this mixture is dropped into urine, each drop becomes red again, or if the urine be first coloured with congo-red, and acid added drop by drop, the cloud caused by the first drops redissolves: so that one cannot use this method for titration. If more acid is added, a precipitate of a rust-red colour in which the pigment is fixed settles, and the urine can be filtered off having its normal colour. The use of congo-red paper is hardly more satisfactory. If the paper be coloured violet by phosphoric acid, it is found that a solution of sodium chloride will render it red. This cannot wholly depend on the unequal diffusion of acid and base. A solution of congo-red rendered violet by hydrochloric acid is also made red by sodium chloride: this is probably not due to a union of the sodium chloride with the acid, but perhaps to a raising of the refractive index of the mixture, and a molecular alteration of the pigment. The colour is

browner than that produced by acids. If the solution of the pigment and sodium chloride be added to urine, it dissolves with a bright red colour. These facts teach that the bases in urine are not so far saturated with acids that the addition of more acid necessarily involves the presence of free acid. Whether the bases are metallic or not must be ascertained by future investigation; urea certainly has no effect on a solution of the pigment rendered violet by acid.

Carbonic acid is also not free in the urine, for congo-red is easily affected by that acid. In certain circumstances, free uric acid is sometimes present in urine in a crystalline form; but in such urine congo-red also shows that there is no free uric acid in solution at the same time.

## Chemistry of Vegetable Physiology and Agriculture.

**Reduction of Silver Salts by Living Protoplasm.** By T. BOKORNY (*Ann. Agronom.*, 13, 239—240).—The blackening of argentic nitrate by the protoplasm of living cells, discovered some years ago by the author and Loew, has been attributed by Beaumann and Hoppe-Seyler to the action of hydrogen peroxide. The author finds, firstly, that hydrogen peroxide cannot be detected in the living cells of *Spirogyra* by any test, secondly, that dead cells of *Spirogyra* even after imbibing a 10 per cent. solution of hydrogen peroxide, will not effect the reduction.

J. M. H. M.

**Changes in the Proteïds of Seeds during Germination.** By J. R. GREEN (*Proc. Roy. Soc.*, 41, 466—469).—Gorup-Besanez (*Ber.*, 1874, 1478) stated that the changes in the reserve proteïd materials during germination are probably due to the action of a proteolytic ferment. This was disputed by Krauch (*Abstr.*, 1878, 996). The present experiments demonstrate in the case of the seeds of the *Lupinus hirsutus*, the correctness of Gorup-Besanez' view. The seeds were allowed to germinate for about a week; they then gave an acid reaction to test-paper; the cotyledons were ground, extracted with glycerol, and the extract dialysed until no trace of any crystalline substances which had formed during the germination could be detected in the dialysate. No trace of peptone passed the dialyser even after a week's exposure. The extract was then acidified with hydrochloric acid to the extent of 0.2 per cent., put into a fresh dialyser, some swollen-up boiled fibrin added, and the dialyser surrounded with 0.2 per cent. hydrochloric acid, and exposed to a temperature of 40°. Control experiments with acid only, or with boiled digestive extract, were carried out side by side. Digestion was slow, but after some time the dialysate contained peptone and leucine, while in the control experiments there were no such substances. The proteïds of the seeds are changed by this ferment in the same way as fibrin is. The ferment exists in the resting seed as a zymogen,

which is easily convertible into the ferment: the resting seeds have moreover a neutral reaction. The ferment acts best in a slightly acid medium; its activity is hindered by neutral salts and destroyed by alkalis, and is most active at a temperature of 40°. The process of germination is started or accompanied by a transformation of the zymogen into ferment on the absorption of water, and the development of vegetable acids in the cells of the seed: the ferment so developed converts the proteïds of the resting seed into acid albumin or parapeptone, peptone, and crystalline amides. The nitrogen travels from the cells of the seed to the growing points in the form of amides, not in that of peptones or other proteïds.

W. D. H.

**Molecular Respiration of Plants.** By N. W. DIAKONOFF (*Ann. Agronom.*, **13**, 229—233).—Experiments with the higher plants lead the author to the following generalisations which amplify those formerly arrived at from a study of intramolecular respiration amongst the moulds. The intensity of disengagement of carbonic anhydride by vegetable cells in the absence of the oxygen of the air is determined by the activity of the fermentative processes which take place in the cells. As soon as oxygen ceases to be supplied in quantities sufficient for normal respiration, fermentation sets in; with a renewed supply of pure oxygen, normal respiration again becomes possible. Without the chemical action of pure oxygen, or as alternative some process of fermentative change (which constitutes the sole means of satisfying the requirements of a living cell in a medium deprived of oxygen), there is no disengagement of carbonic anhydride, that is to say, there is no life.

J. M. H. M.

**Exhalation of Oxygen by Fleshy-leaved Plants in Absence of Carbonic Anhydride.** By A. MAYER (*Landw. Versuchs-Stat.*, **34**, 127—143).—Former researches by the author (*Abstr.*, 1876, i, 95; *Landw. Versuchs-Stat.*, **21**, 277; **30**, 217) have shown that under certain conditions oxygen is exhaled by the leaves of some plants in absence of carbonic anhydride. This is more especially the case with the Crassulaceæ, and it was found that *Bryophyllum calycinum* leaves which contain malates, after a period of darkness (during night) react acid, but this reaction during the day time becomes much less. Comments are here made on the author's own experiments, and on those of others (de Vries and Sachs) who have combated his conclusions. His experiments made since 1883 show that "acid leaves," during insolation in an atmosphere free from carbonic anhydride, yield more oxygen the richer they are in free acid; moreover the older leaves being more acid, yield more gas than younger leaves, which are more nearly neutral; also those Crassulaceæ which emit most oxygen, are more acid in the morning than other plants (compare *Bryophyllum calycinum* with *C. arborescens*), and when the elimination of oxygen has ceased, it is found that the leaves are nearly neutral in reaction. The acid present is a malic acid which differs in some respects from ordinary malic acid, but the calcium salt is a true malate; this acid and the calcium salt diminish during insolation, just as if the whole consisted of free acid, the products produced

by the change being starch, sugar, &c., and the amount of oxygen which should be separated by the produced carbohydrates, agrees well with the quantity of oxygen found to be set free by insolation. From all these facts, the author has drawn the conclusion that the changes which occur as above are part and parcel of the regular assimilation in the plant, that is processes of reduction which take place in the green portions of the plant, and that the malic acid of the Crassulaceæ is to be considered as an intermediate product. Further results have also been obtained, for it was found that the acid in dead leaves was not altered by light, nor did oxalic acid suffer any reduction nor give off oxygen. As regards the formation of malic acid in the dark, it is evidently the result of decomposition. The remainder of the article is occupied by a defence of his own theory against the arguments and experiments of de Vries, Kraus, and Warburg.

E. W. P.

**Relations between Inorganic Salts containing Nitrogen and Plants.** By H. MOLISCH (*Monatsh. Chem.*, 8, 237—259).—The most important conclusions arrived at by the author are the following:—

Nitrates are generally distributed in the vegetable kingdom; they usually occur to a much greater extent in herbaceous than in woody growths.

Nitrites could not be found in any of the plants examined (which amounted to about 100) in spite of their frequent presence in the ground. Former statements on the so-called presence of nitrites in different plants are based on errors and incorrect interpretation of results.

Plants possess the power of reducing nitrites with surprising quickness as soon as assimilated, and this is evidently the reason why they are never found in plants. Nitrates, however, will remain for weeks or even months in the vegetable cells before they are destroyed.

In contrast to the nitrates, nitrites act injuriously on certain plants even when employed in comparatively dilute solutions (0.1—0.01 per cent.).

Plants, to which the nitrogen is offered not in the form of nitrates, but in the form of nitrites or ammonia, never contain nitrates. It, therefore, follows that neither nitrous acid or ammonia undergo oxidation to nitric acid in the vegetable organism.

Contrary to the statement of Berthelot and André, plants, with perhaps the exception of bacteria, have not the power of producing nitrates from nitrogenous compounds. All nitrates in plants originate from outside, and when they exceed the amount contained in the substratum in the plant, the excess can be simply explained by the storing up of the salt. E. Schulze's experiments with lupines (this vol., p. 859) afford additional evidence in favour of this view.

Diphenylamine dissolved in sulphuric acid serves very conveniently for the detection of nitrates under the microscope. In those cases, however, in which humin substances are quickly formed by the action of the sulphuric acid, the reaction is more or less checked.

The paper also contains some observations on the localised appearance of substances which turn guaiacum emulsion and potassium iodide and starch-paste blue.

G. H. M.

**The Proteïds of the Seeds of Jequirity.** By S. H. C. MARTIN (*Proc. Roy. Soc.*, 331—334).—Warden and Waddell ("Non-bacillar Nature of Abrus Poison," Calcutta, 1884) have given the name "abrin" to the poisonous principle of jequirity (*Abrus precatorius*). They showed also that abrin was closely allied to "plant albumin"), but did not enter into any details as to whether it consisted of one or more proteïds. The present examination relates to the kinds of proteïds present in the seed, and is preliminary to an investigation of their physiological action. The red cuticle was first removed by shaking the seeds with chloroform; the cuticle sinks in that liquid, and the yellow kernel powder is readily removed and dried by allowing the chloroform to evaporate. The powder was then extracted with 15 per cent. sodium chloride solution and filtered. The proteïds in the filtrate were separated: (1) by saturation with ammonium sulphate; (2) by saturation with sodium chloride and the subsequent addition of glacial acetic acid.

The former method is the best; it takes shorter time, and precipitates the proteïds more completely. The precipitated proteïds were redissolved in distilled water, and the solution dialysed; this caused a copious precipitate, which was collected, washed with boiled distilled water, and dried over sulphuric acid. The residue consisted of dark-brown scales, which consisted of globulin and colouring matter. All the globulin is not, however, precipitable by dialysis. Alcohol was therefore added to the liquid, which had been in the dialyser for seven days, to precipitate the remaining proteïds. After six to eight weeks, the globulin was rendered insoluble by this means; the precipitate was collected, dried, and treated with distilled water, which dissolved out a proteïd which was an albumose. There are thus two proteïds present; a globulin and an albumose. The globulin is coagulated by heat at 75—80° in a 10 per cent. magnesium sulphate solution, at 66—73° in a 10 per cent. sodium chloride solution. It does not become insoluble when the latter solution is placed in an incubator at 35—40° like vegetable myosins; it belongs to the class of vegetable paraglobulins (this vol., p. 507).

The albumose is soluble in cold or boiling distilled water. It is not precipitated by saturation with sodium chloride unless a large amount of glacial acetic or phosphoric acid is added also. It is readily precipitated by saturation with neutral ammonium sulphate. It is not precipitated by nitric acid unless its solution be nearly saturated with sodium chloride. It gives the biuret reaction. This phytalbumose is seen to be closely allied to Kühne and Chittenden's deutero-albumose, and is identical with the  $\alpha$ -phytalbumose of papaw-juice (Abstr., 1886, 642).

W. D. H.

**Safrole.** By — FLÜCKIGER (*J. Pharm. Trans.* [3], 17, 989—990).—Safrole exists not only in the essential oil of sassafras root, but probably in other plants belonging to the natural order of *Lauraceæ*. In Germany, safrole is now extracted on a large scale from the oil of the camphor tree, *Cinnamomum camphora*. An odour resembling that of sassafras is noted in *C. Parthenoxylon*, *C. glanduliferum*, and in *Beilschmiedia obtusifolia*. Safrole is associated with eugenole in the

fruit of *Illicium religiosum*, and in *Illicium anisatum* it is replaced by anethole. The empirical formulæ of these three highly aromatic substances,  $C_{10}H_{10}O_2$ ,  $C_{10}H_{12}O_2$ , and  $C_{10}H_{12}O$ , suggests that probably they are capable of being converted one into another. R. R.

**Strophanthus.** By W. ELBORNE (*Pharm. J. Trans.* [3], 17, 743—747).—The seeds of *Strophanthus kombé* yield 20·8 per cent. of fixed oil when extracted with light petroleum; 0·9 per cent. of chlorophyll and fat when extracted with ether; 1·5 per cent. of a bitter glucoside to absolute alcohol; and an additional 2·9 per cent. of bitter glucoside to water. These solvents were made to act successively on the dried and powdered seeds. It is remarked that when the alcoholic solution is evaporated to dryness at a low temperature, and the residue dissolved in water and set aside for a few days, the product becomes far more toxic. The cause of this change has not yet been investigated, but in the method adopted by the natives of Eastern Africa in preparing their arrow-poison from the plant, advantage appears to be taken of this fact. Bitter principles from *Strophanthus* have been already described by Fraser, and by Hardy and Gallois under the names of “*strophantin*,” “*strophanthin*,” and “*strophanthidin*.” The author was unable to extract any alkaloid from the comose hair of the seeds. R. R.

**Poisoning of Plants by Lithium Salts.** By J. GAUNERSDORFER (*Landw. Versuchs-Stat.*, 34, 171—206).—Experiments have previously shown that lithium is a constant compound of the ash of some plants, and that it is stored in their leaves, but not in their roots, and they even collect it when the presence of lithium in the soil is scarcely to be detected. Various experimenters are here referred to, also the results obtained by them. The author records the results of experiments made by him on various plants, *Cicer arietinum*, *Vicia faba*, &c., with solutions of lithium chloride of different strengths, 1·1—0·066 per mille; the descriptions are given in full detail, and the following conclusions are drawn: lithium is a fairly constant but not essential constituent of certain plants, but for most plants, in relatively small quantities it is a poison, and produces evident disturbances in the plants. Lithium is deposited in the *fully grown* leaves, whilst the young leaves, buds, and reproductive organs, failing as they do in hardened fibre, are exempt from the action of lithium, which does not reach them. It is the action of transpiration which carries lithium upwards, but this element can move sideways through the hardened cell-walls. Those plants which do not naturally contain lithium will live healthily in a soil which contains but a small portion of lithium, but finally the whole of the lithium is carried into the leaves which, dropping off, denude the soil of the element referred to.

E. W. P.

**Composition of some Leguminous Seeds.** By R. WAAGE (*Bied. Centr.*, 1887, 394—395).

A comparison with blue and yellow lupines shows that the white and blue are nearly of equal value, whilst the yellow contains more nitrogenous and less carbonaceous matter.

|                               | Whole lupins. | Red<br>Sanderbsen. | Peluschken. |

The effect of steeping in water to remove the bitter portion of the lupines is to remove a large portion of the ash, some of the non-nitrogenous and some of the albuminous matter.

The total loss of valuable material amounts to 7·65 per cent., of which 1·86 is albumin and 5·8 is non-nitrogenous. E. W. P.

**Experiments on Potatoes at Harelaw in 1886.** By AITKEN (*Trans. Highland and Agric. Soc.*, 1887 [4], 19, 215—237).—The general results of the Harelaw experiments are summed up by the author as follows:—

*Unmanured Section, Residual Fertility.*—Insoluble phosphates have left a larger available residue than soluble phosphates; the largest has been left by bone-meal. The phosphates which produce the greatest result during the previous rotation have left the least residue. Nitrate of soda alone exhausts the land very much, with other manures it exhausts it more than other nitrogenous manures. Sulphate of ammonia has left considerable residue, or at any rate has not exhausted the land so much as nitrate of soda. Horn-dust and dried blood have left no more for the potato crop than sulphate of ammonia; rape-dust has left more residue than the other nitrogenous manures. Both potassium sulphate and chloride have left a residue for the potato crop, but the chloride has left rather more than the sulphate. Peruvian guano has left the land in better condition for the growth of potatoes than either Ichaboe or fish guano. Low class superphosphate has left more residue than high class.

*Manured Section, Immediate Fertility.*—The manure applied to potato plots in 1886 gave the following results:—Mineral phosphates found to pass through a sieve of 120 wires per linear inch produced nearly as good results as dissolved phosphates; they were more active than bone-meal or pure dissolved bones. Sulphate of ammonia did better than nitrate of soda when no dung was used. Horn-dust and dried blood are not sufficiently active for potatoes when applied with the seed. Potassium salts are of great importance to potatoes, and there

is little difference between the sulphate and chloride. Ordinary superphosphate, 28 per cent. soluble, is better than richer ones. When the potato crop is insufficiently manured, not only is the produce less, but the proportion of small tubers is greater; potash is the most important ingredient for the production of large tubers. A well-balanced manure for raising a potato crop without dung should contain about equal parts potash, ammonia, and phosphoric acid. When applied with dung, half the potash may be used. Manure for potatoes should be within easy reach of the roots, but may be slow acting; dung appears to be the most appropriate manure, producing a crop with a large proportion of large tubers. With dung, nitrate of soda is better than sulphate of ammonia; without it, the sulphate of ammonia is best. Where much dung is used, potash salts may not be required.

J. M. H. M.

**Production of Nitrates in Arable Soil.** By P. P. DEHÉRAIN (*Ann. Agronom.*, 13, 241—261).—The present series of experiments was undertaken to determine the conditions under which different substances acting as manures nitrify in the soil. They were made with the nitrogenous black matter of soil, ammoniacal salts, oil-cakes, farmyard manure, and the black matter of farmyard manure, under varying conditions of moisture and for different periods of time; in some instances, the proportion of manure to soil, and the temperature, both varied. The quantities of nitrate formed in the various mixtures from time to time were determined as follows:—100 grams of the mixture were introduced into a litre flask, the quantity of water required to make it up to the mark measured into it, left in contact for several hours, and repeatedly shaken; then 700 to 800 c.c. were withdrawn and evaporated down to about 10 c.c., and the nitric oxide determined according to Schloesing's method by measurement of the gas.

*Nitrogenous Black Matter of Soil.*—The soil employed contained 0.160 per cent. organic nitrogen and 0.015 per cent. nitric acid ( $N_2O_5$ ?). Quantities of 100 grams of this soil were placed in glass beakers and moistened with 5, 10, 15, 20, and 25 c.c. of water respectively, and all the beakers were placed together under a bell-glass, and the nitric acid formed determined after several periods up to 90 days. With the 5 per cent. of added water, there was no nitrification at the end of 56 days, but all the other mixtures had commenced to nitrify at the end of the first period. After 90 days, the quantity of nitrate formed in a tonne (1000 kilos.) of soil was 250 grams in that moistened with 5 per cent. of added water; 16 grams with 10 per cent. water; 270 grams with 15 per cent. water; 290 grams with 20 per cent. water; and 370 grams with 25 per cent. water—the nitric acid formed thus attaining a maximum in the most humid mixture. The greatest rate of nitrification observed was 1 gram nitrogen nitrified per day per tonne of soil. Supposing this rate to be maintained during the active life of a cereal crop, say 100 days, the nitrogen nitrified would amount to 300 to 400 kilos. per hectare, a quantity greatly in excess of the requirements of the crop.

*Ammoniacal Salts.*—Quantities of soil watered with various propor-

tions of ammonium sulphate were placed in identical conditions with plain soil freely exposed to the air.

Sulphate of ammonia in quantities equivalent to 0.030 gram and 0.010 gram nitrogen per 20 grams of soil far from increasing the quantity of nitrate formed greatly hindered the nitrification in the soil. In a saturated atmosphere, however, with the soil freely supplied with water, doses of sulphate of ammonia up to 0.100 gram nitrogen per 100 grams soil did not prevent nitrification, although the larger the doses employed the less nitrates were formed.

A series of experiments with sulphate of ammonia equivalent to 0.010 gram nitrogen per 100 grams soil, moistened with 5, 10, 15, 20, and 25 grams water, showed that with the smaller proportions of water nitrification was less than in the parallel experiments with plain soil; with the larger proportions of water, more nitrogen was nitrified, that of the ammoniacal salt undergoing oxidation as well as that of the organic matter of the soil, and at a much faster rate, so that, for example, the addition of 0.010 gram nitrogen as ammoniacal salt to 100 grams soil containing 0.160 gram organic nitrogen doubled the quantity of nitrate formed during the course of the experiments. Frequently as much as one-hundredth of the nitrogen added as ammoniacal salt was nitrified per diem, whilst the nitrogenous matter of the soil scarcely gave rise to one-thousandth of its weight of nitric acid in the same time. The whole of the sulphate of ammonia added as manure is probably nitrified in the course of a few months. Some of the nitrates at first formed disappear afterwards, more especially in the most humid mixtures, and this is attributed by the author to the slow growth of moulds.

*Maize Cake.*—The nitrogen of maize cake is nitrified more quickly than that of the organic matter of soil, more slowly than that of ammonium sulphate, so that if a mixture of the two is used as manure, when the action of the latter is exhausted that of the former still continues. The influence of humidity is the same as in the preceding cases.

*Farmyard Manure.*—2 per cent. of farmyard manure was added to the soil, corresponding to a dressing of 72 tonnes per hectare. Even with 5 per cent. of added water some degree of nitrification occurred, whereas with plain soil of the same humidity there was none. With the largest proportions of water, nitrification was very irregular, no more nitrate being formed after 90 days than after 26, and in some cases the nitrate formed was less than with plain soil. These irregularities are doubtless due to the growth of moulds, &c., of which the spores and mycelia abound in farmyard manure. In point of rapidity of nitrification, farmyard manure comes next to ammonium sulphate, and before maize cake and plain soil.

*Black Matter of Farmyard Manure.*—This was obtained by extracting decomposed farmyard manure with water, filtering, and evaporating the filtrate to dryness by exposure to air alone. It contained 3.5 per cent. of nitrogen, and was added to the soil in the proportion of 0.3 per cent., thus introducing the same quantity of nitrogen as that contained in the 0.050 gram ammonium sulphate used in a former series of experiments. With these mixtures, nitrification occurred

exactly as with plain soil, that is to say, the nitrogen of the black matter appeared to undergo no change. It appears to lose the capacity of being nitrified by the act of drying, since in trials with the *undried* extract of farmyard manure the nitrogen of the extract was nitrified in sensible quantities.

J. M. H. M.

**Free Phosphoric Acid and Superphosphates.** By M. WEIL-ANDT (*Landw. Versuchs-Stat.*, **34**, 207—215).—Ritthausen has previously found that a solution of superphosphate and calcium carbonate produces dicalcium phosphate, and generally in the crystallised condition. The author has now studied the results of the reactions of a 10 per cent. solution of orthophosphoric acid on several alkaline carbonates. Pure barium and strontium carbonates produced 65·2 and 45·7 per cent. respectively of the insoluble phosphate, but when carbonic anhydride was passed in rather less of the bibasic and more of the monobasic phosphate and free acid were produced, as also many crystals. When, however, the concentration of the solution was raised, the results were reversed, but when the time of action was lengthened there was rather less of the bibasic salt produced, but in the filtrate was found a large conversion of the free acid into the monobasic salt. It would appear, then, that the crystallised phosphoric acid acts somewhat differently from the superphosphate.

The author, therefore, prepared a superphosphate from Mejillones guano and phosphoric acid, and with the solutions thus obtained he experimented on marble and other forms of carbonate, of which marl appeared to react most energetically. From the results obtained, it is evident that if superphosphate is applied to a well marled soil none will be lost by passing through unabsorbed in the monocalcium form, but all (98 per cent.) of the acid will be retained at the surface. As was to be expected, the more crystalline compounds are least readily acted on, whilst marl, which is readily decomposed, and in which the calcium carbonate is finely dispersed, becomes coated with the bibasic compound and prevents any further reaction.

E. W. P.

**Basic Cinder and other Finely-ground Insoluble Phosphates as Manures.** By AITKEN (*Trans. Highland and Agr. Soc.*, 1887 [4], **19**, 245—253).—The phosphates tried were Curaçoa phosphate with 87 per cent., Canadian phosphate with 59 per cent., Carolina phosphate with 57 per cent., Belgian phosphate with 40 per cent., and basic cinder with 40 per cent. of phosphate of lime. These were tried against each other and superphosphate of 28 per cent. at four different stations on turnips. It was found that only 40 to 50 per cent. of the ground Curaçoa, Carolina, Canadian, and Belgian phosphates would pass through a sieve of 120 wires per linear inch, whereas all the basic cinder passed through this sieve. A large sieve of this gauge was therefore made, and sufficient quantities of the mineral phosphates passed through it to try the sifted against the unsifted portions. Sulphate of ammonia and sulphate of potash were added in all cases to make a general manure, and quantities of the phosphates containing equal weights of phosphoric acid were employed. In almost all cases, the sifted phos-

phates produced a larger crop than the unsifted phosphates, amounting on an average to a gain of 1 to  $1\frac{1}{2}$  tons of roots per acre, and it seems reasonable to suppose that this increase would pay for the extra fineness of grinding. The superphosphate proved little if any superior to the sifted phosphates or the basic cinder, and this last phosphate appears to be at present the most finely ground as well as the cheapest in the market. The nature of the mineral phosphate used appears to be of much less importance than the fineness to which it is ground.

J. M. H. M.

*Note by Abstractor.*—The author says of basic cinder, "I do not doubt that its efficacy as a phosphatic manure is in the main to be attributed to the extraordinary fineness to which it is ground." No doubt fineness of grinding is extremely desirable, but the basic cinder appears to possess a distinct advantage over the mineral phosphates in the great relative solubility of the phosphate of lime contained in it. On some soils this tells very much; in the Downton experiments, conducted in 1885 by the Abstractor and another (this vol., p. 176), the coprolites were much more finely ground than the basic cinder employed, yet the latter produced far better crops than the former.

J. M. H. M.

**Ground Felspar as a Potash Manure.** By AITKEN (*Trans. Highland and Agr. Soc.*, 1887 [4], 19, 223—255).—The result of two small experiments, made at Pumphuston on turnips and at Boon on peas, is that felspar when ground so as to pass through a sieve of 120 meshes per linear inch undoubtedly acts as a potash manure. On the turnips, the felspar did better than an equivalent quantity of sulphate of potash, on the peas not so well.

J. M. H. M.

**Butter from various Districts.** By E. DUCLAUX (*Compt. rend.*, 104, 1727—1730).—The author has determined the proportion of volatile acids in various butters by the methods previously described. The butters examined were obtained from Isigny, Gournay, Brittany, and Cantal.

The ratio of butyric acid to caproic acid is practically constant in butter from the same district, but varies considerably from one district to another. In butter from Gournay, it is 1·6, Brittany 1·9, Isigny 2·1, Cantal 2·4. The total quantity of the two acids varies in different samples even from the same district. The production of butter of fine flavour and good quality is not simply a question of the method of preparation.

## Analytical Chemistry.

---

**Iodine Detection in Laminaria.** By F. A. FLÜCKIGER (*Arch. Pharm.* [3], 25, 519—522).—One decigram of the seaweed is ample for the detection of iodine. The weed in as small pieces as possible is mixed with twice its weight of not too fine pumice powder, boiled with water, and dried on the water-bath whilst being well stirred. The

mass is then roasted over a very gentle flame and extracted with 5 c.c. water in which the iodine can be detected by the addition of ferric chloride solution to acid reaction and shaking up with carbon bisulphide. Or a very dilute solution of chlorine-water may be used with one portion of the filtrate and ferric chloride with another.

J. T.

**Iodimetric Studies: Application of the Method to the Analysis of Commercial Substances.** By G. TOPF (*Zeit. anal. Chem.*, **26**, 277—302. See this vol., p. 688).—Commercial sodium thiosulphate is nearly pure, and usually contains such minute traces of sodium carbonate that its titration by iodine is not affected thereby; nevertheless if present in larger quantity this salt would cause an error in the result equal to double its own amount, unless acidified iodine solution is used.

The iodimetric method serves well for the assay of commercial sodium sulphide. It is necessary to add the sulphide to an excess of acidified iodine solution, otherwise the alkali present induces oxidation of the sulphur, and causes the results to be too high.

Bunsen's explanation of the necessity for diluting sulphurous acid to 0.05 per cent. before titrating with iodine, namely, that above that strength a reverse action occurs, does not seem to be correct. Finkener has shown that with an excess of iodine the action is complete in a solution of any strength. Even sulphuric acid of 20 per cent. strength liberates no iodine from potassium iodide. Stronger acids are reduced, especially when much iodide is added, but up to 71 per cent. the product is hydrogen sulphide. Above that strength, sulphurous acid is also produced, but is not the sole product till 81 per cent. is reached. If Mohr's plan of neutralising the sulphurous acid before titrating it is adopted, it is still necessary to use an excess of iodine and to acidify before titrating back with thiosulphate.

In titrating stannous salts by iodine, the best results were obtained by adding tartaric acid and sodium hydrogen carbonate, then an excess of iodine, and then acid before titrating back. Zinc powder can be assayed by shaking it with excess of neutral iodine solution (in a bottle containing glass balls), and acidifying with acetic acid before titrating the excess.

In examining commercial iodine containing chlorine, it is necessary to dissolve in soda and add a small quantity of a sulphite to reduce the iodate formed by the action of the chlorine. A ferric salt and hydrochloric acid are then added and the iodine is distilled over into potassium iodide. The author figures a special distillation apparatus in which caoutchouc joints are avoided, and which gives excellent results. The same apparatus serves for the analysis of chlorates and hypochlorites by distillation with hydrochloric acid.

Diehl's method of titrating Weldon mud by digesting with potassium iodide and acetic acid and determining the liberated iodine is found to be a very practical one. Lead dioxide and red lead can be estimated in the same manner if sufficient sodium acetate is added to keep the lead iodide in solution. The results are more trustworthy than those obtained by distillation with hydrochloric acid. Nitrates,

which are often present in the commercial dioxide, are without influence.

Lastly, ferrous and ferric oxides, in hydrochloric acid solution, can be determined iodimetrically. For the ferrous oxide, a known excess of iodine is added (which may conveniently be done by adding potassium iodide and a standard solution of iodate), and then an excess of sodium acetate. The iron separates as basic ferric acetate and the residual iodine can either be distilled out, or after digestion at 60–70° in a stoppered bottle and cooling, can be titrated direct without filtering. For the ferric oxide, an excess of potassium iodide is added, and after digestion at 70° the liberated iodine is determined.

M. J. S.

**Weil's Method for the Estimation of Sulphides.** By F. WEIL (*Bull. Soc. Chim.*, **47**, 680–682).—In reply to Friedheim's criticisms (this vol., p. 396) the author states that he does not employ an ammoniacal copper solution, but a solution containing 39.3375 grams of cupric sulphate, 197 grams of sodium potassium tartrate, and 125 grams of pure sodium hydroxide. The gases given off from the decomposition of the sulphide by hydrochloric acid are passed into an excess of this solution, the precipitated cupric sulphide filtered off, well washed, and the copper in the filtrate and washings titrated by means of a solution of stannous chloride. The results obtained by adhering to the details of the author's process are very concordant among themselves, and agree closely with results obtained by Fresenius' gravimetric method.

A. P.

**Detection of Nitrogen-compounds in Seleniferous Sulphuric Acid.** By G. LUNGE (*Ber.*, **20**, 2031–2033).—A solution of diphenylamine in sulphuric acid produces with seleniferous sulphuric acid, obtained by boiling selenium dioxide with pure sulphuric acid, a cornflower-blue colour indistinguishable from that formed when sulphuric acid containing nitrogen acids is similarly treated. The seleniferous acid, as is well known, yields a brownish-yellow or yellowish-red ring with ferrous sulphate or, preferably, ferrous chloride solution which, however, does not disappear on boiling, but darkens with the precipitation of red selenium, so that this test cannot be employed for the detection of nitrogen acids in sulphuric acid containing selenium-compounds, whilst in addition the indigo test cannot be relied on for this purpose, inasmuch as selenic acid oxidises indigo and cannot itself be reduced by boiling with hydrochloric acid without the simultaneous decomposition of the traces of nitrogen acids if these are present. Sulphuric acid containing selenium-compounds, however, gives no colour reaction with brucine, and this test is therefore available for the detection of nitrogen acids in seleniferous sulphuric acid

W. P. W.

**A Simple Nitrometer.** By T. P. BLUNT (*Pharm. J. Trans.* [3], **17**, 763).—A description of an improvised nitrometer for the rapid testing of "sweet spirits of nitre."

**Colorimetric Estimation of Phosphorus.** By F. OSMOND (*Bull. Soc. Chim.*, **47**, 745—748).—When phosphomolybdic, arseniomolybdic, or silicomolybdic acids or their alkaline salts are dissolved in a solution of stannous chloride, a blue coloration is produced the intensity of which is proportional to the amount of the molybdic acid dissolved. This characteristic reaction may be employed to estimate the amount of phosphorus present in irons, steels, &c. The solution of stannous chloride is prepared by dissolving 12 grams of the crystallised salt in 80 c.c. of pure hydrochloric acid and making the solution up to a litre with distilled water. The precipitate of ammonium phosphomolybdate obtained in the usual manner is collected on an asbestos filter (filter-paper must not be employed as it absorbs the colouring matter) and then dissolved whilst on the filter by washing with a sufficient quantity of the stannous chloride solution. The filtered solution is then made up to 100 c.c. for each gram of the original substance taken by the addition of a further quantity of the stannous chloride solution, and the depth of the blue tint estimated by comparison either with standard solutions prepared from weighed quantities of ammonium phosphomolybdate (solutions thus prepared may be kept unaltered for several days), or with discs of tinted glass which have been carefully selected by comparison with the tints of solutions of known composition. The results obtained in this way agree very closely with those obtained by the usual method but are generally somewhat lower, a difference which varies between 0.002 and 0.010 per cent.

A. P.

**Apparatus for Determining Carbonic Anhydride in Carbonates.** By D. SIDERSKY (*Zeit. anal. Chem.*, **26**, 336—338).—This differs from Scheibler's well-known calcimeter mainly in having the graduated tube immersed in a cylinder of water instead of being connected with the usual pressure tube.

M. J. S.

**Portable Apparatus for the Estimation of Carbonic Anhydride in the Atmosphere.** By O. PETTERSSON and A. PALMQUIST (*Ber.*, **20**, 2129—2134).—A portable modification of an apparatus devised for the estimation of aqueous vapour and carbonic anhydride in air at a constant temperature and pressure (this vol., p. 189). The sample of air directly drawn from the surrounding atmosphere, after saturation with aqueous vapour and measurement, is passed into an Orsat's potash tube, and allowed to remain for two minutes to complete the absorption of the carbonic anhydride present, then withdrawn and again measured. The correction required to compensate for the difference in humidity of the air analysed and that of the atmosphere from which it was taken is so small that it can be neglected. The estimation takes only a few minutes, and the results agree well with those obtained by other methods.

A modification of the method employed with the original apparatus (*loc. cit.*) is also described, which materially shortens the time required for the analysis.

W. P. W.

**Lithium Carbonate.** By F. A. FLÜCKIGER (*Arch. Pharm.* [3], 25, 509—515).—An aqueous solution of lithium carbonate saturated at 15° had the sp. gr. 1·0140, and contains 1 part of salt in 70·72 parts of water. A solution of freshly-ignited sodium carbonate in 50 parts of water had the sp. gr. 1·0208. Hence the presence of the latter salt in lithium carbonate can be readily detected by an excess of sp. gr. over 1·0137. In boiling water, lithium carbonate loses some of its carbonic anhydride; but a solution saturated at 15° may be heated on the water-bath for a day without losing any. The solubility of the salt diminishes as the temperature increases. A solution saturated at 15° and heated at 90° for some hours when quickly filtered and allowed to cool to 15°, had a sp. gr. of 1·009, and contained 1 part of the salt in 111·3 parts. By thus taking the sp. gr. of a solution prepared at 15° and one prepared at 90°, the presence of more soluble salts can be readily detected. A further characteristic property of lithium carbonate is its easy fusibility as compared with the corresponding sodium, potassium, and magnesium salts. J. T.

**Titration of Zinc Powder.** By F. WEIL (*Bull. Soc. Chim.*, 47, 877—879).—A reply to Kupferschlaeger. Zinc powder usually does not contain organic matter, but, even should it do so, neither that nor any carbon present would reduce the cupric chloride solution under the conditions specified for the working of the author's process. There is usually the merest trace of metallic cadmium in zinc powder; but whatever its amount, its reducing action is the same as that of zinc and would not affect the result. All metallic iron may be removed from zinc powder by means of the magnet. The valuation of zinc powder is based on the amount of metallic zinc, and any zinc oxide present is of no value. A. P.

**Electrolysis of Copper and of Zinc.** By A. SHAND (*Pharm. J. Trans.* [3], 17, 750).—Copper and zinc are more easily and accurately separated and estimated by electrolysis than by the ordinary processes. Certain essential details and precautions are described in the paper.

R. R.

**Estimation of Formic Acid and of Organic Matter in Water.** By J. KLEIN (*Arch. Pharm.* [3], 25, 522—531).—Formic acid in an alkaline solution is completely oxidised by an excess of potassium permanganate, as is well known, after boiling for a short time. After cooling to 70—80°, excess of standard oxalic acid is added, and then sulphuric acid. The excess of oxalic acid is now determined by a further addition of standard permanganate solution. If the sulphuric acid is added before the oxalic acid, oxygen is evolved and the results are inexact, as the author shows. The decomposing action of the sulphuric acid on the permanganate solution diminishes with the temperature. The foregoing is applied to the estimation of organic matter in water by the Schulze-Trommsdorff's method as follows:—100 c.c. of water is boiled for ten minutes with 0·5 c.c. of aqueous soda solution (1 : 2) and 10 c.c. of centinormal permanganate solution. On cooling to 70—80°, 10 c.c. centinormal oxalic acid solution is added and 5 c.c. dilute sulphuric acid; the excess of oxalic acid is

titrated with permanganate solution, a blank experiment is made upon 100 c.c. of pure distilled water, and the difference is taken as due to organic matter in the water. J. T.

**Determination of Hippuric Acid in Urine.** By O. VÖLKER (*Zeit. anal. Chem.*, **26**, 402).—Evaporate 200—300 c.c. of the urine to one-third in a thin glass basin; add 4 grams of sodium phosphate; concentrate to a syrup. Add excess of plaster of Paris, and dry till the mass can be powdered. Introduce the powder, together with the crushed basin into a Soxhlet's apparatus, and extract with freshly distilled light petroleum. After 4 to 6 hours, change the flask, extract for 6 to 10 hours with absolute ether and distil off the ether. Dissolve the residue in hot water; decolorise with charcoal; wash the charcoal well; concentrate at 50—60° to 1 or 2 c.c., and leave to crystallise. Rinse with the mother-liquor into a weighed filter; wash with a few drops of water and ether; dry and weigh. Add 0.0015 gram for every c.c. of filtrate. M. J. S.

**Separation of Mineral Oils from Saponifiable Fats.** By A. GAWALOWSKI (*Zeit. anal. Chem.*, **26**, 330—331).—In separating mineral oils from those of animal and vegetable origin by saponifying the latter and extracting the former from the soap by light petroleum, it is necessary to use a considerable excess of alkali to ensure complete saponification; but this excess of alkali renders the soap to some extent soluble in light petroleum. This may be obviated by the following procedure:—The fat is saponified by alcoholic potash (2 parts of  $K_2O$  to 10 of fat); after evaporating off most of the alcohol, a solution of chloride of calcium, strontium, magnesium or sodium (? barium) is added, and then sodium hydrogen carbonate or sulphate till the alkalinity has nearly disappeared. The soap is then quite insoluble in light petroleum. M. J. S.

**Test for Oil of Peppermint.** By E. C. FEDERER (*Pharm. J. Trans.* [3], **17**, 808).—If 10 c.c. of pure oil of peppermint is shaken up with 20 c.c. of 94 per cent. alcohol, and 10 to 40 c.c. of cold water are then added, a clear supernatant oily stratum of 14 c.c. separates. With other oils and with admixtures separations occur different in their nature and volume, and of these an extended table is given in the paper. R. R.

**Reaction of Strophanthin.** By H. HELBIG (*Pharm. J. Trans.*, [3], **17**, 924).—When a trace of strophanthin is dissolved in a drop of water, together with a trace of ferric chloride, the addition of a little strong sulphuric acid gives rise to a reddish-brown precipitate, which in an hour or two changes colour to a permanent emerald-green. R. R.

**Urea Estimation.** By C. MÉHU (*J. Pharm.* [5], **15**, 607—609).—In estimating urea in albuminous urines by means of sodium hypobromite, it is frequently necessary to wait for hours before reading off the volume of nitrogen, on account of the persistent froth which results

from the reaction. This can be readily avoided by introducing a pilule of fat into the tube, and inclining the tube once or twice before placing it in position.

J. T.

**A Filter Tube for Use in the Estimation of Alkaloids by Mayer's Reagent.** By F. C. J. BIRD (*Pharm. J. Trans.* [3], 17, 826).—A small disc of thick filtering paper, interposed between two layers of muslin stretched over a small inverted funnel, arrests the passage of the precipitate produced by Mayer's reagent, the filtration being effected by suction, and the paper previously charged with French chalk, finely powdered, and suspended in water.

R. R.

**Theïne Estimation.** By A. LÖSCH (*Arch. Pharm.* [3], 25, 497—498).—10—20 grams of tea leaves are boiled twice with water, filtered, and washed with hot water until the wash-water runs colourless. The filtrate is mixed with calcined magnesia to the extent of one and a half times the weight of the leaves taken, and evaporated to dryness on the water-bath. The residue is finely powdered and extracted with hot chloroform. The chloroform extract is evaporated to dryness in a tared beaker, dried at 100—105°, and weighed. The theïne is thus obtained without loss and perfectly colourless. The method may be employed for the preparation of theïne on a large scale as the chloroform can be distilled off.

J. T.

**Coffee.** By B. H. PAUL and A. J. COWNLEY (*Pharm. J. Trans.* [3], 17, 821 and 921).—When coffee is carefully roasted there is no appreciable loss of caffèine. Infusion of coffee as made in France contains nearly the whole of the caffèine present in the sample of coffee. Caffèine can be easily and accurately determined both in roasted coffee and in mixtures of it, and its amount is the best means of determining the proportion of admixed substances.

R. R.

**Analysis of Coffees.** By L. PADÉ (*Bull. Soc. Chim.*, 47, 501—506).—The frequent cases which have occurred of coffees damaged by sea-water having been manipulated by washing and partial roasting has necessitated some certain but rapid means of detection; this the author finds may be attained by determining the specific gravity of the sample. The specific gravities of 24 varieties of genuine raw coffees varied between 1.368 and 1.041, whilst the specific gravities of the same samples after roasting varied between 0.635 and 0.500. Raw coffees therefore having a specific gravity below 1.000 may be suspected of being damaged samples washed and improved in colour by partial roasting.

A second method of sophisticating coffees consists in moistening the roasted berries with steam, in order to recoup the manufacturer for the loss of weight—17 to 19 per cent.—due to roasting, by this means berries may be made to absorb as much as 20 per cent. of water; the fraud may, however, also be detected by determining the specific gravity of the suspected sample, as it rises from about 0.635, the maximum of genuine roasted berries, to between 0.650 and 0.770.

The addition of artificial colouring matters such as the naphthol oranges may be readily detected by extracting the berries with alcohol in which such colouring matters are soluble, whilst genuine coffee does not yield a coloured solution.

The great inconvenience and difficulty of estimating the specific gravity of such a substance as coffee by the ordinary method with water, may be avoided by estimating the displacement of air due to a known weight of the berries by the following process. A weighed quantity of from 50 to 100 grams is placed in an air-tight cylinder the exact capacity of which is known, the air in the cylinder is then compressed by allowing mercury to rise to a given height in a tube attached, the usual corrections having then been made, the height of the mercury in a manometer gives the tension of the air in the cylinder, and the difference between this tension and the tension under similar conditions when the cylinder contains nothing but air indicates the volume of air, and hence the volume of solid matter contained in the cylinder. By this means very rapid and satisfactory determinations may be made. A drawing and full description of the apparatus employed by the author are given in the paper.

A. P.

**Detection of Albumin in Urine.** By L. BLUM (*Chem. Centr.*, 1887, 345).—The usual test for the detection of albumin in urine, namely, the formation of a white coagulum on addition of metaphosphoric acid, is inconvenient on account of the ready conversion of the meta- into pyro- or ortho-phosphoric acid. Instead of the free acid, the author prefers to use an acidified solution of a manganese salt to which has been added an excess of sodium metaphosphate. This can previously be tested by the addition of lead peroxide, which gives a rose-red coloration. The detection of the albumin is best effected by placing a few c.c. of the above solution in a test-glass and filtering the urine into it, when the albumin separates at the junction of the two liquids.

V. H. V.

**Determination of Milk Constituents.** By R. PALM (*Zeit. anal. Chem.*, 26, 319—330).—By most of the existing methods of milk analysis, albumin and casein are the only proteïds determined, and the whole reducing power of the filtrate is ascribed to milk-sugar. Since, however, hemialbumose and the (perhaps identical) lactopeptone of Millon and Commaille escape precipitation by the ordinary reagents and are capable of reducing Fehling's solution, the proportion of milk-sugar is over-estimated, and that of the total proteïds understated. Ritthausen's copper sulphate process suffers from this defect. Tannin, however, precipitates all the proteïds. The fresh precipitate digested at 30—35° with an excess of neutral lead acetate yields lead tannate and a solution of the proteïds in excess of lead acetate. After precipitating the lead by hydrogen sulphide, the amount of the proteïds is found by evaporating the filtrate and drying at 100°. Mercuric nitrate or acetate likewise precipitates all the proteïds, and by adding potash concurrently with the mercuric solution and finally in small excess, the solvent action of free acid or of an excess of mercuric salt

is prevented. A determination of the oxide of mercury (after drying at  $100^{\circ}$ ) gives the proteïds by difference, or the fresh precipitate can be heated with baryta, the barium carefully precipitated by sulphuric acid and the proteïds weighed after evaporating the filtrate. A process which the author recommends for milk is as follows:—10 c.c. are evaporated to dryness; the residue is washed with light petroleum to remove fat, then with ether, which dissolves a small quantity of lactic acid formed during the evaporation, and therefore ought not to be employed for the fat determination. It is then well mixed with 0.2—0.3 gram of finely-ground ignited litharge and enough water to form a paste. This is again dried and then treated with water, when a clear filtrate is readily obtained containing the milk-sugar with some lead, whilst all the proteïds are left as an insoluble lead compound. The amount of each is ascertained by weighing after drying and then burning off the organic matter, using nitric acid to prevent reduction of lead.

## General and Physical Chemistry.

---

**Influence of Simple and of so-called Multiple Union of the Atoms on the Refractive Power of Compounds. Constitution of Benzene and Naphthalene Compounds.** By J. W. BRÜHL (*Ber.*, 20, 2288—2311).—Gladstone showed that the molecular refraction of aromatic compounds is always in excess of the value calculated from Landolt's formula. The author observed a similar excess in the case of all unsaturated compounds which are supposed to contain double union of atoms, the extent of the excess being dependent on the number of double combinations present. The atomic refraction of the saturated carbon-atom  $rC' = 2.48$ , remains the same whether the four affinities are satisfied by single carbon-atoms or by monatomic substituents. Hence if benzene is represented by nine single carbon combinations it would possess a normal molecular refraction.

The molecular refractions of aldehyde and paraldehyde are 11.50 and 32.40 respectively; the latter number is three times the former less 2.10. This number is nearly the same as that obtained by multiplying the refraction-equivalent of the double combination of oxygen and carbon ( $3 \times 0.76 = 2.28$ ).

Tables are given showing the molecular refraction of hydrocarbons  $C_5H_{10}$ ,  $C_{10}H_{20}$ , and  $C_{10}H_{16}$ . The following conclusions are drawn:—That a so-called double combination of atoms is never optically equivalent to two single combinations, and that in the conversion of the former into the latter the increment of refraction disappears entirely or partially according as all or a portion of the multiple combinations are taken up. The author discusses the constitution of benzene, and considers Kekulé's formula to be established; carvacrol and carvol are probably constituted on the same model. Tables are given showing the refraction-equivalents of naphthalene and some of its derivatives; the numbers point to the presence of five ethylene combinations in naphthalene as shown in Erlenmeyer's formula. N. H. M.

**Fluorescence of Spinel.** By L. DE BOISBAUDRAN (*Compt. rend.*, 105, 261—262).—Spinel usually gives a brilliant red fluorescence in a vacuum, but some specimens show a green fluorescence.

If a mixture of magnesia and alumina free from chromium is strongly heated, it yields spinel in fine granules which show no red fluorescence in a vacuum. A feeble green fluorescence is, however, visible, and its spectrum shows the green band observed with the green fluorescence of natural spinel. If the artificial spinel contains 0.1 per cent. of manganese oxide, it shows an intense green fluorescence, the spectrum of which consists of the same band. If 1 per cent. of chromic oxide is added the spinel shows a splendid red fluorescence. It follows that the green fluorescence of natural spinel is due to the presence of manganese, and the red fluorescence is due to the presence of chromium.

C. H. B.

**Crimson Line of Phosphorescent Alumina.** By W. CROOKES (*Proc. Roy. Soc.*, **42**, 25—31).—The author has repeated his previous experiments on this subject (*Phil. Trans.*, 1879, 660; *Ann. Chim. Phys.*, 1859, **57**, 50; *Proc. Roy. Soc.*, **32**, 206), and now gives careful measurements of the spectrum of phosphorescent alumina. This consists of a very faint pair of bands in the red, an intense crimson double line ( $\lambda = 6942$  and  $6937$ ), a pair of faint and nebulous orange lines ( $\lambda = 6707$  and  $6598$ ), and a continuous spectrum commencing at  $\lambda = 6514$  and shading off into the green. The spectrum is different from that of spinel, first described by Becquerel, which shows a faint double band in the extreme red, a narrow crimson line ( $\lambda = 6857$ ), four hazy red bands, and sometimes a continuous spectrum most intense in the green, and shading off gradually to blue and violet. A detailed description of this is given.

De Boisbaudran (this vol., p. 191) attributes the red fluorescence of calcined alumina, when submitted to the electric discharge in a vacuum, solely to the presence of chromic oxide. The author, however, has obtained the double line from pure alumina, quite free from chromium; and has found, moreover, that the line is reduced in intensity when a little chromium oxide is mixed with the alumina.

Alumina precipitated from its ammoniacal solution by boiling shows no crimson line, but simply a greenish phosphorescence; the red line is fully developed only when the earth is calcined at the highest temperature of the blowpipe flame. The author's previous experiments prove that physical differences may greatly influence the phosphorescence. In view of the possibility of the line belonging to some special variety of the earth, he has submitted pure alumina to three separate processes of fractionation, the operations being repeated 20 to 30 times in each case. Details are not given; but the result was that alumina giving the crimson line became concentrated towards one end of the fractionation, whilst the earth accumulating at the other end phosphoresced either green or hardly at all. Chromium was in no case detected.

It is thus still uncertain whether the line is due to alumina, but capable of being suppressed by the presence of some other earth; or if the line belongs to some accompanying earth; or if it depends on the mode of preparation of the alumina; or, lastly, if the molecule of ordinary alumina is complex and the line belongs to one of its constituents.

CH. B.

**Fluorescences of Manganese and Bismuth.** By L. DE BOISBAUDRAN (*Compt. rend.*, **105**, 45—48 and 206—208; see also this vol., pp. 3, 4, 89, and 873). The author has continued his researches, and has examined the fluorescences of a mixture of two solid solvents behaving towards one another as moderately active substances, and a third substance strongly fluorescent with one of the solvents only, as represented by a mixture of cadmium sulphate (100 parts), bismuth sulphate (10 parts), and calcium sulphate. With a proportion of calcium sulphate not exceeding 14·8 per cent., the calcium cadmium fluorescence is prevented by the presence of bismuth, although the calcium bismuth fluorescence is not visible. When the quantity of calcium

sulphate exceeds 16.1 per cent., the calcium bismuth fluorescence becomes visible, and increases in brilliancy with the proportion of calcium sulphate.

The author has also investigated the properties of a mixture of two solid solvents, the first of which ( $\alpha$ ) behaves towards the second ( $\beta$ ) as a moderately active substance, and two active substances, one of which fluoresces with both solvents, and the other with only one of them. These conditions are fulfilled by a mixture of calcium, cadmium, bismuth and manganese sulphates. With an excess of calcium sulphate, the calcium manganese fluorescence is strongest, the calcium bismuth fluorescence much weaker, and the cadmium manganese fluorescence is not visible. With an excess of cadmium sulphate, the cadmium manganese fluorescence is predominant, the calcium manganese fluorescence is also visible, but the calcium bismuth fluorescence cannot be recognised.

The author's experiments lead to the following general conclusions. A substance may show strong fluorescence when disseminated through another substance, and yet show no fluorescence with a third substance closely analogous to the second. A substance may fluoresce strongly with one compound of a metal and not at all with another compound of the same metal; or it may show fluorescence of a different character in the second case. Strongly coloured substances prevent the fluorescence of active substances by reason of their strong absorptive power. A substance may behave as a solvent to one active substance; and also behave as a more or less active substance itself when mixed with a third substance. When two active substances coexist in the same solvent their individual fluorescences are reduced in intensity, but their spectral character is not altered. Two more or less active substances in the same solvent may, however, neutralise one another. A substance which is active under certain conditions, but is inert when mixed with a particular solvent, may yet reduce the effect of a substance which is usually active with this solvent. Fluorescence in a given solvent seems as a rule to diminish on the addition of a second solvent which is not so effective with the active substance as the first solvent, but in some cases this effect is very slight. An active substance generally produces a double fluorescence with a mixture of two active solvents, but with certain proportions one of the fluorescences diminishes in a greater ratio than the quantity of the solvent which produces it. With one active substance, and equivalent quantities of two effective solvents, the two fluorescences usually are equal in intensity, but the contrary is observed in certain cases. If two substances are unequally active with a given solvent, and the ratio of the two is kept constant whilst the proportion of the solvent is gradually increased, it is possible in some cases to observe successively (1) the effect of the less active body alone, (2) the coexistence of the two effects with increasing predominance of the effect of the more active substance. When the proportion of the more active substance is increased, its effect alone is observed whatever the nature of the solvent. Certain fluorescences which are masked by others can be seen when the tube is heated, or by observing immediately after the cessation of the electrical discharge, or by modifying the strength of the discharge.

C. H. B.

**New Fluorescences with Well-defined Spectra.** By L. DE BOISBAUDRAN (*Compt. rend.*, **105**, 258—261, 301—304, 343—348).—Mixtures of alumina with samarium oxide,  $Zr_2O_3$ , or  $Zb_2O_3$ , treated with sulphuric acid and calcined, give fluorescences the spectra of which are characterised by a large number of well-defined lines and bands instead of by one or a few nebulous bands as is usually the case. Calcination at a very high temperature greatly increases the brilliancy of the fluorescences. The positions and characters of the bands and lines are described in detail.

Mixtures of alumina with uranium oxide give no fluorescence at all, and lanthanum and yttrium oxides give no well-marked fluorescences. Alumina and ytterbium oxide give a blue fluorescence, the spectrum of which consists of four bands, which are also observed in the fluorescences of mixtures rich in ytterbium and thulium, or erbium and thulium, and which therefore may be attributed to thulium or to a new element.

Mixtures of alumina with oxides of cerium, erbium, thulium, dysprosium, and gadolinium, have also been examined, and their fluorescences will be described in detail in a subsequent paper.

C. H. B.

**Spectra of Didymium and Samarium.** By E. DEMARÇAY (*Compt. rend.*, **105**, 276—277).—The author has previously stated that the band at 4690 varies in intensity during the fractionation of praseodymium, and he concluded that the band was not due to praseodymium. The fact is confirmed but the conclusion is withdrawn. The purest fractions of praseodymium containing only small quantities of lanthanum show a strong nebulous band at about 4690, which, however, is very different in character from the band previously referred to, and it follows that there are two bands of very similar wave-length, but of different character, one being due to praseodymium and the other to some other element at present unknown.

Neodymium free from praseodymium and containing only a very little samarium, gave a spectrum in which the following bands not previously described were observed. A somewhat narrow band at about 4640 on the less refrangible side of a nebulous didymium band; a narrow and somewhat feeble band at 4300; and in a nitric acid solution a band at 4760, which really consists of two lines at 4734 and 4768 respectively, the more refrangible being the more intense. This double line is seen with pure neodymium.

The author anticipated Kruss, Nilson, and Gerhardt, in the discovery of the compound nature of samarium (*Abstr.*, 1886, 837; and this vol., p. 551).

C. H. B.

**Development of Voltaic Electricity by Atmospheric Oxidation.** By C. R. A. WRIGHT and C. THOMPSON (*Proc. Roy. Soc.*, **42**, 212—216).—The authors have observed that when metallic copper immersed in aqueous ammonia is exposed to a limited supply of air, the metal dissolves chiefly as cuprous oxide. This action, which the authors regard as in all cases the primary action, is very slow when the liquid is kept perfectly at rest; but it can be greatly

accelerated by arranging horizontally near the surface of the liquid a plate, termed the "aëration" plate, of platinum or other conductor not acted on under the circumstances, and joining this to the copper by a wire. When connection is made through a galvanometer, it is found that a current is generated during the action. The voltaic element thus formed polarises rapidly unless the external resistance is very high. Its electromotive force varies from 0.5 to 0.6 volt, and increases with the concentration of the ammonia solution, or when sodium or ammonium chloride is added thereto, or when spongy platinum is substituted for the platinum plate. In the latter case, and with strong ammoniacal brine, it may amount to 0.8 volt, nearly equalling that due to the heat of formation of cuprous oxide (40810), or 0.88 volt.

This battery has a close connection with the air battery of Gladstone and Tribe (this Journal, 1873, 582), which consists of copper in solution of cupric nitrate, and an aëration plate formed by a trayful of crystals of silver nitrate. Cuprous oxide is here deposited on the aëration plate, whilst in the author's cell it is formed at the surface of the copper. This has been proved by means of a battery of special construction. After continued action, copper was found only in the liquid surrounding the copper plate.

The authors are continuing these experiments, and have found that metals not otherwise prone to oxidation (mercury, silver) may be similarly dissolved in appropriate liquids. CH. B.

**Alteration of Carbon Electrodes used for the Electrolysis of Acids.** By H. DEBRAY and PÉCHARD (*Compt. rend.*, 105, 27—30).—The battery used consisted of four Bunsen cells, and the electrodes had been purified by treatment with chlorine. When hydrochloric acid is electrolysed with carbon electrodes, the gas evolved at the positive pole is a mixture of chlorine, carbonic anhydride, and oxygen; in the case of sulphuric acid it is a mixture of oxygen and carbonic anhydride; and in the case of nitric acid a mixture of nitrogen oxides and carbonic anhydride. In all cases, the positive electrode undergoes disintegration, and the black powder which is formed, after being washed and dried in a vacuum, deflagrates at a temperature below a red heat, with evolution of carbonic anhydride and carbonic oxide. When nitric acid has been electrolysed, the gas also contains nitrogen.

The products were analysed by causing them to deflagrate in a vacuum, and collecting the water and oxides of carbon evolved. The deflagrated matter was then heated to bright redness in a porcelain tube, and the gas given off was collected and analysed.

The amount of water and oxygen contained in the product varies with the nature of the acid electrolysed and its degree of concentration. The proportion of oxygen is sometimes as high as 9 to 10 per cent., and that of water as high as 8 per cent.

In the case of hydrochloric acid, no soluble organic compound is formed. C. H. B.

**Conductivity of Bismuth for Heat in a Magnetic Field.** By A. RIGHI (*Compt. rend.*, 105, 168—169).—The conductivity of bis-

muth for heat varies in a magnetic field in the same ratio as its electrical conductivity, and the isothermal lines undergo rotation in the same manner as the equipotential lines.

C. H. B.

**Comparative Radiation of Fused Platinum and Fused Silver.** By J. VIOLLE (*Compt. rend.*, 105, 163—165).—The total radiation of melting platinum as measured by means of a smoked thermopile is 54 times as great as the total radiation of an equal surface of melting silver. This ratio is much less than that of the luminous intensities of the two metals.

C. H. B.

**Heat of Formation of Hydrogen Telluride.** By BERTHELOT and FABRE (*Compt. rend.*, 105, 92—95).—Tellurides of zinc, iron, and the alkalis do not yield pure hydrogen telluride. Better results are obtained with the tellurides of calcium, barium, and magnesium, especially the latter. Magnesium telluride is obtained by heating a mixture of the two elements to dull redness when combination takes place with great violence. A better method is to pass tellurium-vapour over magnesium heated in an atmosphere of pure hydrogen. The telluride is a white, flocculent substance, which alters very readily on exposure to air, and yields pure hydrogen telluride when treated with hydrochloric acid. The gas is very unstable even in the dark, and decomposes at once in contact with moist air. It is completely absorbed by potash. Its odour is different from that of hydrogen sulphide or selenide, and slightly resembles that of hydrogen arsenide, and its action on the animal economy is very much less irritating than that of the selenide. Its solution in alkalis is colourless, but becomes blue in presence of a trace of oxygen, tellurium being precipitated if the oxygen is in excess.

Hydrogen peroxide decomposes hydrogen telluride with formation of water and liberation of tellurium, but part of the latter undergoes oxidation. The reaction with ferric chloride is, however, very definite, and it was therefore used in the thermochemical measurements. The heat developed by the reaction ( $\text{TeH}_2 = 130$ ) is 58.24 Cal., from which it follows that—

The heats of formation of water, hydrogen sulphide, and hydrogen selenide, are respectively + 59.0, + 4.6, and - 12.3 Cal., and it is evident that in the oxygen-group, as in the chlorine-group, the energy of combination with hydrogen diminishes as the atomic weight of the element rises.

C. H. B.

**Heat of Formation of Crystalline Tellurides.** By C. FABRE (*Compt. rend.*, 105, 277—280).—Tellurides can be prepared by passing the vapour of tellurium over the metal, or by heating the finely-divided metal with tellurium in an atmosphere of hydrogen. Ferrous telluride forms steel-grey crystals which scratch glass; cobalt telluride forms brownish crystals; nickel telluride forms small, reddish-grey crystals; thallium telluride resembles galena in appearance, but rapidly tarnishes in the air and is readily powdered. These tellurides

are not affected by cold hydrochloric and sulphuric acids, but slowly alter in moist air.

All the tellurides dissolve readily in bromine-water and bromine, with formation of hydrogen bromide, a metallic bromide and tellurous acid. This reaction was utilised for the determination of the heats of formation of the tellurides, and the numbers given in the following table are the heats of formation of the crystallised compounds from crystallised tellurium and the solid metal. The heats of formation of the selenides are given for comparison.

|                | Selenide. | Telluride. |
|----------------|-----------|------------|
| Ferrous .....  | 18.44     | 15.58      |
| Cobalt .....   | 18.88     | 15.30      |
| Nickel .....   | 18.42     | 15.10      |
| Zinc .....     | 40.40     | 37.22      |
| Cadmium .....  | 24.20     | 19.96      |
| Cuprous.....   | 20.84     | 14.30      |
| Thallium ..... | 17.72     | 12.24      |
| Lead .....     | 15.76     | 11.42      |

The heats of formation of the tellurides are lower than those of the corresponding selenides.

C. H. B.

**Values of the Heats of Combustion of Organic Compounds Determined by Different Methods.** By F. STOHMANN (*J. pr. Chem.* [2], 36, 131—141).—A comparison of the results obtained by the author in his various researches with those published by Berthelot in conjunction with Vieille, Louguinine, and Recoura. A determination of the heat of combustion of naphthalene by Berthelot's method of combustion in compressed oxygen has given the value 1231.5 cal.

W. P. W.

**Passage from the Benzene Series to the Acetic Series.** By BERTHELOT and RECOURA (*Compt. rend.*, 105, 141—145).—A further connecting link between the two series is furnished by the fact that quercite and inosite can both be converted into quinone.

**Quercite.**—Heat of combustion, 1 gram 4.330 Cal.; per gram-molecule at constant volume, +710.1 Cal.; at constant pressure, 709.8 Cal. Heat of formation (crystallised), +268.2 Cal.

**Inosite.**—Heat of combustion, 1 gram 3.703 Cal.; per gram-molecule at constant volume and pressure, +686.5 Cal. Heat of formation, +3.115 Cal. These values are slightly higher than those for glucose.

**Quinic Acid.**—Heat of combustion, 1 gram 4.342 Cal.; per gram-molecule, +833.7 Cal. Heat of formation (crystallised), +238.3 Cal.

The union of quercite with two atoms of oxygen to form inosite would develop +43.3 Cal., a number intermediate between the heat of conversion of benzene into phenol (36.6), and of phenol into quinol (+52.2). The formation of quinic acid and water by the union of quercite and formic acid would develop +53.9 Cal., a number comparable with the heat developed by the similar reaction between phenol and formic acid (+36.6). The conversion of inosite into quinone by removal of 4 mols. water would develop +9.7 Cal., and hence this is a case of dehydration with change of function, but with-

out condensation, accompanied by development of heat. The conversion of quercite into quinone by removal of 3 mols.  $\text{H}_2\text{O}$  would develop +24.9 Cal., and the conversion of quinic acid into hydroxybenzoic acid by a similar reaction would develop +98.7 Cal. The condensation of acetylene to benzene develops +171.0 Cal.

In all cases, the conversion by dehydration of compounds belonging to the acetic acid series into compounds of the benzene series is accompanied by a development of heat, or in other words by a loss of energy, which corresponds with the increased stability acquired by the nucleus of the fundamental hydrocarbon.

C. H. B.

**Boiling Points of Salt Solutions.** By G. T. GERLACH (*Zeit. anal. Chem.*, 26, 413—530).—The author has carefully redetermined the boiling points of solutions of about 40 salts, acids, and alkalis, making in each case a series of observations on solutions of different strengths. With the majority, the formation of a crust during ebullition begins a little below the highest temperature attainable. In the case of salts which crystallise with water of crystallisation, the salting out which occurs on further evaporation is accompanied by a fall of temperature, which in some cases is very considerable. The crystalline magma obtained by salting out sodium sulphate at the boiling point has been observed to boil at  $72^\circ$ , while the escaping steam showed  $100^\circ$ . If in a constant amount of water equal quantities of salt are successively dissolved, the differences in the boiling points invariably decrease, but if in the case of salts which crystallise with water of crystallisation, only the anhydrous salt is considered, the differences between the boiling points for equal increments of salt increase at first, and only begin to decrease when stronger solutions with higher boiling points are reached. This points to the existence, in the weak solutions, of compounds of salt and water acting as a single substance, even at the boiling temperature, and to the dissociation of these hydrated molecules at the higher boiling points.

By laying down the boiling points in curves, it is seen that when equal weights of the salts are regarded, the curves for different substances follow no regular law, and frequently cut one another. With equal equivalents (molecular weight divided by the valency of the metal) the curves of salts of the same group and similar constitution never cut.

No direct connection can be traced between the molecular weights of the dissolved substances and the boiling points of their solutions, nor between specific gravity or specific heat and boiling point. On the other hand, in most cases, solutions of highly soluble salts boil at higher temperatures (for equal molecular concentration) than those of lower solubility. Also those salts which in the act of dissolving produce the smallest amount of contraction are almost invariably those which for equal molecular concentration show the highest boiling points. Ammonium salts are the chief exceptions to both these laws.

Tammann's law that for a given temperature the lowering of the vapour-tension produced by dissolving one molecule of a salt in an invariable quantity of water is equal for salts of similar constitution, is not borne out by the author's observations.

M. J. S.

**Solidification of Liquids by Pressure.** By E. H. AMAGAT (*Compt. rend.*, 105, 165—167).—The author has examined a large number of organic and inorganic liquids at temperatures between  $0^{\circ}$  and  $50^{\circ}$ , and at pressures up to 3000 atmos., but has not observed any signs of solidification. Carbon tetrachloride, however, behaves differently, and solidifies at a high pressure, melting again when the pressure is released. The solid has a very distinct crystalline structure; solidification takes place under a pressure of 210 atmos. at  $-19.5^{\circ}$ , 620 atmos. at  $0^{\circ}$ , 900 atmos. at  $10^{\circ}$ , and 1160 atmos. at  $19.5^{\circ}$ .

Carbon protochloride,  $\text{C}_2\text{Cl}_4$ , does not solidify under a pressure of 900 atmos. at  $0^{\circ}$ , but benzene seems to solidify at about 700 atmos. at  $22^{\circ}$ .

It is probable that every liquid possesses a critical point of solidification analogous to the critical point of gases, that is, a temperature above which no pressure, however great, will convert the liquid into a solid.

C. H. B.

**Dissociation of some Gases by the Electric Discharge.** By J. J. THOMSON (*Proc. Roy. Soc.*, 42, 343—345).—When the vapour of iodine, at a temperature of  $200$ — $230^{\circ}$ , is subjected in a tube exhausted of air to the action of the sparks from a coil giving a 3-inch spark in air, the pressure as indicated by a sulphuric acid manometer increases at first rapidly, then more slowly, and finally becomes stationary. On stopping the coil, the greater part of this increase is permanent, or at least lasts for some hours. The author attributes it to dissociation of the iodine-vapour. The amount of dissociation has been measured by observing the vapour-density in a special apparatus, sulphuric acid being excluded. The density after sparking then fell to 100, 115, 86, and 84 ( $H = 1$ ) in different experiments. In the last case (temp. =  $232^{\circ}$ ), after standing 24 hours, the dissociation still equalled that produced by Meyer at  $1570^{\circ}$ . The colour of the dissociated vapour is stated to be a little lighter and less uniform than that of the normal vapour. The electric strength was also reduced.

When bromine-vapour is sparked in a similar way, an increase of pressure also occurs, but disappears rapidly, probably owing to reunion of the separated atoms. Vapour-density determinations also showed that bromine is dissociated by simple heating at a low pressure for a long time. In such determinations, therefore, the vapour should be maintained at constant temperature for some time before observing.

Experiments have also been made with chlorine and nitrogen tetroxide.

Ch. B.

**Osmotic Equilibrium and the Concentration of Solutions by Gravitation.** By GOUY and G. CHAPERON (*Compt. rend.*, 105, 117—119).—An application of the laws of thermodynamics to the question of osmotic equilibrium.

**Demonstration of the Coefficient of Expansion of Gas as a Lecture Experiment.** By R. SCHIFF (*Gazzetta*, 17, 190—191).—In this paper, a simple apparatus is described for demonstrating the law

of the expansion of gases as a lecture experiment. In a graduated tube surrounded with a warming jacket is inclosed 273 c.c. of dry gas; the tube is connected with a piece of flexible tubing, bent in the form of a **U**, and provided with a mercury reservoir. Previous to the experiment the level of the mercury in both limbs is adjusted, the tube heated with steam, and the level readjusted. If the barometric pressure has remained the same, the reading on the tube will give the coefficient of expansion. V. H. V.

**Estimation of Pressure in Closed Tubes.** By A. REYCHLER (*Ber.*, **20**, 2461—2462).—In this paper, a simple apparatus is described by means of which the pressure in sealed tubes may be roughly estimated. It consists of a glass tube of small diameter, about 40 cm. long, one end of which is sealed off, and 4—5 cm. length from this end is silvered; the tube is then bent in the form of a **U**, and filled to a certain height with mercury. The whole is enclosed in the tube in which it is proposed to carry on the reaction at an increased pressure, which forces down the mercury in the open limb, thus causing it to rise in the sealed limb and dissolve off the silver. Then from the rise of level of mercury thus determined and the tension of the vapour of mercury at the temperature of the reaction, the pressure within the tube can be directly calculated. V. H. V.

---

## Inorganic Chemistry.

---

**Selenium Alums.** By C. FABRE (*Compt. rend.*, **105**, 114—115).—The author has prepared the selenium alums of the following bases:—Sodium, potassium, caesium, rubidium, thallium, ammonium, ethylamine, diethylamine, triethylamine, methylamine, dimethylamine, trimethylamine, and propylamine, by mixing solutions of the corresponding selenate and aluminium selenate. The products have the general composition and crystalline form of the alums, and are colourless. The caesium and rubidium selenium alums are much more soluble than the corresponding sulphur-alums, and it is worthy of note that the soluble thallium alum is formed from a selenate which is almost insoluble in water. The organic alums closely resemble the ammonium salt.

By mixing violet chromium selenate with the selenates of potassium, sodium, caesium, rubidium, thallium, ammonium, ethylamine, and propylamine, the corresponding alums were obtained. They crystallise well, and frequently form very distinct octahedra. They are violet-red by transmitted light, and their solutions are violet when cold, but become green at 55—60°. The green solutions will only crystallise when allowed to evaporate spontaneously for several months. Thallium chromium selenium alum is deep violet by transmitted, and almost black by reflected light. C. H. B.

**Monoclinic Form and Optical Properties of Prismatic Arsenious Anhydride.** By DES CLOIZEAU (*Compt. rend.*, 105, 96—99).—Prismatic arsenious oxide belongs to the monoclinic system. Measurements of the various angles are given. The angle of the prism is  $135^{\circ} 1'$ , and is similar to that of valentinite or prismatic antimonious oxide,  $137^{\circ} 7'$ , but as the other zones of the crystals are not similar the two compounds are not strictly isomorphous. The crystals are highly birefractive, the plane of the optical axis being parallel with the plane of symmetry.

The fact that thin plates of ordinary arsenious oxide are sometimes feebly birefractive, indicates that the crystals are possibly only pseudo-cubic. C. H. B.

**Preparation and Properties of Carbon Oxysulphide.** By P. KLASON (*J. pr. Chem.* [2], 36, 64—74).—To prepare this substance, Than recommends (*Annalen*, Supp. 5, 245) the addition of solid potassium thiocyanate to a cold mixture of 5 vols. strong sulphuric acid and 4 vols. water. The author finds that the purest product and best yield is obtained on adding 50 c.c. of a concentrated aqueous solution of potassium or ammonium thiocyanate to a cooled mixture of 290 c.c. (520 grams) of strong sulphuric acid and 400 c.c. water. The whole is heated at  $25^{\circ}$  in a water-bath. The gas thus prepared contains only about  $2\frac{1}{2}$  per cent. of carbonic anhydride and 0.05 per cent. of carbon bisulphide. Hofmann recommends passing the gas through an ethereal solution of triethylphosphine to free it from carbon bisulphide. The author finds that the absorption of this latter is much more rapid and complete if a small quantity of pure triethylphosphine is used instead of a solution, the gas being then passed through pure sulphuric acid to free it from traces of the phosphine. Carbon oxysulphide is only absorbed very slowly by a 33 per cent. aqueous solution of potash. If the gas obtained as above is passed slowly through about 20 cm. of such a solution, the whole of the carbonic anhydride is absorbed with a loss of only about 7 per cent. of the oxysulphide. A 33 per cent. aqueous solution of potash mixed with its own volume of alcohol absorbs carbon oxychloride completely and rapidly, and is the best reagent for use in estimating it.

Pure carbon oxysulphide is odourless and tasteless. Its physiological effects are very similar to those of nitrous oxide. When passed through a saturated solution of baryta, no opalescence is produced for at least half a minute, whilst if any carbonic anhydride is present, the solution becomes milky at once. With lead acetate solution, the precipitate is a quarter of an hour forming. L. T. T.

**Action of Chlorine on Carbon Bisulphide and of Sulphur on Carbon Tetrachloride.** By P. KLASON (*Ber.*, 20, 2376—2383).—Carbon bisulphide is but slightly attacked by chlorine at ordinary temperatures, but in presence of chlorine-carriers, especially of iodine, action takes place readily with the ultimate formation of carbon tetrachloride. The author has carefully studied this reaction and the intermediate products formed, and also the derivatives

obtained by the action of heat, reducing agents, &c., on such compounds. He has isolated the following compounds:—Thiophosgene,  $\text{CSCl}_2$ , boiling at  $73.5^\circ$ , and gradually changing to its polymeride; trichloromethylsulphur chloride,  $\text{CCl}_3\cdot\text{SCl}$ , boiling at  $149^\circ$ ; *trichloromethyl bisulphide*,  $\text{CCl}_3\cdot\text{S}_2\cdot\text{CCl}_3$ , boiling at  $135^\circ$  in a vacuum; trichloromethyl trisulphide,  $\text{CCl}_3\cdot\text{S}_3\cdot\text{CCl}_3$ , crystalline, and boiling at  $190^\circ$  in a vacuum; and *chlorothio-carbonylsulphur chloride*,  $\text{CSCl}\cdot\text{SCl}$ , boiling at  $140^\circ$ . The compound  $\text{CCl}_3\cdot\text{S}_3\cdot\text{CCl}_3$  is identical with that described by Rathke as  $\text{S}(\text{CCl}_2\cdot\text{SCl})_2$ .

In the action of sulphur on carbon tetrachloride, only carbon bisulphide, sulphur chloride, and sometimes traces of thiophosgene and  $\text{CCl}_3\cdot\text{SCl}$  were formed.

L. T. T.

**Manganese Compounds.** By B. FRANKE (*J. pr. Chem.* [2], **36**, 166—174).—The blue gas formed when air or carbonic anhydride saturated with aqueous vapour at  $40$ — $50^\circ$  is led over the manganese oxysulphate  $(\text{MnO}_3)_2\text{SO}_4$  (this vol., p. 893), is free from ozone, and consists of a new gaseous oxide of manganese, probably *manganese tetroxide*,  $\text{MnO}_4$ , which condenses to a blue-violet amorphous substance at a lower temperature. The quantity obtained was too small to allow of analysis; the compound itself differs, however, in its properties from the trioxide and heptoxide; it is more volatile than the trioxide, and is less readily acted on by water, with which it combines to form manganic acid with the liberation of oxygen. The tetroxide is decomposed by the action of sulphuric acid and ether.

When warm and moderately strong sulphuric acid is treated with potassium permanganate until the brown solution no longer dissolves the salt, and the mixture is heated, a beautifully crystalline, claret-red salt,  $2\text{Mn}_2(\text{SO}_4)_3 + 5\text{K}_2\text{SO}_4$ , is obtained. This salt dissolves in dilute sulphuric acid with a brown colour, and in concentrated sulphuric acid with a blue-violet colour, decomposes on heating into potassium and manganese sulphates, oxygen and sulphuric anhydride, and when treated with much water yields the hydroxide  $3\text{MnO}_2\cdot 2\text{H}_2\text{O}$ , and manganese sulphate. Small, yellowish, lustrous scales of a *manganic manganous oxide*,  $\text{Mn}_3\text{O}_8$ , are obtained, however, if the salt is added to water, the mother-liquor removed as quickly as possible, and the residue washed with water, alcohol, and finally with ether. On treatment with dilute sulphuric acid, the oxide yields manganese sulphate (2 mols.), and the hydroxide  $3\text{MnO}_2\cdot 2\text{H}_2\text{O}$  (1 mol.); it may therefore be regarded as  $3\text{MnO}_2\cdot 2\text{MnO}$ . When heated, it is converted into trimanganic tetroxide,  $\text{Mn}_3\text{O}_4$ .

W. P. W.

**Thorium Silicates.** By L. TROOST and L. OUVRARD (*Compt. rend.*, **105**, 255—258).—When thorium oxide is fused with silica and calcium chloride at a bright red heat, and the crystalline product is treated with water, and then with hydrochloric acid to remove calcium chloride and silicate, a residue of small, rhombic crystals is left, which are insoluble in acids, but are attacked by potassium hydrogen sulphate; sp. gr. at  $16^\circ = 6.82$ . They have the composition  $2\text{ThO}_2\cdot\text{SiO}_2$  or  $\text{ThO}_2\cdot\text{SiO}_2$ , but are not isomorphous with zircon. The thorium may, however, be present in the form of a dioxide, and this supposition

is supported by Krüss and Nilson's recent determination of the vapour-density of thorium chloride. These numbers were always lower than those required by the formula  $\text{ThCl}_4$ , but the authors have repeated the determination by Dumas' method, and have obtained similar though somewhat higher numbers. In this case, the influence of the hydrogen chloride formed by the action of a small quantity of absorbed moisture on the thorium chloride would be less marked, because the greater part of the gas is expelled together with the nitrogen with which the globe is filled. In Victor Meyer's method, on the other hand, a small quantity of substance is taken, and the hydrogen chloride evolved may introduce very considerable errors.

If the thorium oxide, silica, and calcium chloride are fused together at  $1100^\circ$ , and the product treated with water and hydrochloric acid, a residue of crystals and granules is obtained. The latter are attacked by potassium hydrogen sulphate, whilst the former are not affected, and thus they can be separated. The crystals are triclinic, with an angle of extinction of about  $31^\circ$ ; sp. gr. at  $25^\circ = 5.56$ . They have the composition  $\text{ThO}_2\cdot\text{SiO}_2$  or  $\text{Th}_2\text{O}_3\cdot 2\text{SiO}_2$ . This silicate is therefore not analogous to zircon in form or composition, just as thorium metaphosphate is not analogous to silicon metaphosphate (Abstr., 1885, 1113).

C. H. B.

**Thorium Sodium and Zirconium Sodium Phosphates.** By L. TROOST and L. OUVARD (*Compt. rend.*, 105, 30—34).—Sodium metaphosphate fused at a red heat readily dissolves thorium oxide, amorphous thorium phosphate, and anhydrous thorium chloride, and the product is completely soluble in water after cooling. If, however, the thorium compound is added to saturation, and the fused mixture is allowed to cool slowly and extracted with water, a residue is left, consisting of elongated, triclinic prisms, which act strongly on polarised light, the angle of extinction being about  $44^\circ$  whilst the angle of the axis is  $45^\circ$  and the twinning plane is parallel with the plane of the optical axes. The crystals are insoluble in hydrochloric or nitric acid and in aqua regia, and have the composition  $\text{Na}_2\text{O}, 8\text{ThO}_3, 3\text{P}_2\text{O}_5$  ( $\text{Th} = 116.2$ ), or  $\text{Na}_2\text{O}, 4\text{ThO}_2, 3\text{P}_2\text{O}_5$  ( $\text{Th} = 232.4$ ). They are therefore analogous to the compound previously obtained with potassium metaphosphate (Abstr., 1886, 853).

Zirconium oxide, phosphate, and chloride are less readily soluble in sodium metaphosphate, and the product is a crystalline powder composed of feebly birefractive rhombohedra, extinction taking place along the diagonals. It is insoluble in acids and in aqua regia, and has the composition  $\text{Na}_2\text{O}, 4\text{ZrO}_2, 3\text{P}_2\text{O}_5$ ; sp. gr. at  $12^\circ = 3.10$ .

When fused sodium pyrophosphate is mixed with thorium oxide or phosphate, it yields an insoluble powder, consisting of very thin hexagonal, microscopic leaflets. If sodium chloride is added to the mixture, solidification takes place more slowly, and the product is obtained in hexagonal lamellæ, mixed with fragments of hexagonal prisms which act on polarised light, and are soluble in nitric acid. They have the composition  $5\text{Na}_2\text{O}, 4\text{ThO}_3, 3\text{P}_2\text{O}_5$  or  $5\text{Na}_2\text{O}, 2\text{ThO}_2, 3\text{P}_2\text{O}_5$ . If the fused substance is mixed with excess of sodium chloride, thorium oxide is precipitated in minute cubes.

Thorium chloride and sodium pyrophosphate yield birefractive

crystals, which probably belong to the triclinic system. They have the composition  $\text{Na}_2\text{O}, \text{ThO}_2, \text{P}_2\text{O}_5$ . Zirconium oxide or phosphate added to the fused pyrophosphate, yields a crystalline powder. Zirconium chloride added to the pyrophosphate together with a small quantity of sodium chloride, yields hexagonal plates, which act very feebly on polarised light, and are soluble in acids. Sp. gr. at  $14^\circ = 2.88$ . They have the composition  $6\text{Na}_2\text{O}, 3\text{ZrO}_2, 4\text{P}_2\text{O}_5$ . With a larger quantity of sodium chloride, the compound  $4\text{Na}_2\text{O}, \text{ZrO}_2, 2\text{P}_2\text{O}_5$ , is obtained in prisms which act strongly on polarised light, and have a negative bisectrix. They are soluble in acids. Sp. gr. at  $14^\circ = 2.43$ .

On account of its comparative infusibility, normal sodium phosphate alone yields no similar products, but when mixed with sodium chloride it yields the same products as the pyrophosphate.

Thorium sodium and zirconium sodium metaphosphates are similar to one another and to the corresponding potassium compounds (*loc. cit.*), but they are not isomorphous. The double pyrophosphates are not analogous to one another either in form or composition. These results afford no evidence as to the true atomic weight of thorium and the formula of its oxide.

C. H. B.

**Vanadates.** By A. CARNOT (*Compt. rend.*, 105, 119—122).—When ammonia is added gradually to a cold acid solution containing vanadic acid, the yellow colour becomes deeper and deeper, up to the point at which the reaction becomes neutral; the colour persists for a long time if the liquid remains cold. Conversely, if an acid is added gradually to a colourless alkaline solution of a vanadate, the yellow colour appears as soon as the reaction becomes acid, but diminishes in intensity when excess of acid is added. These facts indicate that in almost neutral solutions acid vanadates are formed with a deeper colour than that of vanadic acid itself. The reactions of such solutions with metallic salts are different from those observed under ordinary conditions, various acid vanadates being formed. In order to ensure the formation of normal vanadates, an ammoniacal solution should be only partially neutralised, or the liquid should be boiled in presence of a slight excess of ammonia.

*Cobalt and Nickel.*—Cobalt nitrate and vanadic acid in a solution exactly neutralised with ammonia give an orange precipitate of the vanadate  $\text{CoO}, \text{V}_2\text{O}_5$ . Precipitation is complete after several hours if the liquid is neutral, but takes place more slowly in presence of any ammonium salt other than the nitrate. Nickel yields a similar precipitate, but its formation takes place more slowly, and is prevented by the presence of ammonium nitrate. Hot solutions of nickel and cobalt salts yield respectively pale-yellow and brown precipitates, but precipitation is always incomplete, and is prevented by ammonium chloride.

Zinc salts with neutral vanadates give yellow precipitates, which become white when heated. Zinc nitrate and ammonium vanadate yield a white precipitate, easily soluble in acids and in ammonia, the whole of the vanadic acid being precipitated.

Cadmium salts in neutral solutions yield a white precipitate, readily

soluble in the slightest excess of acid or ammonia. Precipitation is always incomplete.

Copper salts in the cold give a greenish-yellow precipitate of the vanadate  $\text{CuO} \cdot \text{V}_2\text{O}_5$ , which becomes greenish-brown when heated. If the solution is hot, the precipitate is brownish-yellow, and becomes black when boiled. It has the composition  $2\text{CuO} \cdot \text{V}_2\text{O}_5$ . In both cases precipitation is incomplete, and if ammonium sulphide is added a black precipitate is formed, and the liquid is brown; the precipitated sulphide contains vanadium, and the liquid contains copper. On acidifying the liquid, a rose-brown copper vanadium sulphide is precipitated. Arsenates and copper salts behave in a similar manner.

Mercurous nitrate in neutral solutions precipitates the whole of the vanadic acid in the form of the orange vanadate,  $\text{Hg}_2\text{O} \cdot \text{V}_2\text{O}_5$ . In presence of a slight excess of ammonia, a grey or blackish precipitate of complex composition is formed. When these precipitates are heated in hydrogen sulphide, vanadium sulphide is left in a pure condition, and this method may be used for the isolation and estimation of vanadium. Mercuric chloride produces no precipitate if the solution is acid, but on adding ammonia, a pale-yellow precipitate is formed. If the liquid is neutral when the mercuric chloride is added, the precipitate is white. Precipitation is complete, and this method may also be used for the isolation of vanadium in the manner just described.

Lead salts yield a precipitate which is pale yellow in presence of a slight excess of acetic acid, yellowish in presence of a slight excess of ammonia. Precipitation is almost complete in neutral solutions.

Bismuth nitrate precipitates the whole of the vanadic acid as a yellowish-white precipitate on addition of ammonia. If the liquid is slightly acid, an orange precipitate is formed on boiling, but precipitation is incomplete. If the acid liquid is mixed with sodium acetate and then boiled, a bright yellow precipitate of the vanadate  $\text{Bi}_2\text{O}_3 \cdot \text{V}_2\text{O}_5$  is formed. This becomes orange when heated, but regains its yellow colour on cooling.

C. H. B.

**Atomic Weight of Gold.** By G. KRÜSS (*Ber.*, 20, 2365—2368).—Referring to the discrepancy between his own (this vol., p. 778) and Thorpe and Laurie's (*Trans.*, 1887, 565) determinations of the atomic weight of gold, the author points out that in one of his papers on gold (*Annalen*, 238, 265), he has shown that potassium aurobromide always contains about 0.05 per cent. of free gold, probably formed during crystallisation by the reducing action of organic matter in the air. Thorpe and Laurie have not taken account of this fact. Applying this correction to Thorpe and Laurie's determination, the atomic weight obtained by means (1) of the ratio  $\text{Au} : \text{KBr}$  becomes 196.616; (2) of the ratio  $\text{Au} : \text{Ag}$ , 196.559; (3) of  $\text{Au} : \text{AgBr}$ , 196.575, or lower than the number 196.64 previously obtained by the author. The author therefore upholds the correctness of his determinations.

L. T. T.

**Gold Sulphides.** By L. HOFFMANN and G. KRÜSS (*Ber.*, 20, 2369—2376).—The statements given in various text-books concerning the sulphides of gold are very conflicting, compounds  $\text{Au}_2\text{S}$ ,

$\text{Au}_2\text{S}_2$ , and  $\text{Au}_2\text{S}_3$  being variously given. The sulphide  $\text{Au}_2\text{S}_2$  is perhaps usually accepted, the existence of the other two very often disputed. These conclusions are, however, by no means justified. Berzelius believed he obtained  $\text{Au}_2\text{S}$  by passing hydrogen sulphide into a boiling solution of auric chloride. Levöl, on the other hand, states that under these conditions free gold is alone deposited. The author finds that Levöl's statement is correct, if care is taken to keep the temperature of the whole solution at  $100^\circ$ . If local cooling takes place the precipitate contains varying proportions of combined sulphur, but no definite compound can be obtained. In all their experiments the authors washed the precipitated sulphide by decantation with water, alcohol, ether, and carbon bisulphide successively. They found that the free sulphur was retained very firmly, and could not be completely removed by washing on the filter.

When hydrogen sulphide was passed through a solution of potassium aurocyanide, no apparent change took place, but when excess of hydrochloric acid was added, and the whole heated, *aurous sulphide*,  $\text{Au}_2\text{S}$ , was precipitated as a steel-grey precipitate. This was carefully washed as above, and obtained in a dry state as a brownish-black powder of constant composition, corresponding with the above formula. When freshly precipitated, it dissolves in water to a brown solution. It is therefore necessary in purification to wash it with water containing hydrochloric acid, in which it is not soluble. When once dried, it is no longer soluble in water. It is not decomposed when boiled with dilute hydrochloric or sulphuric acids. Aqua regia, chlorous oxide, and other oxidising agents oxidise it easily. Bromine-water slowly dissolves it, with formation of  $\text{AuBr}_3$  and sulphuric acid. Alkaline monosulphides dissolve it but slowly and slightly, polysulphides rapidly and completely, with the formation of green solutions of sulpho-salts. Caustic potash solution does not attack it even at  $100^\circ$ , whereas the compound  $\text{Au}_2\text{S}_2$  is, under like conditions, decomposed into gold, potassium gold sulphide, and potassium gold oxide. Potassium cyanide dissolves it readily, and the sulphide is reprecipitated by boiling the solution with excess of hydrochloric acid. This reaction gives a good means of purifying the sulphide from free sulphur, as a slightly warmed solution of potassium cyanide dissolves the former and not the latter. When heated in a tube, part of the sulphur distils off, and part passes off as sulphurous anhydride. The compound is completely decomposed at  $240^\circ$ , and ignites in oxygen at a low temperature. When heated in a stream of hydrogen, hydrogen sulphide is formed, but in a stream of hydrogen chloride the sulphur sublimes without the formation of any hydrogen sulphide, and pure gold is left.

The existence of a soluble aurous sulphide and a soluble aurous oxide (Krüss, *Untersuchungen über das Atomgewicht des Goldes*, München, 1885) speaks strongly in favour of placing gold in the alkali-group rather than in the platinum-group.

L. T. T.

## Mineralogical Chemistry.

**Trona, Idrialine, and Zinc-bloom.** By V. v. ZEPHAROVITCH (*Zeit. Kryst. Min.*, **13**, 135—144).—1. *Crystals of Trona*,  $\text{Na}_6\text{C}_4\text{O}_{11} + 5\text{H}_2\text{O}$ .—The author has measured 50 crystals of trona from the soda works of Ebensee. The axial ratio he found to be  $a : b : c = 2.8459 : 1 : 2.9696$ .  $\beta = 77^\circ 23'$ . Analysis gave the following results :—

| $\text{CO}_2$ . | $\text{Na}_2\text{O}$ . | $\text{H}_2\text{O}$ . | $\text{Na}_2\text{SO}_4$ . | Total. | Sp. gr. |
|-----------------|-------------------------|------------------------|----------------------------|--------|---------|
| 38.93           | 40.77                   | 19.96                  | 0.20                       | 99.86  | 2.14    |

2. *Idrialine Crystals from Idria*.—The discovery of idrialite in pistachio-green nodules in the Idria mercury mines was announced by R. Scharitzer (*Abstr.*, 1883, 427). In 1886, specimens of a new variety were found. The specimens are of a yellowish-green to sulphur-yellow colour, and consist of pure idrialine. Microscopic examination shows that the plates belong to the monoclinic system.

3. *Fibrous Zinc-bloom (Hydrozincite) from Carinthia*.—It has hitherto not been observed that hydrozincite frequently exhibits a finely fibrous texture, especially in the reniform masses produced from the alteration of smithsonite. Analysis of some remarkably fibrous specimens of hydrozincite on galena recently obtained at Bleiberg, gave the following results (I) :—

|     | $\text{CO}_2$ . | $\text{ZnO}$ . | $\text{PbO}$ . | $\text{H}_2\text{O}$ . | $\text{Fe}_2\text{O}_3$ . | $\text{SiO}_2$ . | Total. |
|-----|-----------------|----------------|----------------|------------------------|---------------------------|------------------|--------|
| I.  | 17.05           | 70.76          | 1.26           | 10.30                  | 0.42                      | 0.36             | 100.15 |
| II. | 17.05           | 69.79          | 1.26           | 10.12                  | —                         | —                | —      |

After subtracting the percentages of silica present as hemimorphite, and of iron present as limonite, the remainder (II) corresponds with the formula  $4\text{ZnCO}_3 + 5\text{Zn}(\text{HO})_2 + \text{H}_2\text{O}$ . This formula does not agree with any yet given. B. H. B.

**Turquoise from the Kirghise Steppes.** By N. J. v. KOKSCHAROFF (*Zeit. Kryst. Min.*, **13**, 187).—A greenish-blue mineral from the Karkaralinsk district of the Province of Semipalátinsk gave on analysis the following results :—

| $\text{P}_2\text{O}_5$ . | $\text{Al}_2\text{O}_3$ . | $\text{Fe}_2\text{O}_3$ . | $\text{Cu}_2\text{O}$ . | Loss on ignition. | Total. | Sp. gr. |
|--------------------------|---------------------------|---------------------------|-------------------------|-------------------|--------|---------|
| 34.42                    | (35.79)                   | 3.52                      | 7.67                    | 18.60             | 100.00 | 2.887   |

These results show that the new turquoise is characterised by an exceptionally high percentage of copper. It is not soluble in hydrochloric acid or nitric acid, although it is in alkalis. B. H. B.

**Epsomite from Poland.** By W. K. ZGLENITZKIJ (*Zeit. Kryst. Min.*, **13**, 200—201).—In an abandoned level in the Tscharkoffy Sulphur Mines, the author observed an efflorescence having a saline bitter taste. Analysis showed that the mineral had the composition  $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ . Hitherto, epsomite has not been found in Russia any-

where except in the Siberian Steppes. At Tscharkoffy, it occurs in an argillaceous marl, of Upper Cretaceous age, in which well-preserved remains of *Ananchytes ovata* are found. The marl contains magnesia, and encloses beds of gypsum and sulphur. The hydrogen sulphide, formed from the decomposition of gypsum in the presence of organic remains, may be detected throughout the mine, and, on decomposition, yields sulphur and sulphuric acid or epsomite. B. H. B.

**Augite from the Whin Sill.** By J. J. H. TEALL (*Zeit. Kryst. Min.*, 13, 180—181).—The author gives the following two analyses of augite: I, from the normal Whin Sill (diabase containing bronzite), from Cauldron Snout; sp. gr. about 3·3; II, from the coarsest variety of the Whin Sill rocks, half a mile south of Tyne Head; sp. gr. 3·33.

|     | SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | FeO.              | MnO. | CaO.   | MgO.  |
|-----|--------------------|----------------------------------|----------------------------------|-------------------|------|--------|-------|
| I.  | 49·03              | 5·46                             | —                                | 15·57             | 0·22 | 15·34  | 11·66 |
| II. | 48·41              | 4·05                             | 2·36                             | 15·08             | 0·37 | 15·98  | 12·14 |
|     |                    | Na <sub>2</sub> O.               |                                  | H <sub>2</sub> O. |      | Total. |       |
|     |                    | I. 1·24                          |                                  | 0·81              |      | 99·33  |       |
|     |                    | II. —                            |                                  | 1·19              |      | 99·58  |       |

The analysis of the first augite corresponds with the formula  $14\text{CaFeSi}_2\text{O}_6 + 5\text{CaMgSi}_2\text{O}_6 + 6\text{Mg}_2\text{Si}_2\text{O}_6 + 3\text{MgAl}_2\text{SiO}_6 + \text{MgFe}_2\text{SiO}_6$ . B. H. B.

**Andesine from Scourie Bay, Sutherlandshire.** By J. J. H. TEALL (*Zeit. Kryst. Min.*, 13, 181).—A vein of nearly pure felspar occurs in a dyke of hornblende schist at Scourie Bay. The principal cleavage of the felspar is parallel to the brachypinacoid. The sp. gr. is about 2·644. Analysis gave the following results:—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | CaO. | MgO. | Na <sub>2</sub> O. | K <sub>2</sub> O. | Total. |
|--------------------|----------------------------------|------|------|--------------------|-------------------|--------|
| 58·16              | 26·66                            | 5·79 | 0·65 | 6·99               | 1·76              | 100·01 |

B. H. B.

**Minerals from Porthalla Cove, Cornwall.** By J. H. COLLINS (*Zeit. Kryst. Min.*, 13, 180).—The author gives the following analyses of minerals from the rocks of Porthalla Cove:—

|                                      | Ia.   | Ib.   | Ic.   | Id.   | II    | III.  |
|--------------------------------------|-------|-------|-------|-------|-------|-------|

Totals ..... 100·00 100·00 100·00 100·00 100·00 99·18

I. Serpentine from Porthalla Cove, mostly associated with hornblende schist; *a.* greyish-green and granular, sp. gr. 2·65; *b.* dark green, sp. gr. 2·56; *c.* reddish-brown and granular, sp. gr. 2·545; *d.* dark red, sp. gr. 2·644. II. Hornblende from the Porthalla hornblende-schist. III. Plagioclase (anorthite) from the same rock, slightly weathered.  
B. H. B.

**Microscopic Crystals of Albite in Calcareous Rocks of the Western Alps.** By C. LORY (*Compt. rend.*, 105, 99—101).—The author has shown many years ago that the dolomites and limestones of the triassic formation of the Western Alps contain microscopic crystals of albite, often accompanied by bipyramidal quartz and lamellæ of mica. The albite crystals are better developed the more crystalline the limestone in which they occur, but the occurrence of the crystals is not necessarily connected with the general crystalline character of the triassic beds.

The limestones of the lias are not crystalline with the exception of the liassic marble at Villette, which contains crystals of albite, but this is an exceptional deposit and rests directly on the trias. Albite crystals are also found in a very compact, white, nummulitic limestone in the bed of Montricher, near St. Jean de Maurienne.

The genesis of these albite crystals, which has taken place chiefly in the triassic limestones of the Western Alps, has also occurred exceptionally in middle lias and eocene beds. The formation of the crystals is connected with the special nature of the deposits in which they are found and the conditions which have favoured the crystallisation of the latter.  
C. H. B.

**Composition of Volcanic Rocks.** By L. RICCIARDI (*Gazzetta*, 17, 141—154).—The results of analyses of the volcanic rocks of Italy show that their composition is modified by successive eruptions. Thus the eruptive matter emitted from submarine volcanoes in past times was of an acidic nature, and contained about 73 per cent. of silica, but this has gradually changed to a basic character, and now contains only about 48 per cent. of silica. Several examples of this gradual modification are adduced. On the other hand, Etna and Vesuvius, which are always more or less active, have emitted within the last three centuries a product of constant composition, of the basic type. In order to explain this conversion from the acidic or trachytic form into the basic, which is especially exemplified in the case of the submarine volcanoes of Euganei and Pantelleria, the author suggests that the change is brought about by a reaction between the solid constituents of the Mediterranean Sea and the primordial rock. Thus, within the volcanoes, the chlorine is converted into hydrogen chloride by the dissociation of the water, and the radicles  $\text{SO}_4$  and  $\text{CO}_3$  are emitted as sulphurous and carbonic anhydrides, whilst the remaining constituents react with and modify the original rock. In this paper, it is shown that if a typical substance compounded of the fixed residue of the Mediterranean is compared with an argilliferous pliocenic marl, then this substance, mixed in proportions successively decreasing from 50 to 1 with one

proportion of an original trachytic rock as pantellerite, would give products of percentage composition similar to those of the various typical rocks from more recent to more ancient times. For the present, these considerations are limited to the volcanic rocks of Italy, as better studied than other examples, although geological evidence tends to show that similar phenomena occurred in the granitic plateau of central France and in Hungary. Further analyses of the matter emitted in recent eruptions of volcanoes situated in various parts of the world show that the first substance elaborated is always granite.

V. H. V.

**Meteorite at Djati Pengilon, Java.** By DAUBRÉE (*Compt. rend.*, 105, 203—207).—This meteorite fell on March 19th, 1884, and weighed 166 kilos. It possesses a high tenacity, and does not readily break under the hammer. The fractured surface shows a remarkably large number of small cleavage faces, and resembles certain fine-grained felspathic rocks; the crust is not firmly adherent. Mean sp. gr. of the meteorite 3·747.

According to an analysis by Retgers, it consists of nickeliferous iron, 21·3; triolite, 5·1; olivine, 33·4; bronzite, 39·0; and chromite, 0·1 per cent. The metallic portion consists of iron, 88·68; nickel, 10·78; and cobalt, 0·54 per cent. Thin slices of the meteorite are transparent, but contain opaque and tuberculous granules. The olivine and bronzite both contain inclosures.

This meteorite belongs to a somewhat rare type, and is identical in lithological character with one which fell at Tjabé, a neighbouring place, on September 19th, 1869.

**Solid  $\alpha$ -Dichlorethyl Cyanide and its Conversion into Triethyl Cyanuride.** By R. OTTO and K. VOIGT (*J. pr. Chem.* [2], 36, 78—98).—This compound melting at 73—74° was first obtained together with its liquid isomeride by Otto. It crystallises in the clinorhombic system. The lower the temperature at which the chlorination of the propionitrile is carried out, the larger the quantity formed. It would seem to be a polymeride of the liquid compound, the polymerisation being in all probability produced by the hydrogen chloride formed during the chlorination. It is doubtful whether the hydrogen chloride acts mechanically, or really first forms a compound with the liquid cyanide which then breaks up yielding hydrogen chloride and the solid compound. Sulphuric acid does not cause polymerisation. Both the liquid and solid nitriles are converted into  $\alpha$ -dichloropropionic acid when heated with moderately strong sulphuric acid. Alcoholic ammonia at 95° converts the solid cyanide into  $\alpha$ -dichloropropionamide. Nitrous anhydride has no action on it. When treated with alcohol, zinc and acetic acid, the solid cyanide yields *triethyl cyanuride*,  $C_3N_3Et_3$ . This substance crystallises in long, hexagonal

prisms, melts at  $29^{\circ}$ , volatilises at ordinary temperatures, and boils at  $193-195^{\circ}$ . Its vapour-density corresponds with the formula,  $C_9H_{15}N_3$ . It is easily soluble in alcohol, ether, and chloroform, sparingly in water, and has an odour resembling that of opium. The aqueous solution is neutral, has a burning taste, and becomes milky when slightly warmed. It is easily soluble in strong hydrochloric acid, and this solution yields a platinochloride. When heated with hydrochloric acid, the cyanuride is decomposed into ammonia and propionic acid.

E. v. Meyer has lately shown (this vol., p. 364) that the compound which has hitherto been called cyanethine is not really a cyanuric compound, but contains an amido-nitrogen-atom. It is therefore probable that the above compound is the true cyanuric compound, and the original compound would then be tri-dichlorethyl cyanuride,

$CCl_2Me \cdot C \begin{smallmatrix} \text{N} : C(CCl_2Me) \\ \text{N} \cdot C(CCl_2Me) \end{smallmatrix} \geq N$ . The yield of the non-chlorinated com-

pound was only about one-third of that theoretically possible. When, in the reduction experiment, the alcohol is mixed with water, a base,  $C_9H_{16}N_2$ , is obtained. This crystallises in silky needles or plates, melts at  $111^{\circ}$ , boils at  $273^{\circ}$ , but is not volatile in steam. It has an intensely bitter taste, is readily soluble in alcohol, ether, and chloroform, sparingly in water. Its aqueous solution is strongly alkaline, and it is a monacid base. Its *hydrochloride* forms colourless needles, its *platinochloride* doubly refractive orange crystals; and its *silver-derivative* white flocks.

L. T. T.

**Action of Acids on Thiocyanic Acid.** By P. KLASON (*J. pr. Chem.* [2], 36, 57—64).—It is generally stated that thiocyanic acid is decomposed by acids, yielding either perthiocyanic acid and hydrocyanic acid or carbon oxychloride. The author finds, however, that often, under the action of acids, it yields dithiocarbamic acid, its anhydride or bisulphide. When a strong solution of thiocyanic acid contains little or no mineral acid, it is decomposed into perthiocyanic and hydrocyanic acids. A dilute solution is stable either with or without mineral acid. A strong solution in the presence of a large excess of hydrochloric acid gives off carbon oxysulphide, carbonic anhydride, and a little carbon bisulphide, whilst thiocarbamic bisulphide,  $S_2(CS \cdot NH_2)_2$ , is formed. The same compound is produced when hydrogen sulphide is passed into a solution of thiocyanic acid. If sulphuric acid is substituted for hydrochloric acid, carbon oxysulphide is evolved, and a mixture of dithiocarbamic anhydride,  $S(CS \cdot NH_2)_2$ , and thiocarbamic bisulphide is produced. When warmed with water, these substances yield sulphur, carbon bisulphide and ammonium thiocyanate. With aniline, monophenylthiocarbamide and its thiocyanate, diphenylthiocarbamide, ammonium thiocyanate, sulphur, and hydrogen sulphide are formed.

Dry hydrogen chloride has scarcely any action on dry potassium thiocyanate, but if the salt be moist, *thiocarbamic chloride*,  $Cl \cdot CS \cdot NH_2$ , is formed. This is a white, crystalline substance which volatilises without fusing. It dissolves in water, the solution containing hydrochloric and thiocyanic acids in molecular proportion.

L. T. T.

**Crystalline Form of Quercin.** By C. FRIEDEL (*Compt. rend.*, **105**, 95—96).—The crystals were prepared by Vincent and Delachanal (this vol., p. 909), and are very brilliant, anhydrous, monoclinic prisms the dominant faces being  $m$ , and the other faces  $p$  and  $b^1$ , the latter sometimes truncating the edges  $mp$ , sometimes being so largely developed that the base of the prism almost disappears. The following measurements were made:  $mm$ ,  $116^\circ 5'$ ;  $mg$ ,  $31^\circ 57.5'$ ;  $pb^1$ ,  $44^\circ 11'$ ;  $pm$   $75^\circ 47'$ ;  $mb^1$ ,  $60^\circ 2'$ ;  $b^1b^1$ ,  $75^\circ 2'$ . From these numbers it follows that—

$$Dh : Di : h = 0.5526 : 1 : 0.2125,$$

$$b : h = 5.376.$$

The inclination of the edge  $h$  to the inclined diagonal is  $62^\circ 21'$ , and the angle of the base is  $57^\circ 50'$ . Extinction takes place along the plane  $g'$ , which is not parallel with the edges  $mm$  but makes with them an angle of about  $30^\circ$ .  
C. H. B.

**Comparative Sweetness of Cane- and Starch-sugar.** By T. SCHMIDT (*Bied. Centr.*, 1887, 504).—Experiments proved that 1.53 parts of pure grape-sugar was as sweet as 1 part of pure beet- or cane-sugar.  
E. W. P.

**Decomposition of Saccharose by Boiling with Lime.** By W. NIEDSCHLAG (*Bied. Centr.*, 1887, 488—489).—As it is a known fact that the yield of crystalline saccharose is less after the crude sugar has been boiled with lime, 250 grams of saccharose were dissolved in 1500 c.c. water, 250 grams slaked lime added, and the whole boiled for 21 days, the result was that most of the sugar was decomposed, and a non-crystalline calcium salt formed containing 20.5 per cent. calcium. Another experiment made for 24 hours with lime, strontia, and baryta, when a water-bath was used, and air excluded, and carbonic anhydride passed in, showed that here again the sugar was decomposed but not to the same extent.

E. W. P.

**Substituted Methylenediamines.** By A. EHRENBERG (*J. pr. Chem.* [2], **36**, 117—131).—Kolotoff, by the action of trioxymethylene on diethylamine, obtained tetrethylmethylenediamine: this base and its lower homologue could not be prepared by Hofmann's reaction, employing methylene iodide and the corresponding secondary monamine, owing to the fact that the salts of the methylenediamines are extremely unstable, and decompose into trioxymethylene and the hydriodide of the base originally employed. Tetramethylmethylenediamine also could not be obtained by Kolotoff's reaction, but higher homologues were prepared by its means.

Tetrethylmethylenediamine dissolves to the extent of 1 part in 10 parts of water, and on treatment with dilute acids, with perfectly dry hydrogen chloride, and with alcoholic solutions of platinic chloride and of oxalic acid, yields the corresponding salts of diethylamine, whilst prolonged boiling with moist ethyl iodide converts it into tetrethylammonium iodide. When dry carbon bisulphide is added to the dry

base, a molecular compound,  $\text{CH}_2\text{N}_2\text{Et}_4\text{CS}_2$ , is obtained, which boils at  $130\text{--}140^\circ$  with decomposition; if, however, the materials are not quite anhydrous, diethylamine diethyldithiocarbamate is formed.

*Tetrapropylmethylenediamine*,  $\text{CH}_2\text{:N}_2\text{Pr}_4$ , is formed when trioxymethylene is heated with the calculated quantity of dipropylamine. It boils at  $215\text{--}225^\circ$  with slight decomposition, does not solidify in a freezing mixture of ice and salt, is sparingly soluble in water, readily soluble in alcohol, ether, and chloroform, and yields salts with platinum chloride, gold chloride, and trinitrophenol, which, however, could not be obtained in a state suitable for analysis.

*Tetrisobutylmethylenediamine*,  $\text{CH}_2\text{:N}_2(\text{C}_4\text{H}_9)_4$ , prepared in a manner similar to the preceding compound, boils at  $245\text{--}255^\circ$  with slight decomposition. The *platinochloride*,  $\text{C}_{17}\text{H}_{38}\text{N}_2\text{H}_2\text{PtCl}_6$ , is a fawn-coloured, crystalline powder, melts at  $196\text{--}198^\circ$  with decomposition, and when heated to boiling in aqueous solution decomposes into the platinochloride of diisobutylamine. The *aurochloride* is a yellow, crystalline powder, and melts at  $185\text{--}195^\circ$  with decomposition. With dry carbon bisulphide, the base forms a molecular compound,  $\text{C}_{17}\text{H}_{38}\text{N}_2\text{CS}_2$ , which on standing crystallises in large scales, melts at  $54^\circ$ , and in solution stains the skin yellow.

*Dipiperidylmethane*,  $\text{CH}_2(\text{NC}_5\text{H}_{10})_2$ , obtained in like manner from piperidine, boils at  $230^\circ$  without decomposition, has a sharp peppermint-like odour, and on treatment with aqueous acids decomposes into trioxymethylene and piperidine. Perfectly dry hydrogen chloride converts the dry base, dissolved in light petroleum, into the hydrochloride if the action is continued only for a short time: this is a white powder which, when separated and dried in an atmosphere free from moisture, contains an amount of hydrogen chloride intermediate between 1 and 2 mols.  $\text{HCl}$ ; the continued action of the gas, however, results in the formation of piperidine hydrochloride. A molecular compound,  $\text{C}_{11}\text{H}_{22}\text{N}_2\text{CS}_2$ , is obtained on the addition of dry carbon bisulphide to the dry base; this melts at  $58^\circ$ , is soluble in alcohol and ether, insoluble in water, and on treatment with iodine in alcoholic solution is converted into piperidylthiuram bisulphide,  $(\text{CS}\cdot\text{NC}_5\text{H}_{10})_2\text{S}_2$ , which melts at  $130^\circ$ , and is soluble in alcohol and ether, insoluble in water. Moist carbon bisulphide converts the base into piperidine piperidyldithiocarbamate melting at  $174^\circ$ .

*Dipiperidylphenylmethane*,  $\text{CHPh}(\text{NC}_5\text{H}_{10})_2$ , has been prepared by Klotz by the action of benzaldehyde on piperidine. It crystallises from alcohol in large, flat needles, melts at  $78\text{--}79^\circ$ , and is extremely soluble in benzene, carbon bisulphide, ether, chloroform, toluene, and light petroleum. On distillation in a vacuum, or on exposure to a moist atmosphere, it decomposes with the formation of benzaldehyde.

W. P. W.

**Derivatives of Chlorinated Methyl Formate.** By W. HENTSCHEL (*J. pr. Chem.* [2], 36, 99—113).—In the dark, chlorine acts only very slightly on methyl formate even at the boiling point, but in sunlight action is rapid at ordinary temperatures. If the current of chlorine is continued as long as the gas is absorbed, *trichloromethyl chloroformate*,  $\text{Cl}\cdot\text{COO}\cdot\text{CCl}_3$ , is the main product. This boils at  $127\cdot5\text{--}128^\circ$ , and has a sp. gr.  $1\cdot6525$  at  $14^\circ$ . Its vapour-density is  $6\cdot636$  (air = 1).

When heated much above its boiling point, it is decomposed, yielding carbon oxychloride. It also closely resembles carbon oxychloride in its reactions. With dimethylaniline and benzaldehyde, it yields a green, with dimethylaniline a violet colour-base. With sodium acetate it yields acetic anhydride. Methyl alcohol acts on it to form a liquid boiling at 163—164°, probably impure  $\text{OMe}\cdot\text{COO}\cdot\text{CCl}_3$ .

When the chlorination is stopped at an earlier stage, a compound,  $\text{C}_4\text{H}_3\text{Cl}_5\text{O}_4$ , may be obtained. This is a liquid boiling at 108—109°, and having a very irritating odour. Its sp. gr. is 1.4786 at 14° and 1.4741 at 27°, compared with water at the same temperatures. When heated strongly, it decomposes. With water, it yields carbonic anhydride, carbonic oxide, formaldehyde, and hydrochloric acid. With methyl and ethyl alcohol, it yields methylated derivatives which have not yet been isolated. The compound described by Cahours as perchlormethyl chloroformate has probably a more complicated constitution.

L. T. T.

**Derivatives of Isopropylformamide.** By M. SPICA (*Gazzetta*, **17**, 168—171).—*Isopropyl chlorocarbonate*, prepared by the action of carbonyl chloride on isopropyl alcohol, is a colourless oil boiling at 94—96°; sp. gr. at 4° = 1.144; it has an irritating odour, is insoluble in water, but soluble in alcohol and ether.

With  $\alpha$ -naphthylamine, it yields *isopropyl formonaphthylamide*,  $\text{Pr}^\beta\text{O}\cdot\text{CO}\cdot\text{NH}\cdot\text{C}_{10}\text{H}_7$ , together with  $\alpha$ -naphthylamine hydrochloride, of which the former is soluble, the latter insoluble in alcohol. The formonaphthylamide crystallises in long needles melting at 78—79°, of pungent, aromatic taste, soluble in ether and chloroform.

From  $\beta$ -naphthylamine the corresponding  $\beta$ -derivative is obtained; it melts at 70°, and resembles the above compound in crystalline form and appearance.

V. H. V.

**Derivatives of Isopropyl Chlorocarbonate.** By M. SPICA and G. DE VARDA (*Gazzetta*, **17**, 165—168).—On passing a current of ammonia into isopropyl chlorocarbonate, *isopropylformamide* is produced together with ammonium chloride; the former is separated from the latter by its solubility in alcohol. The formamide,  $\text{Pr}^\beta\text{O}\cdot\text{CONH}_2$ , thus obtained crystallises in white, slightly deliquescent needles, melting at 36—37°, soluble in most menstrua.

Similarly from aniline and isopropyl chlorocarbonate, the corresponding *phenyl*-derivative is obtained together with aniline hydrochloride; the two substances are separated by fractional crystallisation from aqueous alcohol. The phenylformamide,  $\text{Pr}^\beta\text{O}\cdot\text{CONHPh}$ , crystallises in prismatic needles melting at 42—43°, soluble in alcohol and ether, insoluble in cold water.

V. H. V.

**Preparation of Valeric Acid.** By E. DUCLAUX (*Compt. rend.*, **105**, 171—173).—The oxidation of amyl alcohol by potassium permanganate should be effected in presence of an excess of alcohol, otherwise the valeric acid first formed is converted into acetic acid, and this is further oxidised to carbonic anhydride and water. It is likewise necessary to keep the liquid cool. Some acetic acid is always

produced, but this is readily removed by taking advantage of the fact that when a dilute solution of the two acids is distilled, almost the whole of the valeric acid is found in the first quarter of the distillate, whilst the acetic acid remains in the retort. This property of valeric acid seems to be independent of its optical properties. C. H. B.

**Isomerism in the Crotonic Acid Series.** By A. MICHAEL and G. M. BROWNE (*J. pr. Chem.* [2], **36**, 174—176).—The authors have not succeeded in obtaining a good yield of  $\alpha$ - $\beta$ -dichlorobutyric acid by passing a current of chlorine through a solution of crotonic acid in carbon bisulphide (compare this vol., p. 655), since the greater part of the crotonic acid is not attacked under these conditions. If, however, the solution, cooled in a freezing mixture, is saturated with chlorine, allowed to remain three days, again saturated with the gas, and finally allowed to remain for three days more, a good yield of the dichlorobutyric acid is obtained. On treatment of an alcoholic solution of the acid (1 mol.) with alcoholic potash (2 mols.) in small portions at a time,  $\alpha$ -chlor-allocrotonic acid is formed; this crystallises in needles which melt at  $67^\circ$ , and are soluble in water and light petroleum. The *potassium* salt crystallises from water in white, thin tables, from alcohol in slender needles; the *sodium* salt forms small, prismatic needles; the *barium* salt forms slender needles; the *lead* salt forms octahedral crystals, and the *copper* salt crystallises in greenish-blue, concentrically-grouped prisms. Although anticipated by Wislicenus (*loc. cit.*) in the publication of this work, the authors reserve to themselves the right of continuing the research. W. P. W.

**Ethyl Acetocyanacetate.** By A. HALLER and A. HELD (*Compt. rend.*, **105**, 115—117).—23 grams of ethyl cyanacetate is dissolved in its own weight of absolute alcohol and mixed with a solution of 4.6 grams of sodium in 60 grams of absolute alcohol; 8 grams of acetic chloride dissolved in 20 grams of ether is then added, and the liquid is heated until the alkaline reaction disappears. The product is evaporated on a water-bath, the residue taken up with water, and treated with ether to remove ethyl cyanacetate. The aqueous solution is then acidified with sulphuric acid, and the ethyl acetocyanacetate is extracted with ether. It is purified by fractionation in a vacuum. The reaction is represented by the equation  $2\text{CN}\cdot\text{CHNa}\cdot\text{COOEt} + \text{AcCl} = \text{NaCl} + \text{CN}\cdot\text{CH}_2\cdot\text{COOEt} + \text{CN}\cdot\text{CNaAc}\cdot\text{COOEt}$ .

This reaction affords positive proof of the accuracy of the constitution generally assigned to this compound.

Three methods of preparing ethyl acetocyanacetate are now known, and the product is the same in all three cases. C. H. B.

**Thio-derivatives of Ethyl Carbonate.** By P. KLASON (*Ber.*, **20**, 2384—2385).—When ethyl alcohol is treated with thiophosgene the principal reaction takes place according to the equation  $\text{EtOH} + \text{CSCl}_2 = \text{HCl} + \text{EtCl} + \text{COS}$ , but at the same time some *ethyl chlorothiocarbonate*,  $\text{CSCl}\cdot\text{OEt}$ , is formed. This is a colourless oil of very irritating odour, and boils at  $136^\circ$ . Ammonia converts it into xanthogenamide. When sodium ethoxide is substituted for alcohol in

the above reaction, the action follows the equation  $\text{OEtNa} + \text{CSCl}_2 = \text{OEtCS}\cdot\text{ONa} + 2\text{NaCl} + \text{Et}_2\text{O}$ . With ethyl hydrosulphide, thiophosgene yields *ethyl chloroperthiocarbonate*,  $\text{CSCl}\cdot\text{SEt}$ . It is a yellow oil of irritating odour resembling garlic. In a vacuum, it distils at  $100^\circ$ . Its density at  $16^\circ$  is 1.1408. With sodium thioethylate, thiophosgene forms *ethyl perthiocarbonate*,  $\text{CS}(\text{SEt})_2$ , which is a yellow oil boiling at  $240^\circ$ .  
L. T. T.

**Acids from Acetone-chloroform.** By C. WILLGERODT (*Ber.*, 20, 2445—2449).—Three acids are derived from acetone-chloroform, namely, acetic acid, acetonaloxymethylbutyric acid, and acetoxymethylbutyric acid. To obtain these oxymethylbutyric acids, acetone-chloroform is heated directly with water or aqueous solutions of the alkalis; for the preparation of acetonaloxymethylbutyric acid, 2 mols. of chloroform and 3 mols. of acetone are condensed with 8 mols. of potash; and for acetoxymethylbutyric acid 1 mol. acetone-chloroform and 1 mol. acetone are required.

Acetonaloxymethylbutyric acid has been described by the author (*Abstr.*, 1883, 177), and more recently by Engel; its *barium* salt can be obtained in a crystalline form by slow evaporation in a vacuum; the *zinc* salt crystallises in aggregates with 1 mol.  $\text{H}_2\text{O}$ , and the *calcium* salt in small pyramids with  $1\frac{1}{2}$  mol.  $\text{H}_2\text{O}$ .

*Acetoxymethylbutyric acid*,  $\text{C}_7\text{H}_{14}\text{O}_4$ , crystallises with 1 mol.  $\text{H}_2\text{O}$  in the monoclinic system:  $a : b : c = 1.719 : 1 : 0.609$ ;  $\beta = 109^\circ 80'$ . Observed faces,  $\infty\text{P}\infty$ ,  $\infty\text{P}$ ,  $\text{P}\infty$ . When kept, it slowly effloresces.

V. H. V.

**Constituents of Rape-seed Oil.** By C. L. REIMER and W. WILL (*Ber.*, 20, 2385—2390).—The authors find that this oil contains the glycerides of erucic, behenic, and *rapic* acids. The behenic acid is only present in small quantities. The oil was saponified, and the erucic and *rapic* acids separated by means of their zinc salts, zinc erucate being very sparingly soluble in boiling ether, *zinc rapate* easily so. The latter salt was recrystallised from alcohol, and then melted at  $78^\circ$ . *Rapic acid*,  $\text{C}_{18}\text{H}_{34}\text{O}_2$ , is an oil. Its composition seems to point to its being a hydroxyoleic acid, and an isomeride of ricinoleic acid, but unlike this acid, it does not yield sebacylic acid when fused with potash. Under these circumstances it yields stearic acid, and a second crystalline acid, which has not yet been isolated. *Barium*, *calcium*, *magnesium*, and *silver rapates* form flocculent precipitates; the sodium salt is soluble in water and boiling alcohol.

Goldschmidt has shown that the oil from black mustard seed contains the glycerides of erucic and behenic acids and of another liquid acid, and it is probable that this oil is identical with rape-seed oil.

*Trierucin*,  $\text{C}_3\text{H}_5(\text{C}_{22}\text{H}_{41}\text{O}_2)_3$ , was obtained by heating dierucin (this vol., p. 233) and erucic acid together at  $300^\circ$ . It is crystalline, melts at  $31^\circ$ , and is soluble in ether and benzene, sparingly so in alcohol. When warmed with nitric acid and sodium nitrite, it is converted into the isomeric tribrassinin.  
L. T. T.

**Preparation of Ethyl Cyanomalonate and Ethyl Benzoyl-cyanacetate.** By A. HALLER (*Compt. rend.*, 105, 169—171).—*Ethyl*

*cyanomalonate*.—22 grams of ethyl cyanacetate is dissolved in its own volume of absolute alcohol and mixed with a solution of 4.6 grams of sodium in 60 grams of absolute alcohol, and about 6 grams of ethyl chlorocarbonate. A rapid action takes place, and the liquid is heated until it is no longer alkaline. The alcohol is then distilled off, the residue dissolved in water, the unaltered ethyl cyanacetate is removed, and the liquid allowed to evaporate spontaneously. It yields slender needles of the composition  $\text{CN} \cdot \text{CNa}(\text{COOEt})_2$ , and when the aqueous solution of this compound is acidified with sulphuric acid, ethyl cyanomalonate is liberated and can be extracted with ether.

*Ethyl benzoylcyanacetate* is obtained in a similar manner, 1 mol. proportion of benzoic chloride being used for each molecular proportion of ethyl cyanacetate taken.

The action of ethyl iodide on the silver-derivative of ethyl cyanacetate yields a liquid which has an odour of carbylamine, and is in all probability ethyl ethylisocyanacetate. C. H. B.

**Action of Ammonia on Ethyl Bromosuccinate.** By G. KOERNER and A. MENOZZI (*Gazzetta*, 17, 171—176).—Although asparagine is justly regarded as amidosuccinamic acid, yet hitherto it has not been obtained from succinic acid by any direct method of synthesis. With this view, the authors investigated the action of ammonia on ethyl bromosuccinate under various conditions. It is found that both alcoholic and aqueous ammonia in the cold yield fumaramide; if, however, the mixture is heated at 105—110°, a substance isomeric with fumaramide is obtained, which yields barium aspartate when heated with barium hydrate. This compound is probably an imide of aspartic acid,  $\text{NH}_2 \cdot \text{CH} < \begin{smallmatrix} \text{CO} \cdot \text{NH} \\ \text{CH}_2 \cdot \text{CO} \end{smallmatrix} >$ , as when heated with aqueous ammonia in a sealed tube it takes up a molecule of water, and is thereby converted into asparagine. This synthetical asparagine resembles the natural substance in crystallising with 1 mol.  $\text{H}_2\text{O}$ , but differs from it in being optically inactive. The crystals are holohedral, with hemihedric faces. V. H. V.

**Ethyl Succinimidoacetate and Camphorimidoacetate.** By A. HALLER and G. ARTH (*Compt. rend.*, 105, 280—283).—Succinimide (1 mol.) is dissolved in absolute alcohol, and mixed with sodium ethoxide (1 mol.) and ethyl monochloracetate (1 mol.), and the mixture heated until the alkaline reaction disappears. The alcohol is then driven off, the residue allowed to crystallise and the product purified by repeated crystallisation from ether. *Ethyl succinimidoacetate*,  $< \begin{smallmatrix} \text{CH}_2 \cdot \text{CO} \\ \text{CH}_2 \cdot \text{CO} \end{smallmatrix} > \text{N} \cdot \text{CH}_2 \cdot \text{COOEt}$ , is thus obtained in slender needles, very soluble in water, alcohol, and ether. They melt at 66.5°, and remain superfused at the ordinary temperature.

*Ethyl camphorimidoacetate*,  $\text{C}_8\text{H}_{14} < \begin{smallmatrix} \text{CO} \\ \text{CO} \end{smallmatrix} > \text{N} \cdot \text{CH}_2 \cdot \text{COOEt}$ , is obtained in a similar manner, and crystallises from alcohol in large transparent crystals, which melt at 86°, and are soluble in ether.

When ethyl succinimidoacetate dissolved in absolute alcohol is

mixed with an equivalent quantity of metallic sodium also dissolved in alcohol, a gelatinous mass is precipitated, which, after being dried in a vacuum, is very hygroscopic, and dissolves completely in water. The percentage of sodium agrees fairly well with the formula  $\langle \text{CH}_2\cdot\text{CO} \rangle \text{N}\cdot\text{CHNa}\cdot\text{COOEt}$ , hence it would seem that the presence of the two CO-groups confers acidic functions on the  $\text{CH}_2$ -group, although they are separated by the nitrogen-atom. C. H. B.

**Action of Carbamide on the Chloralcyanhydrins.** By A. PINNER and J. LIFSCHÜTZ (*Ber.*, 20, 2345—2351).—When equal weights of chloralcyanhydrin,  $\text{CCl}_3\cdot\text{CH}(\text{OH})\cdot\text{CN}$ , and carbamide are heated together at  $90^\circ$  and lastly at  $110^\circ$ , *trichlorethylidenediureide*,  $\text{CCl}_3\cdot\text{CH}(\text{NH}\cdot\text{CO}\cdot\text{NH}_2)_2$ , is formed. This crystallises in white needles, insoluble in the usual solvents, and decomposes at a high temperature without previous fusion. Biuret and cyanuric acid are also formed, but are probably secondary products due to the action of the liberated hydrogen chloride on carbamide.

When butyrochloral-cyanhydrin and carbamide are heated together at  $100$ – $105^\circ$ , and finally at  $120^\circ$ , two compounds,  $\text{C}_6\text{H}_5\text{Cl}_3\text{N}_3\text{O}_2$  and  $\text{C}_5\text{H}_7\text{ClN}_2\text{O}_2$ , are formed. The former crystallises in small needles, easily soluble in alcohol, sparingly in water; when heated strongly, it is decomposed without previous fusion. It is probably *butyrochloral-biuret*,  $\text{CHClMe}\cdot\text{CCl}_2\cdot\text{CH}:(\text{N}_2\text{H}_2\text{C}_2\text{O}_2):\text{NH}$ . The second compound is *chlorocrotonylcarbamide*,  $\text{CHMe}:\text{CCl}\cdot\text{CO}\cdot\text{NH}\cdot\text{CO}\cdot\text{NH}_2$ . It appears to be dimorphic, crystallising sometimes in rhombic plates, melting at  $224$ – $225^\circ$ , easily soluble in alcohol, sparingly in water, and sometimes in flat prisms easily soluble in water; the latter melt at  $194^\circ$ , but the re-solidified mass when again heated melts at  $209^\circ$ . When heated above  $224^\circ$ , both modifications of this carbamide evolve hydrochloric acid and yield *ethylidenemetapyrazolone*,  $\text{CHMe}:\text{C}\langle \text{CO}\cdot\text{NH} \rangle_{\text{NH}\cdot\text{CO}}$ . This substance crystallises in pale grey needles easily soluble in boiling water. When strongly heated it decomposes without previous fusion.

Besides these compounds, a small quantity of an easily soluble substance crystallising in rhombic prisms was formed. This has not yet been obtained in a pure state. L. T. T.

**Behaviour of Furfuraldehyde in the Animal Organism.** By M. JAFFÉ and R. COHN (*Ber.*, 20, 2311—2317).—Furfuraldehyde was given to dogs in daily amounts of 5 to 6 grams without producing any appearance of poisoning. In the case of rabbits, the action was much more marked. In the urine of the animals experimented on, the following compounds were found:—Pyromucic acid, pyromykuric acid, and a glycocine compound of furfuracrylic acid.

*Pyromykuric acid (glycocine pyromucate)*,  $\text{C}_7\text{H}_7\text{NO}_4$ , separates from the ethereal extract of the urine in crystalline crusts; it crystallises from water in colourless, transparent prisms, resembling hippuric acid, and melts at  $165^\circ$ . The *barium salt*,  $(\text{C}_7\text{H}_6\text{NO}_4)_2\text{Ba} + 1\frac{1}{2}\text{H}_2\text{O}$ , is precipitated by alcohol from its concentrated aqueous solution in plates

of a silvery lustre; when boiled with baryta-water, it is decomposed quantitatively into pyromucic acid and glycocine.

*Pyromykuric acid carbamide*,  $C_7H_7NO_4 \cdot CO(NH_2)_2$ , occurs in large quantities in the urine of dogs fed with meat. It crystallises from benzene in groups of colourless needles melting at  $120^\circ$ ; it is very readily soluble in water and alcohol, sparingly in ether. When heated with barium carbonate, it decomposes into pyromykuric acid and urea.

*Furfuracryluric acid (furfuracryl-glycocine)*,  $C_9H_9NO_4$ , is obtained in largest amount when dogs are fed with bread, and the furfuraldehyde applied (in 7 per cent. solution) subcutaneously. It forms colourless needles melting at  $213-215^\circ$ , very sparingly soluble in water, rather readily soluble in alcohol. The *silver salt* forms colourless, microscopic needles. When boiled for six to eight hours with strong baryta-water, glycocine and furfuracrylic acid are formed. The latter melts at  $140^\circ$  (not  $135^\circ$ ). N. H. M.

**Isomeride of Benzene.** By G. GRINER (*Compt. rend.*, 105, 283).—Cuprous acetylide is mixed with an alkaline solution of potassium ferricyanide and the mixture is distilled. A solid compound passes over with the water, and is separated, dried, and redistilled. It melts at  $64^\circ$ , and boils at  $129-130^\circ$ ; vapour-density 2.81. The formula of the compound is  $C_6H_6$ , and it is an isomeride of benzene. It behaves as an unsaturated compound, and in presence of carbon bisulphide combines with four atoms of bromine, forming a crystalline compound which melts at  $44^\circ$ . It does not react with ammonio-cuprous chloride, and therefore is not acetylenic in character.

C. H. B.

**Action of Cyanuric Chloride and Chlorocyanuric Diamide on Phenols of the Higher Series.** By R. OTTO (*Ber.*, 20, 2236—2240).—*Triparanitrophenyl cyanurate*,  $(C_6H_4 \cdot NO_2)_3C_3N_3O_3$ , is obtained by adding 1 gram of phenyl cyanurate in very small quantities to 8 c.c. of well-cooled fuming nitric acid. Water is gradually added, and the yellowish-white flakes which separate crystallised from glacial acetic acid. It forms pale-yellow plates melting at  $194^\circ$ . The yield is almost quantitative. When heated with hydrochloric acid for several hours, it is converted into cyanuric acid and paranitrophenol.

*Triorthocresyl cyanurate*,  $(C_6H_4Me)_3C_3N_3O_3$ , is prepared by adding sodium to an excess of fused orthocresol, and then the calculated amount of cyanuric chloride. The product is warmed several times with dilute aqueous soda and washed with water. It crystallises in long, pale-yellow needles, melting at  $152^\circ$ , insoluble in water, sparingly soluble in alcohol, readily in ether and glacial acetic acid. The *meta-derivative* resembles the ortho-compound; it crystallises from glacial acetic acid in almost white, microscopic needles which melt at  $225^\circ$ . It is very sparingly soluble in ether and alcohol. The *para-compound* crystallises from a mixture of alcohol and glacial acetic acid in white, matted needles of a silky lustre; it melts at  $207^\circ$  and dissolves sparingly in alcohol and ether.

*Tri Eugenyl cyanurate*,  $(C_3H_5 \cdot C_6H_3 \cdot OH)_3C_3N_3O_3$ , is obtained by the action of cyanuric chloride (1 mol.) on the sodium salt of eugenol (3 mols.) in presence of an excess of the phenol as a yellow, oily sub-

stance which solidifies when kept. It crystallises in pale-yellow, microscopic plates, insoluble in cold water, sparingly soluble in ether and alcohol, readily in glacial acetic acid. It melts at  $122^{\circ}$ .

*Trithymyl cyanurate*,  $(C_6H_3MePr)_3C_3N_3O_3$ , resembles triengenyl cyanurate. It separates from alcohol as a pale-yellow, crystalline powder melting at  $151^{\circ}$ . It dissolves readily in alcohol and glacial acetic acid, sparingly in water.

$\alpha$ -*Trinaphthyl cyanurate*,  $(C_{10}H_7)_3C_3N_3O_3$ , is a greenish-yellow powder, sparingly soluble in hot water, alcohol, and ether, more soluble in glacial acetic acid, benzene, and chloroform; it separates from its solutions in flakes which have no constant melting point, but decompose between  $160^{\circ}$  and  $225^{\circ}$ .

$\beta$ -*Trinaphthyl cyanurate* is a sparingly soluble, light grey powder which decomposes at  $220^{\circ}$ .

An excess of sodium phenoxide reacts with chlorocyanuric diamide in presence of phenol, with formation of phenyl cyanurate. When sodium phenoxide and the diamide are employed in molecular proportions *phenylammelina*,  $C_3N_3(NH_2)_2(OPh)$ , is obtained. This forms an almost white crystalline powder melting at  $245^{\circ}$ ; it is sparingly soluble in ether and alcohol, more soluble in dilute alcohol. When boiled with potash (2 mols.), it is converted into ammelide.

The cresols react with chlorocyanuric diamide, yielding *cresylammelines*,  $C_{10}H_{11}ON_3$ ; the *ortho-compound* is a white, crystalline substance which melts at  $225^{\circ}$ .  
N. H. M.

**Nitrochlorotoluenes and Chlorotoluidines.** By M. HÖNIG (*Ber.*, 20, 2417—2420).—By the nitration of orthochlorotoluene, besides metanitro-orthochlorotoluene (*Abstr.*, 1886, 1022) a second nitro-derivative is formed which, when reduced with zinc and hydrochloric acid, yields a liquid chlorotoluidine. The latter forms a chloracetotoluide which crystallises in needles and melts at  $136^{\circ}$ . After purification by conversion into this toluidine, the chlorotoluidine was digested with alcoholic soda and zinc-dust, when orthotoluidine was obtained. The original nitro-derivative must therefore be *orthonitro-orthochlorotoluene*,  $NO_2 \cdot C_6H_3MeCl$  [ $Me : Cl : NO_2 = 1 : 2 : 5$ ].

*Metanitrometachlorotoluene*,  $C_6H_3MeCl \cdot NO_2$  [ $Me : Cl : NO_2 = 1 : 3 : 5$ ], was prepared by removing the amido-group from metadinitro-*para*-toluidine by Staedel's reaction, reducing the metadinitro-*para*-toluidine thus obtained by means of ammonium sulphide to metanitrometachlorotoluidine, and then, by means of Sandmeyer's reaction, displacing the amido-group in the latter compound by chlorine. It crystallises in yellow needles soluble in alcohol, distils in a current of steam, and melts at  $55^{\circ}$ . *Metachlorometatoluidine* is a basic oil and boils at  $242^{\circ}$  under 730 mm. pressure. Its *hydrochloride* and *nitrate* are crystalline; its *aceto-derivative* is soluble in boiling water, crystallises in needles, and melts at  $146^{\circ}$ .

By the nitration of *para*-chlorotoluene with fuming nitric acid, besides the two mononitro-derivatives, *orthometadinitrochlorotoluene*,  $C_6H_3ClMe(NO_2)_2$  [ $Me : NO_2 : NO_2 : Cl = 1 : 2 : 3 : 4$ ], melting at  $76^{\circ}$ , is formed. The corresponding diamine hydrochloride gives no quinone with oxidising agents, nor colour reaction with nitrous acid and diazo-

benzene, but with benzaldehyde hydrogen chloride is evolved, showing the correctness of the above formula. This compound is soluble in alkalis. When orthonitroparachlorotoluene is treated with fuming nitric and sulphuric acids, it yields the compound  $\text{C}_6\text{H}_2\text{MeCl}(\text{NO}_2)_2$  [ $\text{Me} : \text{NO}_2 : \text{Cl} : \text{NO}_2 = 1 : 2 : 4 : 6$ ], melting at  $101^\circ$ . Metanitroparachlorotoluene with fuming nitric acid yields  $\text{C}_6\text{H}_2\text{MeCl}(\text{NO}_2)_2$  [ $\text{Me} : \text{NO}_2 : \text{Cl} : \text{NO}_2 = 1 : 3 : 4 : 5$ ], which melts at  $48^\circ$ .

L. T. T.

**Orthocyanotoluene.** By S. GABRIEL and R. OTTO (*Ber.*, **20**, 2222—2224).—*Orthocyanobenzyl chloride*,  $\text{CN}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\text{Cl}$ , is prepared by passing dry chlorine into 100 grams of almost boiling orthocyanotoluene until there is an increase in the weight of about 30 grams; if the product is left over night in a dish, in the morning it will have solidified to a mass of crystals of a vitreous lustre. The adhering liquid is removed by suction, and the crystals washed with cold alcohol. It dissolves in hot water, more readily in hot alcohol, melts at  $60\text{--}61.5^\circ$ , and boils at  $252^\circ$  under  $758.5$  mm. pressure; the vapour is extremely irritating to the eyes and nose. The crystals are monoclinic;  $a : b : c = 0.7775 : 1 : 0.2939$ ;  $\beta = 60^\circ 2'$ .

*Orthocyanobenzyl cyanide*,  $\text{CN}\cdot\text{C}_6\text{H}_4\cdot\text{CN}\cdot\text{CN}$ , is obtained by adding 30 grams of the chloride to a solution of 15 grams of potassium cyanide (96—98 per cent.) in 60 c.c. of water and 300 c.c. of alcohol, and heating the whole for 45 minutes in a reflux apparatus. Two-thirds of the alcohol is then distilled off, and the residue poured into 500 c.c. of water. The crystals so obtained are freed from adhering liquid by suction, washed and dried. It crystallises from alcohol in colourless plates which melt at  $81^\circ$  and dissolve readily in the usual solvents.

N. H. M.

**Oxidation of the Homologues of Phenol.** By B. HEYMANN and W. KOENIGS (*Ber.*, **20**, 2390—2397).—The authors have now extended their experiments on this subject (see *Abstr.*, 1886, 542, and this vol., p. 241) to dihydric phenols.

When thymoquinol tetrapotassium diphosphate,  $\text{K}_4(\text{C}_{10}\text{H}_{12})\text{P}_2\text{O}_8$ , was oxidised by means of potassium permanganate, paradihydroxyterephthalic acid (Baeyer, *Abstr.*, 1886, 445) was obtained. The yield was very small, but the same acid was obtained with a better yield by the oxidation of paraxyloquinol tetrapotassium diphosphate,  $\text{K}_4(\text{C}_8\text{H}_8)\text{P}_2\text{O}_8$ , which contains no large side-chain detrimental to ready oxidation. Paraxyloquinone is best prepared by dissolving 100 grams of commercial pseudocumidine,  $\text{C}_6\text{H}_2\text{Me}_3\cdot\text{NH}_2$ , in two litres of water containing 800 grams of strong sulphuric acid, and treating this solution with excess of manganic peroxide. The reduction to paraxyloquinol,  $\text{C}_6\text{H}_2\text{Me}_2(\text{OH})_2$ , is best carried out by means of zinc-dust and acetic acid.

In their last communication on this subject, the authors described an acid isomeric with parapropenylsalicylic acid. Several salts of this acid are now described, but its constitution has not yet been determined.

L. T. T.

**Constitution of Chlor- and Brom-anilic Acid.** By A. HANTZSCH and K. SCHNITER (*Ber.*, **20**, 2279—2282; compare this vol., p. 719).—When meta- and para-dichloroquinone are brominated, they yield the same dichlorodibromoquinone [ $O_2 : Cl_2 : Br_2 = 1 : 4 : 2 : 6 : 3 : 5$ ]. When the quinone is reduced by means of hydroxylamine, a quinol is formed, melting at 233·5—234°. The acetyl-derivative melts at 268—270°. (Compare also Levy, *Abstr.*, 1885, 1210.) N. H. M.

**Preparation of Quinones: Halogen-derivatives of Toluquinone.** By K. SCHNITER (*Ber.*, **20**, 2282—2288).—Toluquinone is prepared in the following manner:—20 grams of orthotoluidine is dissolved in 600 c.c. of water and 160 grams of sulphuric acid, the solution cooled to 10—15°, and treated for an hour with 20 grams of very finely powdered potassium dichromate. The whole is left over night and is then treated with 33 grams of potassium dichromate. The product is extracted with ether, the extract dried and the ether distilled off. The almost pure and dry quinone so obtained weighs about 19 grams. In a similar manner 19 grams of quinone was obtained from 20 grams of aniline.

*Chlorotoluquinol*,  $C_6H_2MeCl(OH)_2$ , is formed when finely powdered toluquinone is kept in contact with strong hydrochloric acid for 12 to 24 hours. The product is crystallised first from light petroleum, and then from water in presence of sulphurous acid. It separates in needles or plates which melt at 175° with decomposition; it dissolves sparingly in light petroleum, readily in ether, chloroform, and in hot water, and becomes oxidised when exposed to air.

*Bromotoluquinol*,  $C_6H_2MeBr(OH)_2$ , is prepared in a manner similar to the chloro-derivative. It crystallises from water in lustrous plates melting at 160°.

*Chlorotoluquinone*,  $C_6H_2MeClO_2$ , is obtained by distilling the quinol with a solution of ferric chloride, or by oxidising it with chromic mixture. The product contains higher substituted quinones which could not be removed; it melts constantly at 105°, dissolves readily in ether, chloroform, and alcohol, sparingly in hot water. The *bromo-derivative* crystallises from alcohol in broad, yellow crystals, melting at 105°; it could not be obtained pure.

*Chlorobromotoluquinol*,  $C_6HMeClBr(OH)_2$ , is formed by the union of chlorotoluquinone and hydrogen bromide. It is soluble in benzene and chloroform, and dissolves very readily in ether and alcohol, crystallising from the latter solvent with 1 mol.  $H_2O$ . It dissolves slowly in water and in light petroleum. The anhydrous compound melts at 123°.

*Bromochlorotoluquinol*,  $C_6HMeBrCl(OH)_2 + H_2O$ , is prepared by the action of hydrogen chloride on bromotoluquinone. It crystallises from hot water in stellate groups of needles melting at 120—121°. Unlike its isomeride, it retains its water of crystallisation when kept over sulphuric acid.

*Chlorobromotoluquinone*,  $C_6HMeClBrO_2$ , obtained by oxidising chlorobromotoluquinol, crystallises from alcohol in needles melting at 109—111°; it dissolves very readily in ether, benzene, and chloroform, but is scarcely soluble in water.

*Bromochlorotoluquinone*,  $C_6HMeBrClO_2$ , prepared from bromochlorotoluquinol, crystallises from alcohol in lustrous, yellow needles which melt at  $150^\circ$ .

Monochlorotoluquinone reacts with hydrogen chloride with formation of dichlorotoluquinol melting at  $120$ — $121^\circ$  (Claus and Schweitzer, Abstr., 1886, 614). The reaction is accompanied with considerable rise of temperature.

N. H. M.

**Formation of Primary Amines from the Corresponding Halogen-derivatives.** By S. GABRIEL (*Ber.*, 20, 2224—2236).—*Ethylenediphthalimide*,  $C_8H_4O_2:N\cdot CH_2\cdot CH\cdot N:C_8H_4O_2$ , is prepared by heating potassium phthalimide (10 grams) with ethylene bromide (12 grams) for two hours at  $200^\circ$ , and boiling the product with water containing a little caustic soda. The insoluble, oily substance thus obtained solidifies on cooling, and is boiled with 50 c.c. of alcohol. When cold, the ethylenediphthalimide is collected and crystallised from glacial acetic acid, from which it separates in long, lustrous needles melting at  $232^\circ$ . The chief product of the reaction is *bromethylphthalimide*,  $C_8H_4O_2:N\cdot C_2H_4Br$ , which crystallises from water, in which it is very sparingly soluble, in long needles melting at  $82$ — $83.5^\circ$ . When ethylenediphthalimide is heated with 3 parts of fuming hydrochloric acid at  $200^\circ$ , it is converted into ethylenediamine and phthalic acid.

*Benzylphthalimide*,  $C_8H_4O_2:N\cdot CH_2Ph$ , is obtained by heating potassium phthalimide (3 parts) and benzoic chloride (2 parts) for two hours at  $170$  to  $180^\circ$ ; it crystallises from alcohol in long needles melting at  $115$ — $116^\circ$ . When heated with fuming hydrochloric acid at  $200^\circ$ , it is decomposed into benzylamine and phthalic acid.

*Orthonitrobenzylphthalimide*,  $C_8H_4O_2:N\cdot CH_2\cdot C_6H_4\cdot NO_2$ , is prepared by rubbing 37 grams of potassium phthalimide with 31.5 grams of orthonitrobenzoic chloride, shaking the mixture loosely into a glass, and heating it for half an hour in a water-bath; the temperature is then slowly raised (during two hours) to  $150^\circ$  in an oil-bath. The product is treated with water containing soda, heated in a water-bath, filtered, and extracted with boiling alcohol. It crystallises in lustrous, well-formed prisms, which melt at  $217.5$ — $219^\circ$ ; it dissolves sparingly in boiling glacial acetic acid, less so in hot alcohol.

*Orthonitrobenzylamine*,  $NH_2\cdot CH_2\cdot C_6H_4\cdot NO_2$ , is obtained by heating the above imide with fuming hydrochloric acid (4 parts) at  $190^\circ$  to  $200^\circ$ . It is an oily substance, readily soluble in water; when exposed to air, it absorbs carbonic anhydride and becomes solid. The *hydrochloride* crystallises in lustrous needles an inch long, readily soluble in water; the *platinochloride*,  $(C_7H_8N_2O_2)_2\cdot H_2PtCl_6 + 2H_2O$ , crystallises in amber-coloured prisms. The *acetyl-derivative* crystallises in colourless needles melting at  $97$ — $99^\circ$ .

*Orthamidobenzylamine*,  $NH_2\cdot C_6H_4\cdot CH_2\cdot NH_2$ , prepared by reducing the nitro-compound with tin and hydrochloric acid, forms a crystalline mass, which dissolves readily in water and distils slowly with steam. The *primary hydrochloride*,  $C_7H_{10}N_2\cdot HCl$ , and the *secondary hydrochloride*, both crystallise in colourless needles; the *picrate* forms lemon-coloured needles. The *diacetyl-compound* crystallises from

benzene in needles melting at  $136\text{--}137^\circ$ ; it is readily soluble in warm water, sparingly in ether.

*Orthocyanobenzylphthalimide*,  $\text{C}_8\text{H}_4\text{O}_2 : \text{N} \cdot \text{CH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{CN}$ , is prepared by slowly heating an intimate mixture of orthocyanobenzoic chloride (7 parts) and potassium phthalimide (9 parts) from  $100^\circ$  up to  $120^\circ$  for half an hour. The product is extracted with boiling water, and the undissolved portion dissolved in boiling glacial acetic acid, from which it separates in long prisms melting at  $181\text{--}182^\circ$ .

*Orthocyanobenzylamine*,  $\text{CN} \cdot \text{C}_6\text{H}_4 \cdot \text{CH}_2 \cdot \text{NH}_2$ , is formed when the above phthalimide compound is digested with fuming hydrochloric acid. It is a colourless oil, which crystallises when rubbed, and dissolves readily in water. The hydrochloride (with 1 mol.  $\text{H}_2\text{O}$ ) crystallises in lustrous needles; the *picrate* is obtained as a sparingly soluble, yellow, crystalline precipitate. When the acid solution of the hydrochloride is treated with sodium nitrite, nitrosophthalimidine is formed.

*Orthochloromethylbenzamide*,  $\text{CH}_2\text{Cl} \cdot \text{C}_6\text{H}_4 \cdot \text{CONH}_2$ , is obtained by heating a solution of orthocyanobenzoic chloride in strong sulphuric acid at  $80^\circ$  to  $90^\circ$ ; the product is poured into water and filtered; the crystals are then washed and dried over sulphuric acid. It is insoluble in cold water, and is decomposed by boiling with water or alcohol with formation of phthalide and ammonium chloride. When slowly heated until a temperature of  $150^\circ$  to  $160^\circ$  is reached, dissolved in warm water and treated with potash, *pseudophthalimidine*,  $\text{C}_8\text{H}_7\text{NO}$ , is obtained as a brownish oil, having a peculiar odour. The *picrate* forms a sparingly soluble, yellow, crystalline powder; the *platinochloride* crystallises in orange-coloured, flat needles (with 2 mols.  $\text{H}_2\text{O}$ ). When distilled, the base decomposes with evolution of ammonia; and if boiled with a mixture of phosphorus oxychloride and pentachloride, orthochlorobenzoic cyanide is formed. N. H. M.

**Action of Dilute Nitric Acid on Substituted Amido-compounds.** By L. M. NORTON and W. D. LIVERMORE (*Ber.*, 50, 2268—2274).—*Trinitromethylparatoluidine* is prepared by boiling acetylmethylparatoluidine for 2 to 3 hours with 5 per cent. nitric acid, or for 1 to 2 hours with 10 per cent. nitric acid. It is crystallised several times from alcohol; it melts at  $129\text{--}130^\circ$ . When boiled with 4 per cent. aqueous potash, it is converted into Martius' dinitrocresol (*Ber.*, 2, 207), melting at  $82\text{--}83^\circ$ . The constitution of the trinitro-compound is therefore probably  $[\text{Me} : \text{NO}_2 : \text{NMe}(\text{NO}_2) : \text{NO}_2 = 1 : 3 : 4 : 5]$ ; the compound is possibly identical with that obtained by van Romburgh (*Rec. Trav. Chim.*, 1884, 392), by the action of nitric acid on dimethylparatoluidine. It is also obtained by the action of dilute nitric acid on acetylmethylpropionylparatoluide.

Dinitromethylaniline (m. p.  $174.5^\circ$ ) is formed when methylformanilide is boiled with  $12\frac{1}{2}$  per cent. nitric acid for 30 minutes. *Methylformanilide* is prepared by heating sodium formanilide with methyl iodide; it melts at  $12.5^\circ$  and boils at  $250^\circ$ .

*Methyloxanilide* is prepared by adding a concentrated alcoholic solution of oxalic acid to methylaniline mixed with a little alcohol; the precipitate is separated and heated at  $160\text{--}180^\circ$  until no more

gas is evolved. It is liquid and boils at 249—251°. When boiled with nitric acid, it is converted into dinitromethylaniline, melting at 176—177°. This, when boiled with aqueous potash, is converted into dinitrophenol [1 : 2 : 4]. (Compare also Abstr., 1885, 1213.)

N. H. M.

**Phenyl-derivatives of Ethane.** By K. HEUMANN and J. WIERNIK (*Ber.*, 20, 2421—2427).—When glycol is heated with dimethylaniline and zinc chloride for some days at 100—120°, *dimethamidophenylethane*,  $C_6H_4Et \cdot NMe_2$  [ $Et : NMe_2 = 1 : 4$ ], is formed together with small quantities of hexamethylparaleucaniline. The former crystallises in greyish-blue scales or prisms, easily soluble in alcohol and ether, and melting at 89°. It is soluble in acids, but its salts crystallise with difficulty. Nitrous acid yields *nitrosomethamidophenylethane*,  $C_6H_4Et \cdot NMe \cdot NO$ , which crystallises in needles and melts at 162°. When reduced with acetic acid and zinc, the nitrosamine yielded an oil boiling at about 260°, probably a hydrazine base,  $C_6H_4Et \cdot NMe \cdot NH_2$ , which gave an *acetyl*-derivative melting at 68°.

Monochlorethylene chloride and dimethylaniline, under like conditions, yield dichlorethylene, *hexamethyltriamidotriphenylethane*,  $NMe_2 \cdot C_6H_4 \cdot CH_2 \cdot CH(C_6H_4 \cdot NMe_2)_2$ , and another crystalline compound melting at 84°, the constitution of which has not yet been determined. The former compound is easily soluble in ether, benzene, and acetic acid, sparingly in alcohol, and insoluble in water. With many oxidising agents, it gives greenish colouring matters.

Carbon hexachloride, dimethylaniline, and zinc chloride when heated together yield perchlorethylene and tetramethyldiamidodiphenylmethane; the latter is also formed when perchlorethylene is substituted for carbon hexachloride in this reaction.

L. T. T.

**Cumylamine.** By H. GOLDSCHMIDT and A. GESSNER (*Ber.*, 20, 2413—2416).—Cumylamine was prepared by the reduction of cuminaldoxime with sodium amalgam. It is a colourless, limpid liquid boiling at 225—227° under 724 mm. pressure, and not at 280°, as usually stated. *Acetocumylamine*,  $C_3H_7 \cdot C_6H_4 \cdot CH_2 \cdot NHAc$ , forms micaceous scales soluble in alcohol, ether, and benzene, sparingly in boiling water: it melts at 65°.

*Cumylthiocarbamide*,  $C_3H_7 \cdot C_6H_4 \cdot CH_2 \cdot NH \cdot CS \cdot NH_2$ , prepared from cumylamine hydrochloride and potassium thiocyanate, forms colourless scales melting at 110°. It is easily soluble in benzene and in cold water. *Phenylcumylthiocarbamide*,  $C_3H_7 \cdot C_6H_4 \cdot CH_2 \cdot NH \cdot CS \cdot NHPh$ , from cumylamine and phenyl thiocyanate, forms microscopic plates soluble in alcohol, benzene, and boiling water, and melting at 106°.

L. T. T.

**Orthamidophenyl Mercaptan and its Derivatives.** By A. W. HOFMANN (*Ber.*, 20, 2251—2265).—When a small quantity of phenyl mercaptan is dissolved in a strong alcoholic solution of cyanogen, the liquid becomes coloured, and after 10 to 15 minutes a separation of almost colourless, lustrous needles takes place, and in an hour the reaction is finished. Analyses show that the new compound is

formed by simple addition of the elements of cyanogen ; it probably has the constitution  $C_6H_4<\overset{N}{S}>C\cdot C(NH)\cdot NH_2$ . It melts at  $150^\circ$ , with evolution of gas, and dissolves in benzene, ether, and alcohol. The *aurochloride*,  $C_8H_7N_3S\cdot HAuCl_4$ , crystallising in slender needles, and the *platinochloride*,  $C_8H_7N_3S\cdot H_2PtCl_6$ , were prepared.

*Monophenylamidine*,  $C_6H_4<\overset{N}{S}>C\cdot C(NH)\cdot NHPh$ , is formed together with the diphenyl-derivative when the amidine is heated with aniline. The reaction is accompanied by an evolution of ammonia, and afterwards of hydrogen cyanide. The product is steam-distilled to remove the excess of aniline ; the monophenylamidine remains as a yellow oil which solidifies on cooling, whilst the diphenyl compound is contained in the aqueous solution. Monophenylamidine crystallises in pale-yellow plates which melt at  $118^\circ$  and dissolve in alcohol and ether. The *hydrochloride* forms long needles ; the *platinochloride* separates from its solution in small, concentrically-grouped needles ; the *aurochloride* crystallises in bright-yellow, rhombic plates.

*Diphenylamidine*,  $C_7H_4NS\cdot C(NPh)\cdot NHPh$ , separates in part from the aqueous solution on cooling ; the rest is extracted with ether. It crystallises from water in white plates of a silvery lustre which melt at  $129^\circ$  ; it dissolves readily in alcohol and ether. The *platinochloride*,  $C_{20}H_{15}N_3S\cdot H_2PtCl_6$ , crystallises in dark-yellow plates ; the *aurochloride*,  $C_{20}H_{15}N_3\cdot (HAuCl_4)_2$ , forms gold-coloured, hair-like needles. Both salts are sparingly soluble.

When the amidine, dissolved in alcohol, is warmed with a few drops of mercaptan, ammonia is evolved and crystals of the oxalyl-compound,  $C_{14}H_8N_2S_2$  (*Ber.*, **13**, 1228), separate. Alcoholic potash solution decomposes the amidine with evolution of ammonia and formation of the potassium salt of an acid,  $C_6H_4<\overset{N}{S}>C\cdot COOH$ . The *free acid* crystallises in groups of needles readily soluble in alcohol, less soluble in water and in hydrochloric acid. It melts at  $108^\circ$ , with evolution of carbonic anhydride. When the aqueous solution is boiled, the acid decomposes into the methenyl base,  $C_6H_4<\overset{N}{S}>CH$ , and carbonic anhydride.

The preparation of amidophenyl mercaptan is described in detail.

The vapour of amidophenyl mercaptan or its solution is a powerful irritant, causing blisters when in contact with the skin ; all its derivatives appear to have this property.

When the aqueous solution of the amyl iodide of the methenyl base,  $C_7H_5NS$ , is treated with ammonia, no dye is formed ; the same result is obtained with the ethenyl base. When both solutions are mixed and then boiled, a dark-red, resinous mass is obtained which yields splendid, well-formed plates of a green metallic lustre, violet-red in transmitted light ; analyses of it point to the formula  $C_{25}H_{31}N_2S_2I$ . It dissolves in alcohol yielding a deep-red solution which is decolorised by acids ; the colour returns on the addition of alcohol or water. In a similar manner, dyes can be prepared from the corresponding naphthyl base (this vol., p. 839), and from a mixture of the phenyl and naphthyl

bases. Experiments with the amyl iodides of quinoline bases and with those of mercaptan-derivatives also gave dyes; these could not be obtained in a crystalline form. N. H. M.

**Anisamine.** By H. GOLDSCHMIDT and N. POLONOWSKA (*Ber.*, **20**, 2407—2413).—Anisamine,  $\text{OMe}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\cdot\text{NH}_2$ , is easily obtained by the reduction of anisaldoxime by sodium amalgam. The free base is a colourless oil, soluble in water, and boils at  $234\text{--}235^\circ$ . When exposed to the air, it absorbs carbonic anhydride and forms white needles melting at  $110^\circ$ . This substance, which is probably *anisylamine anisylcarbamate*, is what Cannizzaro described (*Annalen*, **117**, 240) as the free base. The *hydrochloride*,  $\text{C}_8\text{H}_{11}\text{NO}\cdot\text{HCl}$ , yields transparent prisms melting at  $231^\circ$ , the *mercurochloride*,  $\text{C}_8\text{H}_{11}\text{NO}\cdot\text{HgCl}_2 + \text{H}_2\text{O}$ , in silvery scales which lose water at  $130^\circ$  and melt with decomposition at  $200^\circ$ .

*Acetanisamine (anisylacetamide)*,  $\text{OMe}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\cdot\text{NH}\cdot\text{C}_2\text{H}_3\text{O}$ , crystallises in needles melting at  $96^\circ$ ; *anisylcarbamide*,

in long thin needles melting at  $167^\circ$ ; *anisylthiocarbamide*,

in transparent needles melting at  $95^\circ$ . *Dianisylthiocarbamide*,

is formed by mixing together anisamine and carbon bisulphide, and boiling the resulting product with alcohol as long as hydrogen sulphide is evolved. It is soluble in alcohol, crystallises in colourless needles, and melts at  $149\text{--}150^\circ$ .

When acetanisamine is gradually added to well-cooled strong nitric acid, *metanitracetanisamine*,  $\text{OMe}\cdot\text{C}_6\text{H}_3(\text{NO}_2)\cdot\text{CH}_2\cdot\text{NHAc}$  [ $\text{CH}_2\text{NHAc} : \text{NO}_2 : \text{OMe} = 1 : 3 : 4$ ], is formed. This dissolves in alcohol, crystallises in pale-yellow prisms, and melts at  $137^\circ$ . When oxidised with chromic mixture, it yields metanitransic acid, and small quantities of paranitransol,  $\text{OMe}\cdot\text{C}_6\text{H}_4\cdot\text{NH}_2$ .

When metanitracetanisamine is treated with tin and hydrochloric acid, *metamidanisamine*,  $\text{OMe}\cdot\text{C}_6\text{H}_3(\text{NH}_2)\cdot\text{CH}_2\cdot\text{NH}_2$ , is formed. This is a basic oil which absorbs carbonic acid from the air and becomes solid. It is sparingly soluble in ether, and almost non-volatile in steam. The *hydrochloride* forms unstable, colourless needles; the *platinochloride* has the formula

*Diacetometamidanisamine*,  $\text{OMe}\cdot\text{C}_6\text{H}_3(\text{NHAc})\cdot\text{CH}_2\cdot\text{NHAc}$ , forms white needles melting at  $185^\circ$ .

Anisaldoxime melts at  $61^\circ$ , and not at  $45^\circ$ , as stated by Westenberg. L. T. T.

**Behaviour of Tertiary Amines towards Nitrous Acid.** By E. KOCH (*Ber.*, **20**, 2459—2461).—Heidberg has recently described

a compound, believed by him to be a nitroso-derivative of parachloro-dimethylaniline (this vol. p. 475). This view, however, is improbable, as in the action of nitrous acid on the tertiary amines the nitroso-grouping takes up the 4 position, which in this case is already occupied. On repeating the experiments, the course of the reaction was found to be different from that described by Heidelberg, in that a nitro-derivative is formed as shown by analysis and the non-production of Liebermann's reaction. Further, the diamine obtained on reduction gives the reaction of a meta-compound. From the mother-liquor of the nitro-compound, a *nitrosamine*,  $C_6H_4Cl \cdot N(NO)Me$ , is obtained crystallising in light-brown needles which melt at  $51^\circ$ ; this gives Liebermann's reaction.

V. H. V.

**Preparation of Phenylhydrazine.** By A. REYCHLER (*Ber.*, **20**, 2463—2464).—In order to avoid the production of diazobenzene chloride in the preparation of phenylhydrazine, the following plan is recommended. Aniline (1 mol.) and potassium carbonate ( $\frac{1}{2}$  mol.) are mixed with water and brought into solution by passing in the quantity of sulphurous anhydride required to form aniline sulphite and hydrogen potassium sulphite. The solution thus obtained is added gradually to an aqueous solution of potassium nitrite (1 mol.), carefully neutralised with acetic acid. If the operation is successful, no gas is evolved. The whole is then allowed to remain for two hours, and the precipitate formed is brought into solution by heating on a water-bath; the liquid is acidified with dilute acetic acid, and decolorised by careful addition of dilute hydrochloric acid and zinc-dust. After filtering, adding hydrochloric acid and evaporating the liquid to half its bulk, the phenylhydrazine hydrochloride may be precipitated by concentrated hydrochloric acid. The yield of the crude precipitate is 85·90 per cent. of that required by theory; this is reduced to 65·70 per cent. on purification.

V. H. V.

**Preparation of Iodobenzene from Phenylhydrazine and Titration of the Latter.** By E. v. MEYER (*J. pr. Chem.* [2], **36**, 115—116).—E. Fischer has shown (*Ber.*, **10**, 1335) that hydriodic acid, diazobenzimide, and aniline hydriodide are formed when iodine acts on an excess of phenylhydrazine. The author finds that if the iodine is kept in excess the decomposition takes place according to the equation  $N_2H_3Ph + 2I_2 = 3HI + N_2 + PhI$ . This reaction may be employed to prepare iodobenzene and to titrate phenylhydrazine. In the latter case, the phenylhydrazine is added to a titrated solution of iodine, and the excess of iodine determined by hyposulphite. The titration of phenylhydrazine may also be effected by iodic acid in the presence of dilute sulphuric acid.

L. T. T.

**Action of Carbamide on Phenylhydrazine.** By A. PINNER (*Ber.*, **20**, 2358—2360).—If carbamide (1 mol.) is heated with two molecular proportions of phenylhydrazine hydrochloride, phenylsemicarbazide,  $NHPh \cdot NH \cdot CO \cdot NH_2$  (E. Fischer, *Abstr.*, 1878, 307), is formed. If, however, three or more molecular proportions of the hydrazide are

employed, a new compound, *phenylurazole*,  $C_6H_7N_3O_2$ , is produced. This crystallises in colourless, glistening scales, easily soluble in boiling alcohol and boiling water, sparingly so in ether. It melts at 262—263°. It is soluble in alkalis, and is reprecipitated from this solution by acids; it does not reduce silver or copper solutions. Its constitution is either  $NPh<\begin{smallmatrix} CO:NH \\ NH:CO \end{smallmatrix}>$  or  $NPh<\begin{smallmatrix} C(OH):N \\ N:C(OH) \end{smallmatrix}>$ , probably the latter. As other hydrazines and amides may yield similar compounds, the author proposes the name *urazoles* for the whole class of derivatives.

L. T. T.

**Derivatives of Acetylorthamidobenzamide.** By A. WEDDIGE (*J. pr. Chem.* [2], 36, 141—154).—*Ethyl acetylorthamidobenzoate*,  $NHAc \cdot C_6H_4 \cdot COOEt$ , is prepared by the action of acetic anhydride on ethyl orthamidobenzoate, and crystallises from alcohol in nacreous needles, or by slow evaporation in large transparent prisms, melts at 61—62°. It is not attacked by alcoholic ammonia at 150—160°, but is converted into anhydroacetylorthamidobenzamide when heated with aqueous ammonia.

Anhydroacetylorthamidobenzamide (Abstr., 1885, 661) can be obtained by heating acetylorthamidobenzamide at 230—240°, by boiling an aqueous solution of the compound for some time, or by dissolving it in aqueous alkalis, and precipitating with an acid. In the last reaction, a salt of the anhydro-compound seems to be at once formed by the action of the alkali with the elimination of the elements of water, since the addition of silver nitrate to the alkaline solution (which could not be crystallised) precipitates a white *silver* salt,  $C_9H_7N_2OAg$ ; whilst long silky needles of the *potassium* salt containing alcohol of crystallisation are obtained, when an alcoholic solution of acetylorthamidobenzamide is treated with alcoholic potash. The anhydro-compound crystallises in white, silky, lustrous needles, melts at 232—233°, and dissolves readily in hot water, from which it separates on cooling in thick prisms with 1 mol.  $H_2O$ ; in benzene, ether, chloroform, and cold alcohol it is sparingly soluble. The *hydrochloride*,  $C_9H_7N_2O \cdot HCl$ , crystallises in bright-yellow or white needles, is soluble in hot water, and yields precipitates with various metallic salts. The *methyl* salt,  $C_9H_7N_2O \cdot Me$ , is formed when either acetylorthamidobenzamide or its anhydro-derivative are heated with methyl iodide and alcoholic potash in a reflux apparatus for two to three hours. It crystallises from water in long silky needles, which melt at 70°, or when anhydrous at 108—109°, and effloresce on exposure to the air. It dissolves readily in alcohol, less readily in ether and benzene, and forms salts with acids: of these the hydrochloride crystallises in small prisms.

*Orthamidobenzomethylamide*,  $NH_2 \cdot C_6H_4 \cdot CONHMe$ , is obtained by the action of an alcoholic solution of methylamine on isatoic acid. It crystallises from benzene in long, thick, yellowish prisms, or occasionally in long thin feathery needles showing a nacreous lustre, melts at 79—80°, and is very readily soluble in alcohol and ether, readily soluble in hot benzene, and soluble in hot water. On treatment with acetic anhydride, the *acetyl*-derivative is obtained; this crystallises in long,

colourless, lustrous prisms, melts at 171—172°, and is sparingly soluble in ether, benzene, and cold alcohol. When boiled with water or aqueous alkalis, or when heated at 200—220° for some time, it is converted into *anhydroacetylorthamidobenzmethylamide*,  $C_{10}H_{10}N_2O$ , a compound identical with the methyl-derivative of *anhydroacetylorthamidobenzamide* just described.

*Orthomethamidobenzamide*,  $NMeH \cdot C_6H_4 \cdot CONH_2$ , is prepared by adding methyl iodide to orthamidobenzamide in alcoholic solution, and precipitating the base from an aqueous solution of the crystalline hydriodide by ammonia. It crystallises in nacreous scales, melts at 159—160°, and dissolves in alcohol yielding a solution fluorescing blue. When heated with acetic anhydride, it is converted into the *acetyl*-derivative, which crystallises in long, white needles, melts at 155°, and is sparingly soluble in benzene, ether, and cold alcohol. If it is heated above its melting point, the *anhydro*-derivative is formed; this crystallises from water in pale-yellow prisms with 3 mols.  $H_2O$ , melts at 199° when anhydrous, is very readily soluble in alcohol, and yields a well-crystallised hydrochloride.

Anhydroacetylorthamidobenzamide is regarded as a derivative of a hypothetical base, *quinazoline*,  $C_6H_4 \begin{smallmatrix} CH:N \\ N:CH \end{smallmatrix}$ , isomeric with cinnoline and quinoxaline, and since its methyl-derivative is identical with the anhydroacetyl-derivative obtained from orthamidobenzmethylamide, it must have either the constitution

it is therefore termed  $\beta$ -methyl- $\delta$ -oxyquinazoline. Adopting this nomenclature, anhydroacetyl orthamidobenzmethylamide,

is termed  $\beta$ - $\gamma$ -dimethyl- $\delta$ -pseudoxyquinazoline, and anhydroacetyl orthomethylamidobenzamide,  $C_6H_4 \begin{smallmatrix} CO \cdot N \\ NMe : CMe \end{smallmatrix}$ , is termed  $\alpha$ - $\beta$ -dimethyl- $\delta$ -pseudoxyquinazoline.

W. P. W.

**Derivatives of Benzoylorthamidobenzamide.** By M. KÖRNER (*J. pr. Chem.* [2], **36**, 155—165).—*Benzoylorthamidobenzamide*,  $NHBz \cdot C_6H_4 \cdot CONH_2$ , is formed by adding benzoic chloride in small quantities at a time to orthamidobenzamide dissolved in ether. It crystallises from absolute alcohol in long, white, lustrous, matted needles, melts at 218—219°, becomes strongly electrical when rubbed in a mortar, and is insoluble in water, sparingly soluble in all ordinary solvents. Aqueous potash and soda dissolve it on heating, but the solutions on treatment with an acid yield the anhydro-derivative,  $\beta$ -phenyl- $\delta$ -oxyquinazoline,  $C_{14}H_{10}N_2O$  (for nomenclature, compare preceding Abstract). This compound can also be readily obtained by heating the benzoyl-derivative at 250—260° for an hour; it crystal-

lises in pale-yellow microscopic needles, melts at 233—234°, and is insoluble in water, sparingly soluble in benzene, chloroform, and absolute alcohol. It becomes strongly electrical when powdered in a mortar. The *hydrochloride* crystallises from concentrated hydrochloric acid in lustrous, transparent, rhombic tables, and is decomposed by washing with water or treatment with hot alcohol; the *platinochloride*,  $(C_{14}H_{10}N_2O)_2 \cdot H_2PtCl_6$ , crystallises in long brick-red needles.

*Benzoylorthamidobenzmethylamide*,  $C_{15}H_{14}N_2O_2$ , is obtained by the action of benzoic chloride on orthamidobenzmethylamide dissolved in ether. It crystallises in large, transparent tables, apparently hexagonal, melts at 181°, and is insoluble in water, sparingly soluble in benzene and absolute alcohol. When heated at 250° for half an hour, it is converted into the anhydro-compound,  $\beta$ -phenyl- $\gamma$ -methyl- $\delta$ -pseud-oxyquinazoline,  $C_6H_4 < \begin{smallmatrix} CO \cdot NMe \\ N : C_{Ph} \end{smallmatrix} >$ , which crystallises from alcohol in large scales or prisms, from water in large, lustrous lamellæ, and melts at 130—131°. This compound is identical with that obtained when a mixture of  $\beta$ -phenyl- $\delta$ -oxyquinazoline, or benzoyl orthamidobenzamide and potassium hydroxide dissolved in absolute alcohol, is heated to 110°, treated with methyl iodide, and afterwards heated at 120° for six hours.

*Acetylorthamidobenzophenylamide*,  $NHAc \cdot C_6H_4 \cdot CONHPh$ , is formed by the action of acetic anhydride on orthamidobenzophenylamide, itself obtained by adding aniline in alcoholic solution to isatoic acid. It crystallises in drusy aggregates of long, white needles, melts at 167—168°, and is insoluble in water and ether, readily soluble in benzene, acetic acid, &c. When heated at 210° for some time, it is converted into the anhydro-compound,  $\beta$ -methyl- $\gamma$ -phenyl- $\delta$ -pseud-oxyquinazoline,  $C_6H_4 < \begin{smallmatrix} CO \cdot NPh \\ N : CMe \end{smallmatrix} >$ ; this crystallises in large, yellow prisms, melts at 146—147°, and is soluble in absolute alcohol, insoluble in water.

W. P. W.

**Action of Yellow Ammonium Sulphide on Ketones and Quinones.** By C. WILLGERODT (*Ber.*, 20, 2467—2470).—The reaction of yellow ammonium sulphide on ketones and quinones is very variable, depending on the constitution of the compound, the proportion of sulphur in the ammonium sulphide, and the temperature at which the reaction is effected.

Thus in the case of acetone there is formed a *duplodithioacetone*,  $(CS_2Me)_2$ ;  $a : c = 1 : 0.8675$ ; observed faces,  $P, \infty P\infty$ , which crystallises in the tetragonal system; it melts at 98°, and boils at 243°, with partial decomposition; it has a characteristic disagreeable odour, is insoluble in water, but soluble in most organic menstrua.

$\alpha$ -Naphthyl methyl ketone, when heated with carbon bisulphide in sealed tubes at 210—230°, yields a compound,  $C_{12}H_{11}NO$ , crystallising in colourless needles, which melt at 154°, and sublime without decomposition. This compound is isomeric with both amido- $\alpha$ -naphthyl methyl ketone, and  $\alpha$ -naphthyl acetoxime; probably it has the composition of a ketone-imide, the formation of which is explained by the reaction of the sulphuretted ammonium sulphide on the carboxyl-

group, with evolution of hydrogen sulphide and separation of sulphur.

Methyl meta-xylyl ketone under similar conditions yields a compound of the formula  $C_{10}H_{13}NO$ , which crystallises in delicate needles, melting at  $183^\circ$ , soluble in alcohol and ether.

Acetophenone forms a compound of similar composition, but tolyl phenyl ketone yields tolylphenylmethane, and anthraquinone yields anthranol.

V. H. V.

**Tetrachlorobenzoic Acid and its Derivatives.** By P. TUST (*Ber.*, 20, 2439—2442).—*Tetrachlorobenzoic acid*,  $C_6HCl_4 \cdot COOH$  [ $COOH : Cl_4 = 1 : 2 : 3 : 4 : 5$ ], is readily obtained by heating tetrachlorophthalic acid with glacial acetic acid for 3 to 4 hours at  $300^\circ$ , and crystallising the crude product from water. It forms in colourless needles melting at  $186^\circ$ , sparingly soluble in water, soluble in alcohol and ether. Its *barium* and *calcium* salts are sparingly soluble in water, the *lead* and *copper* salts, insoluble; the *ethyl* salt crystallises in colourless needles melting at  $34.5^\circ$ . An acid of the same melting point has previously been described by Beilstein and Kuhlberg (*Annalen*, 152, 245). The *nitro-derivative*,  $NO_2 \cdot C_6Cl_4 \cdot COOH$ , crystallises in glistening leaflets, its *barium* salts with  $2\frac{1}{2}H_2O$  in colourless needles, and the *calcium* salt in leaflets. On reduction, the corresponding *amido-compound* or tetrachloranthranilic acid,  $NH_2 \cdot C_6Cl_4 \cdot COOH$ , is produced, which separates in white insoluble flocks; its alkaline earth and copper salts are also insoluble.

V. H. V.

**Constitution of Phenyl- $\alpha$ - and Phenyl- $\alpha$ - $\beta$ -hydroxypropionic Acids.** By E. ERLENMEYER, jun. (*Ber.*, 20, 2465—2466).—The acid described by Plochl as phenylglycidic acid has been shown by the author to be phenylpyruvic acid, as evidenced by its reactions with phenylhydrazine, hydroxylamine, and thiophen (this vol., p. 142). On the other hand, Glaser's phenylhydroxyacrylic acid is probably, as supposed by Erlenmeyer, sen., phenylglycidic or phenyl- $\alpha$ - $\beta$ -hydroxypropionic acid. In the paper this view is confirmed by the formation from the sodium salt of the acid of phenyl- $\beta$ -chloro- $\alpha$ -hydroxypropionic acid, identical with that obtained by Leschhorn from phenylglyceric acid. The salts of this acid, when decomposed with aqueous soda, yield a sodium phenylhydroxyacrylate identical with that obtained from phenyl- $\alpha$ -chlorolactic acid. The constitution of Glaser's acid is expressed by the formula  $\langle \begin{smallmatrix} CHPh \\ \text{---} O \text{---} \end{smallmatrix} \rangle CH \cdot COOH$ , whilst Plöchl's acid has the formula  $CH_2Ph \cdot CO \cdot COOH$ .

V. H. V.

**Action of Aniline on Ethyl Dibromosuccinate.** By N. LOPATINE (*Compt. rend.*, 105, 230—231).—10 parts of ethyl dibromosuccinate, 20 parts of aniline, and 40 parts of alcohol of 95 per cent. are boiled together for 12 hours. A precipitate gradually forms and eventually the mass becomes solid. The product is treated with cold

alcohol, and the residue is dissolved in boiling alcohol which, when cooled, deposits silky needles of the composition

This compound forms long, rhomboidal prisms which melt without decomposition at  $145^\circ$ , and are insoluble in boiling water, and only slightly soluble in alcohol or boiling benzene. When heated with barium hydroxide, it decomposes with evolution of carbonic anhydride; with potash solution, it yields a crystalline substance soluble in water and in alcohol, and it forms a crystalline product with hydrogen chloride.

C. H. B.

**Glycosuric Acid.** By J. MARSHALL (*Arch. Pharm.* [3], 25, 593).—This new acid, extracted from pathological urine, reduces Fehling's solution more strongly than does glucose. *Glycosuric acid* crystallises in the form of opaque tetragonal prisms, which melt at  $140^\circ$ , dissolve easily in water, alcohol, and ether, less easily in chloroform, and not at all in benzene, toluene, and light petroleum. To prepare it, the urine is treated with half its volume of lead acetate, the precipitate after being washed with 45 per cent. alcohol, is suspended in warm water and freed from lead by means of hydrogen sulphide. The boiled filtrate after treatment with excess of lead carbonate, is again boiled, filtered, and evaporated to crystallisation. The lead salt thus obtained is washed with 45 per cent. alcohol, dissolved in water, decomposed by hydrogen sulphide, boiled, and the filtrate evaporated to dryness at  $70^\circ$ ; the residue extracted with ether is finally allowed to evaporate spontaneously. The crystals thus obtained are still very impure and require repeated crystallisation from ether, ether containing water, and lastly water alone. Glycosuric acid contains neither oxygen nor nitrogen: animal charcoal absorbs it completely; picric acid gives no brown colour reaction, on the contrary aqueous soda solution gives a brown reaction. Bismuth salt in Böttger's test is not reduced; but Fehling's solution and silver nitrate are reduced. Fermentative action was not observed, neither does the aqueous solution affect polarised light. Neutral dilute ferric chloride solution produces a blue colour which soon disappears. The new acid may be considered as a derivative of phenol. A characteristic reaction, similar to that of murexide, may be observed on evaporating at  $60^\circ$  the solution in ether. The solution takes a wine-red colour, which is imparted to the separating crystals; on dissolving the latter in water, however, the colour disappears.

J. T.

**Behaviour of Aromatic Sulphinic Ethers towards Hydrogen Sulphide.** By R. OTTO and A. RÖSSING (*Ber.*, 20, 2275—2278).—When hydrogen sulphide is passed through ethyl benzenesulphinic acid heated at  $45$ – $50^\circ$ , ethyl hydrogen sulphide and benzenesulphinic acid are formed. The sulphinic acid can be isolated only partially, as it further decomposes into benzenesulphonic acid and benzene disulphoxide. The greater part of the ethereal salt is, however, converted into phenyl ethyl sulphide with separation of sulphur. Ethyl paratoluenesulphinic acid

is converted by hydrogen sulphide into paratoluenesulphonic acid (in small amount), tolyl hydrogen sulphide, toluenesulphinic acid, ethyl hydrogen sulphide, sulphur, and a thick oil, probably consisting of toluene polysulphides. No ethyl tolyl sulphide is formed in the reaction.

N. H. M.

**Manufacture of  $\alpha$ -Naphthylamine.** By O. N. WITT (*Ding. polyt. J.*, 265, 225—230).—An important feature in the success attending the manufacture of naphthylamine is the purity of the naphthalene employed. The nitration is effected in cast-iron cylinders fitted with stirrers and cooling jacket. The charge consists of 250 kilos. of naphthalene, 200 kilos. of nitric acid of 40° Baumé, 200 kilos. of sulphuric acid of 66° Baumé, and 600 kilos. of the waste acid from a previous nitration, the latter being used as diluent. The nitration is performed at 45—50°, the temperature being regulated by the rate at which the naphthalene is added and the flow of cold water through the cooling jacket. The reaction is completed in about 12 hours. The contents of the apparatus are then transferred to wooden vats lined with lead and allowed to cool. The waste acid is run off and the nitronaphthalene boiled out with water until free from acid. It is then reduced in apparatus similar in construction to those employed in the manufacture of aniline. For this purpose, 600 kilos. of air-dried nitronaphthalene are added gradually to a mixture of 800 kilos. of iron borings and 40 kilos. of hydrochloric acid, the temperature being regulated by the introduction of the nitro-product, so that it is about 50°. When all the nitronaphthalene has been put in, the operation is continued for 6—8 hours, the temperature being kept at 50°. At the end of the reduction, milk of lime is stirred into the mass, and the contents are transferred to shallow iron trays and distilled in retorts constructed to carry several tiers of trays. The distillation is assisted by the introduction of superheated steam. A black oil is obtained which solidifies on cooling. The crude product is purified by rectification in wrought-iron stills which are heated directly by the fire. Naphthylamine comes over as an almost colourless oil, which is poured into moulds to solidify, when it forms crystalline cakes which are light grey or nearly white.

The author is of opinion that the reduction of nitronaphthalene is effected essentially by ferrous chloride, which during the reaction is converted into a basic chloride, possibly  $\text{Fe}_2\text{Cl}_4\text{O}$ , according to the following equation:— $24\text{FeCl}_2 + 4\text{C}_{10}\text{H}_7\cdot\text{NO}_2 + 4\text{H}_2\text{O} = 12\text{Fe}_2\text{Cl}_4\text{O} + 4\text{C}_{10}\text{H}_7\cdot\text{NH}_2$ . The basic compound is then attacked by the excess of iron, and reduced to ferrous chloride with formation of ferrosoferrous oxide, thus:  $12\text{Fe}_2\text{Cl}_4\text{O} + 9\text{Fe} = 3\text{Fe}_3\text{O}_4 + 24\text{FeCl}_2$ . The ferrous chloride then acts on a further portion of nitronaphthalene.

As commercial naphthylamine is frequently supposed to contain small quantities of the beta-compound, the author has made a series of experiments, the results of which showed that no trace of  $\beta$ -naphthylamine is formed. The author has, however, detected the presence of a base in crude naphthylamine, which judging from its properties seems to be *paranaphthylenediamine*.

D. B.

**Action of Bromine on Anthranol.** By F. GOLDMANN (*Ber.*, 20, 2436—2437).—When two molecular proportions of bromine are added to one proportion of anthranol dissolved in carbon bisulphide, *anthraquinone dibromide*,  $\text{C}_6\text{H}_4\langle\begin{smallmatrix} \text{CO} \\ \text{CBr}_2 \end{smallmatrix}\rangle\text{C}_6\text{H}_4$ , separates in large, rhombic crystals, decomposed by acetic acid with formation of anthraquinone. If, however, one proportion of bromine is used, *bromanthranol*,  $\text{C}_6\text{H}_4\langle\begin{smallmatrix} \text{C(OH)} \\ \text{CBr} \end{smallmatrix}\rangle\text{C}_6\text{H}_4$ , is produced, which crystallises in small, transparent tables melting at 148—151°, soluble in carbon bisulphide and chloroform.

V. H. V.

**Erythrolhydroxyanthraquinonecarboxylic Acid.** By W. BIRUKOFF (*Ber.*, 20, 2438—2439).—Methylerythrohydroxyanthraquinone, when heated with concentrated sulphuric acid, yields a *carboxylic acid* by oxidation of the methyl-group, with evolution of sulphurous anhydride. The acid,  $\text{C}_{15}\text{H}_8\text{O}_5$ , crystallises in citron-yellow needles melting at 236—238° with decomposition; it is readily soluble in water and ammonia, thus differing from the methyl compound; its *barium* and *calcium salts* are sparingly soluble. When heated above 270°, it is decomposed into carbonic anhydride and erythrohydroxyanthraquinone.

V. H. V.

**Derivatives of Dianthryl.** By A. GIMBEL (*Ber.*, 20, 2433—2435). *Dinitrodianthryl*,  $\text{C}_{28}\text{H}_{16}(\text{NO}_2)_2$ , obtained by the direct nitration of dianthryl, crystallises in pale-yellow needles melting at 337° with decomposition. When oxidised with chromic acid, it yields anthraquinone, a result which proves that the nitro-groups displace the hydrogen-atoms combined with the central carbon-atoms. On reduction, the nitro-compound is converted into the corresponding *amido-derivative*,  $\text{C}_{28}\text{H}_{16}(\text{NH}_2)_2$ , which crystallises in glistening, yellow leaflets melting at 307—309° with decomposition. Its *acetyl-derivative*,  $\text{C}_{28}\text{H}_{16}(\text{NHAc})_2$ , crystallises in yellow leaflets, sparingly soluble in alcohol and benzene; the *picrate* forms brown leaflets decomposed completely by ammonia into acid and base.

V. H. V.

**Azines of Chrysoquinone.** By C. LIEBERMANN and O. N. WITT (*Ber.*, 20, 2442—2444).—As an extension of the applicability of the azine-reaction of the diketones, the formation and properties of the azine-derivatives of chrysoquinone are described.

*Chrysotoluazine*,  $\text{C}_{25}\text{H}_{16}\text{N}_2$ , prepared from chrysoquinone and ortho-toluediamine, crystallises in yellow, glistening needles; the corresponding *naphthyl-derivative*,  $\text{C}_{28}\text{H}_{16}\text{N}_2$ , is a yellow, minutely crystalline powder. The formation of these compounds confirms the analogy of chrysoquinone with phenanthraquinone. Picequinone did not yield satisfactory results, but only a large quantity of a tarry matter; in this respect it resembles  $\beta$ -naphthaquinone.

V. H. V.

**Derivatives of Camphor.** By L. BALBIANO (*Gazzetta*, 17, 155—164).—As V. Meyer has recently raised the question as to whether the phenylhydrazine reaction can be considered to be charac-

teristic of ketonic and aldehydic compounds only, the constitution and reactions of camphyldiphenylhydrazine are here discussed. This compound, when decomposed by hydrochloric acid, yields aniline and ammonia in considerable quantities, together with phenylhydrazine and a rather indefinite resinous substance; the latter is considered to be a nitrile as, when boiled with alkali, it yields ammonia and acid compounds, and gives a basic substance,  $C_{16}H_{25}N_3$ , on hydrogenation. This base forms a hydrochloride melting at  $155-157^\circ$ , and crystallising in delicate needles, very soluble in water. Its solution reduces the salts of the heavy metals and Fehling's solution. The compound is probably a camphylamine in which one of the hydrogen-atoms is displaced by the phenylhydrazine residue.

V. H. V.

**Racemic Camphol and its Derivatives.** By A. HALLER (*Compt. rend.*, **105**, 66—68).—The author has prepared and examined camphol, camphor, monobromocamphor, and camphoric acid, inactive by compensation. The last three compounds were obtained in two ways, namely, by mixing dextrogyrate and lævogyrates in equivalent proportions, and by oxidising racemic camphol to camphor, part of which was then used for the preparation of a monobromocamphor, and part for the preparation of camphoric acid. The product of bromination in the latter case is a buttery mass very difficult to purify. No variations in the mode of preparation gave a better product. Similar difficulties have been experienced with other racemic compounds. The melting points of the products are as follows:—

|                        | By mixture.       | From camphol.     |
|------------------------|-------------------|-------------------|
| Racemic camphol.....   | $210\cdot3^\circ$ | —                 |
| „ camphor.....         | $178\cdot6$       | $178\cdot8^\circ$ |
| „ monobromocamphor.... | $51\cdot1$        | $51\cdot1$        |
| „ camphoric acid.....  | $204\cdot8$       | $205\cdot2$       |

The melting points of the corresponding optically active compounds are camphol,  $208-210^\circ$ ; camphor,  $177-178^\circ$ ; monobromocamphor,  $76^\circ$ ; camphoric acid,  $187^\circ$ .

The racemic compounds obtained by the two methods are identical, but there is considerable difference between the melting points of the racemic compounds and the corresponding active substances. Their solubilities are likewise different; racemic monobromocamphor is more soluble in alcohol than the active derivative, whilst racemic camphoric acid is less soluble than the active modifications.

C. H. B.

**Inactive Borneols yielding Active Camphors.** By A. HALLER (*Compt. rend.*, **105**, 227—230).—The author confirms Montgolfier's earlier results.

Montgolfier has shown that when camphol is heated with sodium, the rotatory power increases. It seemed probable that the camphol obtained by the action of the sodium on camphor is a mixture of equivalent quantities of the dextrogyrate and lævogyrates, but that the sodium acts on the unstable modification, and converts it into the more stable form. This supposition is confirmed by the

following results. 100 grams of camphor was dissolved in 250 grams of toluene, and mixed with 5 grams of sodium (one-third the theoretical quantity). The mixture was heated, and when the action began the lamp was removed. The liquid was then saturated with carbonic anhydride, agitated with water, and the aqueous solution removed and allowed to remain for several days, when the borneol separates out and can be purified by the usual methods. This experiment was repeated with both dextrogyrate and lævogyrates camphors, and the melting points and rotatory powers of the products were as follows:—

|                            | M. p.  | Rotatory power.<br>[ $\alpha$ ] <sub>D</sub> . |
|----------------------------|--------|--|
| Dextrogyrate camphor ..... | 178·4° | +41° 44'                                       |
| Camphol .....              | 210·4  | 0 0  |
| Camphocarbonic acid.....   | 128·7  | +66 7  |
| Regenerated camphor.....   | 178·6  | +41 44   |
| Lævogyrates camphor .....  | 178·6  | —42 76   |
| Camphol .....              | 210·6  | 0 0  |
| Camphocarbonic acid .....  | 128·7  | —66 86   |
| Regenerated camphor.....   | 178·6  | —42 7  |

It is evident that when camphor is converted into borneol and back, its rotatory power does not alter. It would seem that by whatever process camphor is hydrogenised, the product is never a single substance, but always an unstable mixture.

C. H. B.

**Alkannin.** By C. LIEBERMANN and M. RÖMER (*Ber.*, **20**, 2428—2431).—Although alkannin, the colouring matter of the alkanna root, was described more than 70 years ago, and has frequently been investigated, yet at present little is known as regards its constitution. Carnelutti and Nasini (*Abstr.*, 1881, 53) ascribe to it a formula  $C_{15}H_{44}O_4$ , and state that of the hydrogen-atoms two may be displaced by acetyl. As the tinctorial properties of alkannin resemble those of quinalizarin, and their absorption spectra are similar, the authors prepared considerable quantities of the dye; the process used is fully described. The results of analysis pointed to a formula either identical with that of Carnelutti and Nasini or to  $C_{15}H_{12}O_4$ . When alkannin is passed over hot zinc-dust, methylantracene is formed (m. p. 175—177°), a result which points to the constitution of alkannin as a derivative of methylantracene, probably the dihydroquinone or its dihydride.

V. H. V.

**Ruberythric Acid.** By C. LIEBERMANN and O. BERGAMI (*Ber.*, **20**, 2241—2247).—Ruberythric acid,  $C_{26}H_{28}O_{14}$ , is obtained by extracting powdered madder root with absolute alcohol (9 litres of alcohol to 1 kilo. of root). The yield was 0·1 per cent. of the weight of root. It is identical with Schunck's rubianic acid, and has all the properties ascribed to it by Rochleder. It forms lemon-coloured needles of a silky lustre, which melt at 258—260°. The *octacetyl-derivative*,  $C_{26}H_{20}Ac_8O_6$ , crystallises in bright yellow needles melting at 230°; it

dissolves readily in glacial acetic acid, sparingly in alcohol, and is insoluble in water. The acetyl compound was decomposed, and the alizarin, sugar, and acetic acid determined. The following two constitutional formulæ are suggested for ruberythric acid, preference being given to the second:—

The authors intend preparing the ethyl salt of the acid, which, assuming the correctness of the second formula, should decompose into the acid ether of alizarin and sugar. N. H. M.

**Action of Acetone on Pyrroline.** By M. DENNSTEDT and J. ZIMMERMANN (*Ber.*, **20**, 2449—2459).—One of the products of the condensation of acetone with pyrroline by hydrochloric acid (compare this vol., p. 598) is a crystalline substance, to which the authors attribute the formula  $\text{C}_{14}\text{H}_{18}\text{N}_2$ , as obtained thus:— $2\text{C}_3\text{H}_6\text{O} + 2\text{C}_4\text{H}_5\text{N} = \text{C}_{14}\text{H}_{18}\text{N}_2 + 2\text{H}_2\text{O}$ . To this same compound, Baeyer assigned the formula  $\text{C}_{14}\text{H}_{26}\text{O}_2$ , and considered that hydrogen was evolved in the course of the reaction, a view not confirmed by investigations described in this paper. The substance crystallises either in pale-yellow or colourless crystals belonging to the tetragonal system: axial ratio  $a : c = 1 : 0.8343$ ; observed faces,  $\infty\text{P}$ ,  $\text{P}$ ,  $2\text{P}$ ,  $5\text{P}$ . As regards its constitution, it is pointed out that the imide-group of pyrroline is attacked in the reaction, inasmuch as no acetyl- or potassium-derivative is obtainable; with silver nitrate, it gives a compound which crystallises in needles, and is not a substitution but an additive product,  $(\text{C}_{14}\text{H}_{18}\text{N}_2)_2, \text{AgNO}_3$ .

In like manner, methyl ethyl ketone yields a compound  $3\text{C}_{16}\text{H}_{22}\text{N}_2 + 5\text{H}_2\text{O}$ , which forms glistening crystals melting at  $142^\circ$  when anhydrous; so also diethyl ketone yields a compound,  $\text{C}_{18}\text{H}_{26}\text{N}_2$ , melting at  $208$ — $210^\circ$ . Both substances form crystalline combinations with silver nitrate.

On fractionation of the crude product of the condensation of acetone with pyrroline, an oil is obtained boiling at  $275$ — $285^\circ$ , and of the composition  $\text{C}_{10}\text{H}_{13}\text{N}$ ; this is shown to be a derivative of pyrroline in that it gives the pinewood reaction, and a yellow precipitate with mercuric chloride. Potassium also dissolves in it with evolution of hydrogen. To it is ascribed the following constitutional formula:

V. H. V.

**Formation of Pyrrolidine.** By A. LADENBURG (*Ber.*, **20**, 2215—2216).—A solution of succinimide in absolute alcohol is warmed on a water-bath and gradually treated with a large excess of sodium. The product is diluted with water and distilled so long as the distillate is alkaline; the latter is made slightly acid, distilled until free from alcohol, and evaporated to a small bulk. The solution is precipitated with bismuth potassium iodide, and the precipitate washed and distilled with soda; the free base thus obtained is then converted into

the platinochloride and crystallised from alcohol. The yield of pure pyrrolidine is small. The author hopes to obtain phenyleneethylenimine from phthalimide by means of this reaction. N. H. M.

**Pyridine-derivatives from Metanitrobenzaldehyde.** By R. LEPETIT (*Ber.*, 20, 2397—2400).—In a previous communication (this vol., p. 845), the author has described the formation of lutidine-derivatives by the action of ammonia and ethyl acetoacetate on the isomeric nitrobenzaldehydes. In the present paper, further compounds derived from metanitrobenzaldehyde are described.

*Ethyl metahydroxyphenyllutidinedicarboxylate,*

obtained from the corresponding amido-ether (*loc. cit.*) by means of the diazo-reaction, crystallises in white needles, soluble in benzene, and melting at 174°. The same amido-compound yields well-defined colouring matters with amines, phenols, and naphthols. *Ethyl dimethylamidobenzeneazophenyllutidinedicarboxylate,*

crystallises in flat, red needles, soluble in alcohol, and melting at 167°. *Ethyl β-naphtholazophenyllutidinedicarboxylate,*

forms small, silky, scarlet needles, soluble in acetic acid, and melting at 152°. *Metamidophenyllutidinedicarboxylic acid,*

obtained by the hydrolysis of its ethereal salt, forms small, white needles, sparingly soluble in alcohol and water, and melting with decomposition at 238°. The salts are soluble. With amines and phenols, the acid forms dyes similar to those obtained from its ethereal salt. On distillation, its calcium salt yields *metamidophenyllutidine,*

This is crystalline, dissolves in benzene, and melts at 110°. Its yellow *picrate* forms minute crystals, and its mercuriochloride glistening needles decomposing at 160°. By means of the diazo-reaction, it yields *metahydroxyphenyllutidine*,  $\text{OH} \cdot \text{C}_6\text{H}_4 \cdot \text{C}_5\text{NH}_2\text{Me}_2$ , which forms white crystals, soluble in ether and melting at 191°. It is basic in character, and yields well-characterised *platino- and mercurio-chlorides*. Amidophenyllutidine when treated with nitrobenzene, glycerol, and sulphuric acid, yields *lutidyl-quinolyl*,  $\text{C}_5\text{NH}_2\text{Me}_2 \cdot \text{C}_9\text{NH}_6$ . This base forms colourless, rhombic crystals, melting at 107—109°. Its *hydrochloride*, *nitrate*, and *auro- and platino-chlorides* are all crystalline.

L. T. T.

**Pyrimidines.** By A. PINNER (*Ber.*, 20, 2361—2365).—Referring to his last paper on this subject (*Abstr.*, 1886, 45), the author states that the formula  $\text{C}_{11}\text{N}_2\text{H}_9\text{Br}$  there given for a bromo-derivative is incorrect. The correct formula is  $\text{C}_{11}\text{N}_2\text{H}_9\text{BrO}$ , and the compound is *phenylmethylhydroxybromopyrimidine*,  $\text{N} \begin{smallmatrix} \text{CPh} : \text{N} \\ \text{CMe} : \text{CBr} \end{smallmatrix} \text{C} \cdot \text{OH}$ .

A concentrated aqueous solution of dimethylhydroxypyrimidine, when treated with bromine, yields *dimethylhydroxybromopyrimidine hydrobromide*,  $\text{N} \begin{smallmatrix} \text{CMe} \cdot \text{N} \\ \text{CMe} \cdot \text{CBr} \end{smallmatrix} \text{C} \cdot \text{OH}, \text{HBr}$ . This crystallises in colourless needles, moderately soluble in water. *Ethylmethylhydroxybromopyrimidine* crystallises in long, colourless needles, sparingly soluble in water and melting at 194–195°. The formation of a *potassium-derivative* (which crystallises in needles with 1 mol.  $\text{H}_2\text{O}$ ) shows the continued presence of a hydroxyl-group.

Phenylmethylchloropyrimidine,  $\text{C}_{11}\text{N}_2\text{H}_9\text{Cl}$  (Abstr., 1885, 158), yields with ammonia *phenylmethylanidopyrimidine*,  $\text{C}_{11}\text{N}_2\text{H}_9\cdot\text{NH}_2$ , which crystallises in prisms or scales and melts at 130°. Its *chloride* and *platinochloride* are crystalline.

When phenylmethylhydroxypyrimidine is treated with a mixture of strong sulphuric and nitric acids, it yields a compound which is probably a *nitro-nitroso-derivative*,  $\text{C}_{11}\text{N}_2\text{H}_9\text{O}(\text{NO}_2)\cdot\text{NO}$ . It crystallises in needles and melts at 238–243°. When reduced with hydriodic acid, it yields *diamidophenylmethylhydroxypyrimidine*, which crystallises in needles and melts with decomposition at 230–240°. It is soluble in soda solution. The *hydrochloride*, *hydriodide*, and *platinochloride* are crystalline.

L. T. T.

**Derivatives of Pyrazole.** By L. BALBIANO (*Gazzetta*, 17, 176–182).—Wislicenus has recently shown that phenylhydrazine and phthalide combine directly to form the hydrazide of a hydroxy-methylbenzoic acid. In the present paper, the reaction between phenylhydrazine and compounds of the type of ethylene oxide is studied: epichlorhydrin being selected as a suitable substance. When phenylhydrazine and epichlorhydrin are heated in presence of benzene, to moderate the action, phenylhydrazine hydrochloride at first separates; the crude product is then heated in an oil-bath to 140° to remove the benzene, and the residue is distilled, when a yellow oil passes over. This substance is shown by its reactions to be a *phenylpyrazole*,  $\text{C}_3\text{H}_3\text{PhN}_2$ ; it is insoluble in water, soluble in alcohol and ether, as also in fuming hydrochloric acid. Its *platinochloride* crystallises in yellowish-red prismatic needles, and its *ethiodide*,  $\text{C}_3\text{H}_3\text{N}_2\text{EtI}$ , in small white prisms melting at 116–117°, soluble in water, sparingly soluble in alcohol.

The formation of a phenylpyrazole in the above reaction is explained thus:  $\text{C}_3\text{H}_5\text{OCl} + 2\text{PhN}_2\text{H}_3 = \text{C}_3\text{H}_5\text{O}\cdot\text{N}_2\text{H}_2\text{Ph} + \text{PhN}_2\text{H}_3\cdot\text{HCl} = \text{NH}_2\text{Ph} + \text{NH}_4\text{Cl} + \text{H}_2\text{O} + \text{C}_3\text{H}_3\text{N}_2\text{Ph}$ .

It would appear from this reaction that in the pyrazole the two atoms of nitrogen are combined to all three atoms of carbon, and thus it differs from the pyrazole obtained by Knorr, in which the nitrogen-atoms are combined with only two carbon-atoms; further investigation is required, however, to settle this point.

V. H. V.

**Action of Carbamide on Cyanhydrins.** By A. PINNER and J. LIFSCHÜTZ (*Ber.*, 20, 2351–2358).—When the cyanhydrins of aldehydes are heated with carbamides, derivatives of carbamide of the general formula  $\text{CN}\cdot\text{CHR}\cdot\text{NH}\cdot\text{CONH}_2$  are formed. Attempts to

obtain the corresponding acids by hydrolysis of these compounds with alkalis yielded only uncertain results, but when the saponification was carried out with dilute acids, anhydrides of the corresponding acids were obtained of the general formula  $\text{CO} \begin{smallmatrix} \text{CHR} \cdot \text{NH} \\ \text{NH} \cdot \text{CO} \end{smallmatrix}$ .

This class of compounds, to which the authors give the name *metapyrazolones*, pass easily into isomeric compounds of the formula  $\text{OH} \cdot \text{C} \begin{smallmatrix} \text{CHR} \cdot \text{N} \\ \text{N} \end{smallmatrix} \text{C} \cdot \text{OH}$  or  $\text{OH} \cdot \text{C} \begin{smallmatrix} \text{CHR} \cdot \text{NH} \\ \text{N} \cdot \text{CO} \end{smallmatrix}$ , to which the authors ascribe the name *metapyrazoles*, as they differ from Knorr's pyrazoles mainly by having the two nitrogen-atoms separated by a CO-group.

*Phenylcrotonitrilecarbamide*,  $\text{CHPh} : \text{CH} \cdot \text{CH}(\text{CN}) \cdot \text{NH} \cdot \text{CONH}_2$ , formed from cinnamaldehyde cyanhydrin and carbamide, crystallises in needles easily soluble in boiling alcohol, very sparingly in boiling water. It melts with decomposition at  $160^\circ$ . Alkalis convert it into a mixture of acid compounds. When boiled with dilute hydrochloric acid, it yields *styrylmetapyrazolone*,  $\text{CHPh} : \text{CH} \cdot \text{CH} \begin{smallmatrix} \text{CO} \cdot \text{NH} \\ \text{NH} \cdot \text{CO} \end{smallmatrix}$ , which crystallises in glistening, white scales easily soluble in alcohol, sparingly in boiling water. This melts at  $171\text{--}172^\circ$ , but if retained at this temperature resolidifies after a time to the isomeric compound *styrylmetapyrazole*, which melts at  $194\text{--}195^\circ$ . The same conversion seems to be brought about by dissolving the pyrazolone in boiling water containing a little alkali. The pyrazole obtained by fusion forms small needles which, even after repeated recrystallisation, melt at  $194\text{--}195^\circ$ ; that by heating with water forms flat needles melting at  $190^\circ$ , but in other respects they are similar, and are both easily soluble in acids and alkalis. The authors cannot at present determine whether these two substances are identical or isomeric.

*Phenylacetoneitrilecarbamide*,  $\text{CN} \cdot \text{CHPh} \cdot \text{NH} \cdot \text{CONH}_2$ , prepared from benzaldehyde cyanhydrin, forms long prisms easily soluble in alcohol and boiling water and melting with decomposition at  $170^\circ$ . With acids, it yields a compound,  $\text{C}_9\text{H}_8\text{N}_2\text{O}_2$ , which crystallises in quadratic scales, is easily soluble in alcohol and boiling water, and melts at  $181\text{--}182^\circ$ . Neither heating nor the action of alkalis converts it into an isomeride, and it is therefore probably *phenylmetapyrazole*. It is easily soluble in alkalis and in acids.

*Isobutyronitrilecarbamide*,  $\text{C}_4\text{H}_9 \cdot \text{CH}(\text{CN}) \cdot \text{NH} \cdot \text{CONH}_2$ , from isovaleraldehyde cyanhydrin and carbamide, is an oil soluble in alcohol and ether, insoluble in water. With hydrochloric acid, it yields *isobutylmetapyrazole*,  $\text{C}_4\text{H}_9 \cdot \text{CH} \begin{smallmatrix} \text{C}(\text{OH}) \\ \text{NH} \cdot \text{CO} \end{smallmatrix} \text{N}$ , which forms small, white needles, soluble in alcohol and boiling water and melting at  $209\text{--}210^\circ$ . The isomeric pyrazolone does not appear to be formed. Besides the above oil, a small quantity of imidoisocaproitrile (Erlenmeyer, Abstr., 1882, 191),  $\text{NH}(\text{C}_5\text{H}_{10} \cdot \text{CN})_2$ , is obtained. Its hydrochloride forms silky needles soluble in alcohol, insoluble in ether.

Similar compounds appear to be obtainable from acetaldehyde cyanhydrin, and are now under investigation.

L. T. T.

**Sparteïne.** By F. AHRENS (*Ber.*, **20**, 2218—2222).—*Dihydro-sparteïne*,  $C_{15}H_{28}N_2$ , is prepared by reducing sparteïne dissolved in strong hydrochloric acid with a slight excess of tin. The hydrochloride obtained by decomposing the stannochloride with hydrogen sulphide is treated with potassium nitrite and the nitroso-compound extracted with benzene; it is then decomposed by hydrochloric acid, the hydrochloride treated with potash and steam-distilled. It is a thick, colourless oil, which boils at  $281-284^\circ$ . The *platinochloride* crystallises well, and becomes black at  $239^\circ$ . The *picrate* forms matted needles which melt at  $123-125^\circ$  and decompose at  $215^\circ$ . The *mercuriochloride* crystallises in long needles; the *hydrochloride* and *sulphate* were also prepared.

When sparteïne is added to a solution of hydrogen peroxide, it dissolves with evolution of gas. The product of the reaction is an almost colourless *base*,  $C_{15}H_{26}N_2O_2$ ; this could not be obtained crystalline and distils with difficulty with steam; it dissolves readily in water and alcohol, sparingly in benzene and chloroform, and is insoluble in ether. The *platinochloride*,  $C_{15}H_{26}N_2O_2 \cdot H_2PtCl_6$ , becomes black at  $235^\circ$ ; the *auorchloride* crystallises in densely matted needles melting at  $143-146^\circ$ ; the aqueous solution decomposes quickly when warmed, with separation of gold. The *sulphate* forms a thick syrup; the *hydriodide* separates from its solution in colourless, feathery crystals melting at  $121-122^\circ$ ; the *picrate* and *mercuriochloride* were also prepared.

N. H. M.

**Reactions of Creatinine.** By G. COLASANTI (*Gazzetta*, **17**, 129—133).—The most delicate test for creatinine in the presence of other reducing agents is that proposed by Weyl, which consists in adding to the liquid to be examined a few drops of sodium nitroprusside and a dilute solution of sodium hydroxide, which gives a yellow coloration. On adding acetic acid and warming an emerald-green colour is produced at first, which changes after some time to blue, a reaction peculiar to creatinine according to Salkowski, and to acetone contained in urine according to Nobel. This reaction is due to the formation of a sodium ferrocyanide derived from the decomposition of the nitroprusside and its subsequent conversion into Prussian blue. In the paper it is shown that other organic and inorganic acids can be substituted for acetic acid, and that the creatinine reaction can be obtained even after ammoniacal fermentation has proceeded for some time. The same reaction is also obtained even after the urine has been preserved for 30 months in sterilised vessels.

V. H. V.

**Acetylhydrocotarnineacetic Acid.** By W. BOWMAN (*Ber.*, **20**, 2431—2433).—Acetic anhydride combines directly with cotarnine to form *acetylhydrocotarnineacetic acid*,  $C_{16}H_{19}NO_6$ ; this substance crystallises in pale-yellow needles melting at  $201^\circ$ , sparingly soluble in water, soluble in alcohol and benzene. Its *silver* and *mercury* salts are white, the *copper* a blue precipitate; the *ethyl* salt crystallises in delicate needles melting at  $113^\circ$ . The acid is decomposed when boiled with dilute hydrochloric acid, forming a hydrochloride of a compound,  $C_{16}H_{17}NO_5$ .

V. H. V.

**Identity of Cadaverine with Pentamethylenediamine.** By A. LADENBURG (*Ber.*, 20, 2216—2217).—When a solution of pentamethylenediamine hydrochloride (1 mol.) is mixed with a solution of mercuric chloride (4 mols.), a mercuriochloride with 3 mols.  $\text{HgCl}_2$  is formed (this vol., p. 126); if a greater excess of mercuric chloride is employed, the compound  $\text{C}_5\text{H}_{14}\text{N}_2 \cdot 2\text{HCl} \cdot 4\text{HgCl}_2$  is obtained. The identity of pentamethylenediamine with cadaverine is therefore established. (Compare also this vol., p. 742.) N. H. M.

**Hydrastine and its Derivatives.** By M. FREUND and W. WILL (*Ber.*, 20, 2400—2406).—This is a continuation of the author's previous work (this vol., p. 383). Hydrastinine when treated with an aqueous solution of potash yields hydrohydrastinine and *hydroxyhydrastinine*,  $\text{C}_{11}\text{H}_{11}\text{NO}_3$ . The reaction appears to take place according to the equation  $2\text{C}_{11}\text{H}_{11}\text{NO}_2 + \text{H}_2\text{O} = \text{C}_{11}\text{H}_{13}\text{NO}_2 + \text{C}_{11}\text{H}_{11}\text{NO}_3$ . Hydroxyhydrastinine is a feeble base, crystallises in needles, melts at  $97-98^\circ$ , and distils above  $350^\circ$ . It is easily soluble in alcohol, chloroform, ethyl acetate, benzene, &c. The *hydrochloride* is crystalline, melts at  $138^\circ$ , and is decomposed into acid and the free base by water and by alcohol. The *platinochloride*,  $(\text{C}_{11}\text{H}_{11}\text{NO}_3 \cdot \text{HCl})_4 \cdot \text{PtCl}_4$ , forms yellow needles melting at  $160^\circ$ ; the *aurochloride*,  $(\text{C}_{11}\text{H}_{11}\text{NO}_3 \cdot \text{HCl})_2 \cdot \text{AuCl}_3$ ,

a reddish-brown mass melting at  $100^\circ$ .

*Nitrohydroxyhydrastinine*,  $\text{C}_{11}\text{H}_{10}\text{NO}_3 \cdot \text{NO}_2$ , formed by dissolving the base in dilute nitric acid, yields crystals which are soluble in alcohol and acetic acid, and melt at  $271^\circ$ . It is insoluble in hydrochloric acid, sodium carbonate, or ammonia.

Several fresh salts of hydrohydrastine are described. The *hydrochloride*,  $\text{C}_{11}\text{H}_{13}\text{NO}_2 \cdot \text{HCl}$ , forms white crystals melting at  $273-274^\circ$ ; the *platinochloride*,  $(\text{C}_{11}\text{H}_{13}\text{NO}_2)_2 \cdot \text{H}_2\text{PtCl}_6$ , yellow scales melting at  $216^\circ$ ; the *dichromate*,  $(\text{C}_{11}\text{H}_{13}\text{NO}_2)_2 \cdot \text{H}_2\text{Cr}_2\text{O}_7$ , red scales which explode at  $150^\circ$ . The hydrobromide previously described melts at  $272^\circ$ . The *hydriodide* melts at  $232^\circ$ , the *ethiodide* crystallises in needles melting at  $206-207^\circ$ . Hydrastinine dichromate has the formula

and not that previously given.

L. T. T.

**Synthesis of Pilocarpine.** By HARDY and CALMELS (*Compt. rend.*, 105, 68—71).—The synthesis of pilocarpine was effected by converting  $\beta$ -pyridine- $\alpha$ -lactic acid into pilocarpidine, which was then transformed into pilocarpine by oxidation.

One gram  $\beta$ -pyridine- $\alpha$ -lactic acid was mixed with 100 grams of carbon bisulphide and 10 grams of phosphorus bromide and distilled to dryness. The residue was extracted with water, the solution neutralised with baryta, the excess of baryta removed by means of carbonic anhydride, and the solution evaporated to dryness at a temperature not exceeding  $60^\circ$ . The residue thus obtained was purified by repeated treatment with alcohol, and then mixed with hydrobromic acid and auric chloride, when crimson plates of the normal aurobromide of  $\beta$ -pyridine- $\alpha$ -bromopropionic acid are obtained. The gold is removed by means of hydrogen sulphide, and the free acid is heated in

sealed tubes at  $150^{\circ}$  for several hours with excess of triethylamine. The product is treated with an aqueous solution of potassium carbonate, and the oily drops of the liberated alkaloid are dissolved in ether-alcohol, and purified by treatment with animal charcoal. When mixed with auric chloride, it yields the modified aurochloride of pilocarpidine,  $\text{AuCl}_3 \cdot \text{C}_{10}\text{H}_{14}\text{N}_2\text{O}_2$ , melting at  $144^{\circ}$ .

In order to convert pilocarpidine into pilocarpine, the extra-pyridic nitrogen of the former must be rendered pentavalent by the addition of a methyl-group, whilst the pyridic nitrogen remains trivalent.

When pilocarpidine is mixed with methyl iodide in alcoholic solution at  $60$ – $100^{\circ}$ , it combines with 1 mol. of methyl iodide, forming a compound which crystallises with difficulty. If this compound is mixed with auric chloride an oily precipitate is formed and gradually changes to large prismatic needles which melt at  $152$ – $153^{\circ}$  and have the composition  $\text{AuCl}_4\text{Me} \cdot \text{C}_{10}\text{H}_{14}\text{N}_2\text{O}_2$ . This compound readily loses methyl chloride when fused, and yields modified pilocarpidine aurochloride, melting at  $144^{\circ}$ . Pilocarpidine mixed with excess of methyl iodide in concentrated methylic solution, and then with fragments of solid potassium hydroxide, care being taken that the temperature does not rise too high, combines with methyl iodide (1), and methyl hydroxide (2), and if this product is treated with carbonic anhydride, and the liberated alcohol removed, a methiodide is obtained identical with that formed by the action of methyl iodide on pilocarpidine at  $60^{\circ}$ . The hydroxymethylpilocarpidine obtained by the action of silver oxide on the corresponding methiodide, yields pilocarpidine when boiled with water. These results show that it is difficult if not impossible to remove the methyl hydroxide from position (1), and replace it by methyl hydroxide in position (2).

When, however, pilocarpidine methiodide is oxidised by means of silver permanganate, an unstable group,  $\text{MeN}^{(1)}\text{MnO}_4$ , is formed, and decomposes without affecting the remainder of the molecule. An aqueous solution of pilocarpidine methiodide is mixed with silver permanganate until the greater part of the silver iodide is precipitated. Oxidation takes place immediately, and the liquid contains pilocarpine and formic acid. The alkaloid is liberated by addition of potassium carbonate, and yields the aurochloride  $\text{AuCl}_3 \cdot \text{C}_{11}\text{H}_{16}\text{NO}_2$ , melting at  $88^{\circ}$ . Synthetical pilocarpidine and pilocarpine yield gummy derivatives similar to those obtained by Harnack and Meyer from the natural products. This phenomenon is confined to the gold compounds, and is purely physical.

The physiological action of synthetical pilocarpine is identical with that of the natural alkaloid.

C. H. B.

## Physiological Chemistry.

**Relation between Muscular Activity and the Chemical Effect of Respiration.** By M. HANRIOT and C. RICHET (*Compt. rend.*, 105, 76–79).—The work done consisted of raising a weight of 18 kilos. to a height of 0.5 metre several times, the air expired during the

process being collected and measured. The oxygen absorbed was less than that evolved in the form of carbonic anhydride, and the quantity of carbonic anhydride over that originally existing in the air was equal to 4·5 per cent. of the expired gas. This is the limit towards which the proportion of carbonic anhydride in the expired air tends when work is being done. Correcting for the work done in raising the arms and other bodily movements, it was found that ten lifts or 95 kilogrammetres correspond with the absorption of 0·301 litre of oxygen, the evolution of 0·401 litre of carbonic anhydride, or in round numbers, to do work equivalent to 100 kilogrammetres requires the inhalation of 11 litres of air above the normal volume, the absorption of 0·300 litre of oxygen, and the evolution of 0·400 litre of carbonic anhydride. The ratio between the oxygen absorbed and the carbonic anhydride evolved, shows that the chemical change involved is more complicated than the simple oxidation of glucose or glycerol. Assuming that the energy is provided by the combustion of glucose, the 0·8 gram of carbonic anhydride evolved is equivalent to 0·545 gram of glucose, which corresponds with 2·05 cal. or 860 kilogrammetres. The work actually done was 95 kilogrammetres, and hence the efficiency of the human machine is one-ninth. Taking the oxygen absorbed as the basis of calculation, and assuming that it is all used in the combustion of glucose, it corresponds with a development of heat equivalent to 645 kilogrammetres, and hence the efficiency in this case is one-seventh.

C. H. B.

**Heat Developed by the Activity of Muscles.** By A. CHAUVÉAU and KAUFMANN (*Compt. rend.*, 105, 296—301).—The temperature of the muscles of the jaws of a horse was taken by a thermoelectric method, fine needles being inserted one into the left muscle the other into the right muscle. So long as the muscles remained at rest the scale of the galvanometer remained at rest, but when the muscles were active the galvanometer needle began to oscillate. The enervation of one muscle does not affect the relative temperature whilst in repose, but when in action the temperature of the muscle which performs its functions rises. Cooling by radiation and evaporation is prevented by a casing of cotton-wool. The heat developed is calculated from the weight and temperature of the muscle and the quantity of blood which traverses it. The rise of temperature when the muscle is engaged in mastication is 0·42, but when the muscle makes the same movements without doing any work the rise of temperature is 0·47, or the work done corresponds with a rise of temperature of 0·05°. It is evident that a very considerable amount of heat is developed when a muscle is in operation, but only a small part of this energy (one-seventh or one-eighth) is used up in doing useful work.

C. H. B.

**Action of Micro-organisms from the Mouth and from Fæces on Food-stuffs.** By W. VIGNAL (*Compt. rend.*, 105, 311—313).—The 19 organisms isolated from the mouth exert very considerable digestive and fermentative action. Many of them dissolve albumin and fibrin, curdle milk, invert saccharose, ferment glucose,

and saccharify starch. Many of them resist the action of the gastric juice, pancreatic juice and bile.

The fæces contain an enormous number of microbes, including at least 10 species, six of which are also found in the mouth. The other four possess digestive and fermentative powers.

These organisms play a very important part in digestive changes, and there is little doubt that these changes are of a much more complex character than is generally supposed. C. H. B.

**Sugar in Urine.** By C. MÉHU (*J. Pharm.* [5], 16, 145—149).—The author has frequently proved the presence of small quantities of sugar in the urine of persons passing albuminous urine after a longer or shorter course of milk food. The observations have only been made in the cases of patients whose urine was absolutely free from sugar before the milk treatment was commenced. It is only very rarely that the sugar has amounted to 4 grams per kilo. of urine, usually not more than 2 grams occurs. The urine is acidified slightly and boiled to coagulate albumin, filtered, and treated with  $\frac{1}{10}$ — $\frac{1}{20}$  its volume of basic lead acetate, filtered, and freed from lead by sodium carbonate. The resulting liquid added to its own volume of recently prepared Fehling's solution is heated for 10 minutes in boiling water; the reduction is very evident if sugar is present. The urine must be recent and non-ammoniacal. Preliminary concentration of the liquid at a moderate temperature to one-third its volume favours the reaction. Instead of Fehling's solution, the author has also used a solution of bismuth prepared as follows:—Bismuth subnitrate, 15.3 grams; tartaric acid, 30 grams; soap lye, 360 grams, or fused sodium hydrate, 80 grams. The soap lye is gradually added to the powdered mixture of the two first substances and the volume is made up to 500 c.c. with hot water. The solution is filtered and can be easily preserved. 1 c.c. is added to 10 c.c. of urine and the mixture heated to boiling, or better still heated in a boiling saturated salt solution. If the mixture does not blacken in about 10 minutes, it is concluded to be free from sugar. This reagent does not blacken in contact with uric acid or pure calcium oxalate. It is more certain than Fehling's solution but somewhat less rapid. It is absolutely necessary that the liquid to be tested should be free from albumin and albuminose, or a black precipitate of bismuth sulphide results. In all cases, it is well to filter the liquid before applying the test. J. T.

**Per-ruthenic Acid in Histology.** By L. RANVIER (*Compt. rend.*, 105, 145—147).—Per-ruthenic acid is more readily reduced by animal tissues than is osmic acid, but the action is so energetic that no differences are observed in the behaviour of different kinds of tissues, all becoming equally black. C. H. B.

## Chemistry of Vegetable Physiology and Agriculture.

---

**Microbe of the Indigo Fermentation.** By E. ALVAREZ (*Compt. rend.*, 105, 286—289).—In the fermentation of the indigo plant, the colouring matter forms on the surface of the liquid that is in contact with the air, and the fermenting liquid contains an enormous number of bacilli and micrococci which can be isolated and cultivated by the usual methods. A sterilised solution of the indigo plant will not ferment. The fermentation is due to one bacillus alone and is not produced by any other. It is about  $3\mu$  long and  $1.5\mu$  broad with rounded extremities, and groups of six, eight, or more are frequently arranged end to end in the form of a chain. The bacillus is surrounded by a capsule like the bacilli of pneumonia and rhinoscleroma. It is readily cultivated by the ordinary methods, and when placed in an infusion of the plant, indigo is formed, and the bacilli become stained blue and rapidly multiply. The microbes of pneumonia and rhinoscleroma also determine the fermentation of indigo. Other pathogenic microbes produce no effect. The indigo bacillus is strongly pathogenic. When injected subcutaneously, it produces only local effects, but when injected into the veins or any of the more vascular organs, such as the lungs, of the guinea-pig it rapidly causes death. The principal effects are congestion of the digestive tube and strongly marked lesions of the excretory organs. C. H. B.

**Aleurone-grains in the Seed of *Myristica Surinamensis*.** By A. TSCHIRCH (*Arch. Pharm.* [3], 25, 619—623).—The seeds are peculiar in the extraordinary development of the albumin crystalloïds of the aleurone-grains. Each cell is almost filled with a large crystalloïd of the hexagonal system, either a rhombohedron (R) or a combination of the same with the basal plane (R·OR). Twin forms are rare. These crystalloïds form the matrix of very large aleurone-grains. As a rule, to each crystalloïd is attached a greater or less number of globoïds, each including a needle-shaped crystal of calcium oxalate. Besides the globoïds, the oxalate crystals, and the protein-crystalloïds, the aleurone-grains also contain a residue of amorphous substance. To separate these constituents, a section is freed from fat by means of ether, then very dilute aqueous potash dissolves the albumin crystalloïds after washing, acetic acid dissolves the globoïds, and then the calcium oxalate is dissolved in dilute hydrochloric acid. J. T.

**Examination of Caucasian Madder Root.** By O. BERGAMI (*Ber.*, 20, 2247—2251).—The dried powdered root was extracted with boiling absolute alcohol, and the extract reduced to  $\frac{1}{3}$  to  $\frac{1}{4}$  of its bulk by distillation; a yellowish-brown, crystalline substance separated, consisting of crude glucosides. By further evaporation, crystals of cane-sugar were obtained; the mother-liquor from these were treated with water to precipitate the colouring matter present. The method employed in purifying the glucosides is described. The yield

of pure ruberythric acid is 0.1 per cent. of the weight of root. The amount of cane-sugar is about 3 per cent. The pure colouring matter, which consists of alizarin together with much purpurin, amounts to about 6 per cent. of the weight of root. N. H. M.

**Experiments with Ensilage in Holland.** By H. THIEL (*Bied. Centr.*, 1887, 445—447).—After allowing the grass to make for a day, it was formed into heaps 10 m. square, the outer portions being higher than the inner, whereby a more even mass is produced, the top was then covered with boards, and weighted with stones to 500 kilos. per square metre.

The composition of the ensilage compared with that of some of the same grass made into hay was as follows:—

|  | Hay in<br>100 parts. | Ensilage in 300<br>parts corresponding<br>with 100 parts hay. |
|--|----------------------|---|
| Albumin .....                          | 12.1                 | 13.5  |
| Fat .....                              | 2.9                  | 5.7   |
| Carbohydrates and lactic<br>acid ..... | 32.7                 | 46.8  |
| Crude fibre .....                      | 23.7                 | 27.0  |
| Ash .....                              | 7.3                  | 9.0   |
| Water.....                             | 21.7                 | 213.9   |

Six milch cows and six heifers were then fed on the hay and ensilage, in addition to other foods including roots and linseed cake. It was afterwards found that those heifers and cows fed with hay increased in live-weight to a greater extent than those fed on the ensilage, the increase being 104 and 64 per cent. respectively. The yield and quality of milk was, however, best from those cattle fed on ensilage.

The editor of the *Centralblatt* considers that this last fact is due more to the individuality of the cows than to the ensilage.

E. W. P.

## Analytical Chemistry.

**A Source of Error in Gas Analysis.** By W. HEMPEL (*Ber.*, 20, 2344).—The author points out that cuprous chloride absorbs gases of the ethylene series, but that when such solutions are further brought in contact with carbonic oxide, varying quantities of the hydrocarbons are again evolved. In analyses in which cuprous chloride is used as an absorbent for carbonic oxide, it is therefore necessary first to remove the heavy hydrocarbons. L. L. T.

**A Gas-burette which is Independent of Atmospheric Pressure and Temperature.** By W. HEMPEL (*Ber.*, 20, 2340—2343).—As in Petterson and Palmquist's apparatus (this vol., p. 999) the influence of atmospheric temperature and pressure is obviated by

connecting the measuring tube with a closed volume of moist air. The eudiometer is connected at the bottom with a movable mercury receiver, and at the upper end terminates in a Greiner-Friedrich slanting-bore three-way tap with two capillary outlet tubes. One of these tubes serves to draw in the gas to be analysed, the other is connected by a rubber joint with a small U-shaped mercury manometer, the other end of which is similarly connected with the air-chamber. The eudiometer and air-tubes are placed side by side in a cylinder of water.

L. T. T.

**Estimation of Phosphoric Acid.** By MALOT (*J. Pharm.* [5], 16, 157—159).—This communication is supplementary to one which appeared in the July number of *J. Pharm.* on the titration of phosphoric acid by means of uranium nitrate. The green lake formed by uranium oxide with the colouring matter of cochineal being decomposed by dilute acids, not excepting acetic acid, it is necessary to operate with a liquid slightly acidified with acetic acid. Hence, instead of adding 5 c.c. of sodium acetate solution to the assay slightly acidified with nitric acid, it is better after having brought the colour of cochineal to violet by means of ammonia to remove this colour by adding one or two drops of acetic acid. This also produces the best conditions for the precipitation of phosphoric acid by means of uranium acetate. The solution should be kept boiling, especially at the termination of the operation, which is reached when a definite green tint is produced, neither modified by boiling nor by the further addition of uranium salt. Instead of uranium nitrate, it seems preferable to employ the acetate, whose solution better preserves a constancy of composition if care has been taken to boil during a few hours in order to precipitate phosphate, which is always present in commercial acetate. Alcoholic tincture of cochineal serves as well as the solution obtained by boiling in water. The ammonium magnesium phosphate precipitate need not be dissolved off the filter, but may be thrown along with the latter into a 200 c.c. flask for the titration. This precipitate may be impure, either from the presence of citric or molybdic acid. Either of these acids interferes with the accuracy of the assay. It is convenient to dissolve the ammonium phosphomolybdate in concentrated ammonia, and to precipitate with citro-magnesium solution in a liquid strongly ammoniacal, and to wash once at least with strong ammonia, finishing the washing with dilute ammonia to remove the last traces of citric acid.

J. T.

**Examination of Crude Soda Lyes and Red Liquors.** By W. KALMANN and J. SPÜLLER (*Dingl. polyt. J.*, 264, 456—459).—In examining crude soda liquors, it is the practice to calculate the total consumption of iodine as sodium sulphide, the separate estimation of sodium sulphite and sodium thiosulphate being rarely attempted owing to the want of a rapid and accurate method. The authors recommend a process based on the insolubility of barium sulphite and the solubility of barium thiosulphate in alkaline solutions. The estimation is performed in the following manner:—(1.) The total

alkalinity is determined in a measured volume of the liquor under examination by titration with normal acid, methyl-orange being used as indicator. The acid consumed equals sodium carbonate + sodium sulphide, + sodium hydroxide, + one-half sodium sulphite ( $\text{Na}_2\text{SO}_3$  is alkaline and  $\text{NaHSO}_3$  neutral to methyl-orange). (2.) An equal volume of the liquor is titrated with a decinormal solution of iodine, the volume consumed corresponding with the sodium sulphide + the sodium sulphite, + the sodium thiosulphate. (3.) Twice the volume of liquor as that used in (1) and (2) is precipitated with an alkaline zinc solution, and the mixture made up to a certain measure, one-half of which is filtered, acidified, and titrated with decinormal iodine solution. The iodine consumed equals sodium sulphite + sodium thiosulphate. (4.) Three or four times the volume of liquor used in (1) and (2) is treated with an excess of a solution of barium chloride, the mixture made up to a known volume with water, and filtered. (a.) One-third or one-fourth (as the case may be) of the filtrate is titrated with normal acid, the amount used corresponding with the sodium hydroxide + the sodium sulphite. (b.) A new third or fourth of the filtrate is acidified and titrated with decinormal iodine solution, the iodine consumed being equal to sodium sulphite + sodium thiosulphate. The calculation is made as follows:—

|    |                          |   |                                     |
|----|--------------------------|---|-------------------------------------|
| 2  | — 4b .....               | = A c.c. decinormal iodine solution<br>corresponding to ..... | $\text{Na}_2\text{SO}_3$ .          |
| 2  | — 3 .....                | = B c.c. decinormal iodine solution<br>corresponding to ..... | $\text{Na}_2\text{S}$ .             |
| 4b | — (2—3) ....             | = C c.c. decinormal iodine solution<br>corresponding to ..... | $\text{Na}_2\text{S}_2\text{O}_3$ . |
| 4a | — $\frac{3}{10}$ B ..... | = D c.c. normal acid corresponding<br>to .....                | $\text{NaOH}$ .                     |
| 1  | — $(4a + \frac{1}{10}A)$ | = E c.c. normal acid corresponding<br>to .....                | $\text{Na}_2\text{CO}_3$ .          |

The results of several test analyses are given.

D. B.

**Estimation of Titanic Acid.** By L. LÉVY (*J. Pharm.* [5], 16, 56—61).—Titanic acid is estimated by fusing the material with hydrogen potassium sulphate, extracting with cold water the mixture of titanate and sulphates thus formed, boiling for six hours to precipitate the titanic acid, calcining, and weighing. In presence of alkalis, magnesium, zinc, aluminium, or copper oxides, it is only necessary to fuse with the sulphate as above, dissolve the mass in water acidified with a sufficient quantity of sulphuric acid, neutralise with potash or ammonia, then add 0.5 gram of sulphuric acid to each 100 c.c. of solution, and finally boil for six hours, constantly replacing the water driven off. This method is not applicable in the case of iron sesquioxide. The results are high.

J. T.

## General and Physical Chemistry.

---

**Oxygen in the Sun.** By J. TROWBRIDGE and C. C. HUTCHINS (*Phil. Mag.* [5], 24, 302—310).—In these experiments, a powerful alternating current was caused to pass between electrodes of aluminium, and the spectrum, obtained by a grating, photographed on one half of a photographic plate, then, without altering the arrangement of the apparatus, sunlight was admitted, and its spectrum photographed on the other half of the plate. The wave-lengths of the air or sun spectra were tabulated. The authors point out that in order to be certain of the existence of an element in the sun, the coincidence of a large number of the lines of the element in position and grouping with the dark lines of the solar spectrum is necessary, or else a general similarity in the character of the lines; they find no such coincidence for oxygen so far as they have examined (wave-lengths 3749·8—5033·85). They find that the bright lines of Draper's spectrum vanish in their high-dispersion apparatus, and contain numerous dark lines, and, moreover, that there is no general coincidence between the oxygen lines and the bright spaces of the solar spectrum. H. K. T.

**Existence of Carbon in the Sun.** By J. TROWBRIDGE and C. C. HUTCHINS (*Phil. Mag.* [5], 24, 310—313).—The authors find that the solar spectrum near H contains dark lines exactly agreeing with the spaces between the bright lines of the flutings of the carbon spectrum. The carbon spectrum is wanting in the green and blue. This may be due to the effect of vapour in the sun's atmosphere, the lines due to any element being unaltered, obliterated, or reversed, according to the temperature of the vapour through which the light passes. The temperature of the luminous vapour itself may also vary. Further the spectrum from one element may be partially obliterated by the passage of the light through the vapour of another element. The photographic spectrum of carbon can be obliterated in the green and blue by superimposing upon it that of iron, of nickel, and of cerium. The fluted carbon spectrum of the voltaic arc is due to a reversal of the continuous spectrum of the ignited carbon by its own vapour; hence the temperature of the sun's atmosphere where the carbon is volatilised must approximate to that of the voltaic arc.

H. K. T.

**Existence of Certain Elements and Discovery of Platinum in the Sun.** By C. C. HUTCHINS and E. L. HOLDEN (*Phil. Mag.* [5], 24, 325—330).—The spectra of different metals in the voltaic arc are compared with the solar spectrum by means of apparatus already described (see preceding Abstracts). The authors confirm the results of Lockyer for the metals cadmium, bismuth, silver, potassium, and lithium, whilst they find insufficient coincidence for the metals lead, cerium, molybdenum, uranium, and vanadium. Platinum, which has not hitherto been found in the solar spectrum, gives 64 lines between

wave-lengths 4250 and 4950, 16 of which agree with solar lines, whilst seven are doubtful. H. K. T.

**Spectrum Analysis.** By A. F. SUNDELL (*Phil. Mag.* [5], **24**, 98—106).—The author examines the spectra of considerable thicknesses of rarefied gases at low temperatures. The gases were contained in glass tubes, viewed end on, the ends of the tubes being coated with tinfoil connected with the conductors of a Holtz machine.

Air first became luminous at a pressure of 10 to 12 mm.; at 8 mm. the light took up peculiar stratifications, which oscillated rapidly. The spectroscope showed a large number of bands, which are tabulated. With pressures less than 0.0003 mm., the luminosity ceased. The author finds that even with a tube which had been frequently exhausted during a period of four months, evidence of air appears shortly after exhaustion. If the discharge is made to take the form of sparks, luminosity ceases at a pressure of 0.004 mm. Hydrogen, oxygen, and nitrogen were also examined. The first was luminous in the highest vacua; oxygen was brightest at 0.2 mm.; nitrogen gave the same spectrum as air. H. K. T.

**Radiant Matter Spectroscopy: Examination of the Residual Glow.** By W. CROOKES (*Proc. Roy. Soc.*, **42**, 111—131).—The author has devised the following modification of Becquerel's phosphoscope. The phosphorescent substance in an exhausted bulb is excited in the usual way by the spark from the secondary of an induction coil, and is viewed through a rotating disc having 12 symmetrically placed apertures near its margin. A brass cylinder, one end of which is cut into 12 teeth, is fixed upon the axis of the disc, and two springs, one pressing on the continuous part of the cylinder, and the other (adjustable) rubbing over the teeth, serve to complete the circuit through a battery and the primary of the coil. By adjusting the movable spring the spark from the secondary can be made to coincide with the passage of an aperture between the substance under examination and the eye or a spectroscope, or to precede it by a short interval of time, easily calculated when the velocity of the disc is known. By moving the adjustable spring towards or from the bases of the teeth, the relative duration of the makes and breaks can be varied at pleasure. Since the line spectrum of the residual gas in the bulb has no appreciable duration, much lower vacua are necessary for the examination of the residual glow by this method.

When yttria, free from samaria, is thus examined, it is found that all the bands in its phosphorescent spectrum do not appear at the same speed of rotation. As this is gradually increased they come into view in the order  $G\beta$  (545), greenish-blue, and  $G\alpha$  (482), deep blue (duration 0.0035 sec.);  $G\delta$  (574), citron (0.0032 sec.);  $G\zeta$  (647), deep red (0.00175 sec.). At an interval of 0.00125 sec.  $G\delta$  and  $G\beta$  are equally bright, and  $G\eta$  just visible; and at 0.000875 sec. all are seen of their usual brightness. The author confirms the absence of the citron band from the spectrum of phosphorescent yttric phosphate.

Elsewhere the author has pointed out that 1 per cent. of lime added to a badly phosphorescing substance containing yttrium or samarium

brings out the phosphorescence well. In the former case, it diminishes the sharpness of the line  $G\delta$ , but increases its brightness, as well as that of  $G\alpha$ . In the phosphoroscope, lime is observed also to change the order in which the yttric lines appear to  $G\delta$ ,  $G\alpha$ ,  $G\beta$ ,  $G\eta$ .

The author attributes this action to the long residual phosphorescence of the lime, which induces or assists certain yttric vibrations ( $G\delta$ ), and is antagonistic to others ( $G\beta$ ). The influence of baryta and strontia on the phosphorescence of yttria has also been studied, and the author gives the order of appearance and intensities of the lines. The results cannot well be condensed, the action of each alkaline earth not only being fundamentally different, but varying with the relative proportions of the mixtures. An interesting result is obtained on adding strontia to a mixture of yttria and samaria and viewing it in the phosphoroscope with the wheel rotating rapidly. The line  $G\delta$  is then completely suppressed, and a spectrum is obtained undistinguishable from that of Marignac's  $Y\alpha$  (*Proc. Roy. Soc.*, **40**, 236).

Many earths and oxides, or mixtures of these with lime, have been examined, mostly as sulphates. The results are given in more or less detail.

Arsenious acid, cadmium, copper, lead, and nickel sulphates, tin, tungsten, and uranium, in small quantity with lime, give the phosphorescence of the latter.

Alumina, giving the crimson line, has a very persistent residual glow. In the phosphoroscope, rubies shine with great brilliancy.

Antimony oxide (5 per cent.) with lime phosphoresces white, with a broad space in the yellow. In the phosphoroscope, the glow is green and very strong: the red and orange are obliterated.

Barium (5 per cent.) with lime, bright reddish-orange phosphorescence, with specks of yellow and violet. The spectrum is continuous, faint in the red, strong in the green, and with a broad black band in the orange.

Bismuth (15 per cent.) with lime, bright reddish-orange. The spectrum shows a broad dark band in the red and orange, a black band in the yellow, and great concentration in the green and blue. In the phosphoroscope, red and orange are obliterated.

Calcium sulphate, greenish-blue phosphorescence, without bands or lines. In the phosphoroscope, the colour is green, red and orange being cut off.

Chromium (5 per cent.) with lime, pale-reddish phosphorescence. The phosphoroscope cuts off red and orange.

Diamonds glowing pale-blue have the longest residual glow; next come those glowing yellow. Those phosphorescing red have no residual glow.

Glucina, rich blue; no residual glow.

Lanthanum sulphate, reddish. The spectrum shows a broad orange band with a sharp line— $1/\lambda^2$  280—superposed. This is identical with the line  $G\epsilon$ . Lime changes the colour to yellow, bringing out lines of yttrium and samarium, these being present as impurities.  $G\beta$  is, however suppressed, together with a portion of the neighbouring spectrum.

Lead sulphate, nearly white. In the phosphoroscope, red and orange are cut off.

Magnesia, pink; 5 per cent. with lime greenish, turning red as the powder heats.

Potassium with lime, bright. Residual glow persistent.

Samarium (see *Phil. Trans.*, 1885, 709).

Scandium as earth or sulphate, very faint blue.

Sodium sulphate gives a greenish tinge to the phosphorescence of calcium sulphate. The sodium line is visible in the spectrum.

Strontia, rich blue with continuous spectrum. In the phosphoroscope, the glow is bright green, the red and blue ends being cut off.

Thorium, as oxide or sulphate, alone or with lime, does not phosphoresce at all, and the tube rapidly becomes non-conducting, the spark passing across the gauge (37 mm. in air) rather than through the tube; in the same vacuum, when yttria takes the place of thoria, a spark of 7 mm. length in air will pass through the tube. This phenomenon is inexplicable; evidently the passage of electricity through the tube depends mainly on the phosphorogenic properties of the earth opposite the poles.

Thulium and erbium together phosphoresce green (*Proc. Roy. Soc.*, **40**, 77). The spectrum shows a faint blue double line, which is intensified by the presence of lime. Some of the yttrium lines are also seen.

Ytterbium when pure gives blue phosphorescence without bands. Some specimens, not quite pure, give bands in the blue which are intensified by the addition of lime, and which the author has carefully measured. Their origin is still uncertain.

The higher fractions of yttria sometimes show a sharp green line ( $1/\lambda_2$  325 approximately). These fractions phosphoresce of a golden-yellow colour, the fractions at the other end phosphorescing yellowish-green. The green line may possibly belong to a new earth.

The phosphorescence of various mixtures of oxides with yttria (usually as sulphates) is then described. Most earths have the effect of destroying, or diminishing the brilliancy of the yttric phosphorescence. Yttria (5 per cent.) with alumina gives a good yttrium spectrum. In the phosphoroscope, the lines  $G\beta$  and  $G\alpha$  first appear together, then  $G\delta$ . 0.5 per cent. of bismuth with yttria then suppresses the citron line  $G\delta$ , thereby rendering visible the samarium double green line and  $G\beta$ . With larger proportions of bismuth, the spectrum either is that of yttrium, or is bad. Cerium and didymium tend to deaden the yttrium spectrum. With zinc (95 per cent.), the phosphorescence is yellowish-white and brilliant. In the phosphoroscope, the colour becomes reddish and the line  $G\beta$  appears first.  $G\delta$  is suppressed. If samarium is present, its spectrum now comes out distinctly.

Zinc sulphide (Sidot's hexagonal blende, *Compt. rend.*, **62**, 999, and **63**, 188) phosphoresces most brilliantly even in a vacuum of several inches. The glow is then green; but as the exhaustion proceeds it becomes blue at the edges of the crystals. At a high exhaustion, the two colours are of equal brightness, but in the phos-

phoroscope the blue is only seen at a high speed. The green glow lasts for an hour or more.

The author then reviews the evidence on which he bases the claims of the bodies  $G\alpha$ ,  $G\beta$ , &c., to be regarded as separate entities, and the influence of baryta, strontia, and lime is discussed at length in each case. It is remarkable that the spark spectra of old yttrium, and of the higher and lower fractions obtained from it, are perfectly identical, although the phosphorescent spectra and chemical properties of the three are markedly different. Two theories of the true nature of these substances are suggested, namely, the hypothesis of sub-molecules which differ from each other "according to the position they occupy in the yttrium edifice," and the hypothesis that each of them is an independent element. On the latter view, the spark spectrum of yttrium may be supposed to belong to  $G\delta$ , which is nowhere completely separated during the process of fractionation. A third view is that of de Boisbaudran, who considers that yttrium is an element giving a spark spectrum, but not phosphorescing in a vacuum; and that the phosphorescent spectra are due to impurities; these are two in number, and are provisionally named  $Z\alpha$  and  $Z\beta$ .

**Sharp Line Spectrum of Phosphorescent Alumina.** By W. CROOKES (*Chem. News*, 56, 59—62, 72—74).—A rejoinder to Boisbaudran (this vol., pp. 191, 409, 538, 625, 755). The author has proved by direct experiment the possibility of removing very minute proportions of chromium from large quantities of alumina:—1. By boiling the alkaline solution; 2. By passing chlorine through the alkaline solution; 3. By fractional crystallisation of ammonia alum. All these methods were employed in the preparation of the author's "high alumina," in which not the slightest indication of chromium could be detected, nevertheless a sharp line phosphorescent spectrum was obtained, including the red line; hence proving that alumina without chromium can produce it. Next the author shows that chromium in admixture with glucina, magnesia, lime, zinc oxide and other similar substances, and subjected to heating with and without sulphuric acid, and to temperatures varying from cherry-red to full white, did not show any sharp red line. "The general character of the phosphorescence was reddish-orange, the spectrum being almost continuous, with the extreme red and blue ends obliterated." Hence chromium in many solid solvents does not appear to give the sharp red line spectrum. Moreover, Boisbaudran's chromium-gallium red

line has a wave-length  $\lambda 6897$  to  $6898$  ( $= \frac{1}{\lambda^2} 2102$ ), very far from the alumina red line  $\lambda 6940$  or  $\frac{1}{\lambda^2} 2076$ ; besides owing to the chemical analogy of aluminium and gallium, it is quite natural to expect a resemblance in their spectra.

In connection with alumina and samaria (Boisbaudran, this vol., p. 1008), it is shown that alum may be obtained quite free from samaria by fractional crystallisation; hence the author's high alumina is free from this impurity. And he finds that the mixed sulphates of

aluminium and samarium heated to redness give the phosphorescent spectrum of the latter modified by the presence of the former, which is explained in this way: a red heat is not sufficient to decompose the sulphates, and samarium sulphate is phosphorescent, whereas aluminium sulphate is not. On the other hand, when the sulphate mixture is heated at a very high temperature, both are decomposed, and the residue of alumina and samaria gives the new sharp line spectrum of alumina, which might be expected, since samaria alone gives practically no phosphorescent spectrum. Maps and detailed descriptions of the spectra are given in the paper. D. A. L.

### Sharp Line Spectra of Phosphorescent Yttria and Lanthana.

By W. CROOKES (*Chem. News*, 56, 62, 81—82).—Yttria precipitated from the sulphate by ammonia, and heated to redness, does not phosphoresce; but when ignited at a full white heat, it phosphoresces with a clear yellow light, and gives a spectrum containing sharp lines:—from  $\frac{1}{\lambda^2}$  224 to 370 these are numerous and in many cases sharp lines;

then follows a clear space, and from  $\frac{1}{\lambda^2}$  409 to 500 some nebulous groups.

A specimen of lanthana, treated in a similar manner, phosphoresced of a superficial yellow colour, and gave a very brilliant spectrum. A line at  $\frac{1}{\lambda^2}$  224, groups of bands from 237 to 285, a band at about 330 and 383, and 407. Maps, tables, and descriptions of both the spectra are furnished in the papers. At present no striking results have been obtained by treating in the same manner niobic acid, samaria, ytterbia, and erbia. D. A. L.

**Chemical Structure of Oxygen and Hydrogen, and their Dissociation in the Sun's Atmosphere.** By A. GÜNWALD (*Phil. Mag.* [5], 24, 354—367).—Let  $[a]$  be the volume of a primary element in a gaseous substance A, and let  $[a']$  be the volume which the element occupies when A has combined with another gas, then the wave-lengths of the rays which the element emits in its first combination are to the wave-lengths which it emits in its second combination, as a  $[a] : [a']$ . Thus, whilst HCl, HBr, and HI give spectra consisting of hydrogen and halogen lines only, H<sub>2</sub>O gives a spectrum which may be obtained by multiplying the second hydrogen spectrum by  $\frac{1}{2}$ . By this means, water lines hitherto unnoticed have been detected. Further the wave-lengths of the hydrogen spectrum can be divided into two groups, (a) and (b), such that  $(a) \times \frac{9}{30}$  and  $(b) \times \frac{4}{5}$  give lines in the water-spectrum; hence by the preceding reasoning hydrogen consists of two elements, a and b. Let  $[a]$  and  $[b]$  be the volumes which they occupy in a unit volume of hydrogen, then  $[a] + [b] = 1$ , moreover  $\frac{9}{30} [a] + \frac{4}{5} [b] = \frac{2}{3}$ ;  $\therefore [a] : [b] = 4 : 1$ , or hydrogen consists of 4 vols. of the element a combined with 1 vol. of the element b. Spectra are given for the elements a and b. In accordance with the above principle, the wave-lengths of oxygen and hydrogen multiplied by  $\frac{2}{3}$  give the water-spectrum. In the same

way, the oxygen spectrum may be split up into sets of lines, which when multiplied by suitable factors give lines in the compound H spectrum and water-spectrum, and from these factors the formula  $O = H' [b_4(b_4c_5)_3]$  is obtained, or oxygen is composed of the modified hydrogen H', which radiates the compound line spectrum of hydrogen, of the element *b*, and of a new element *c*. The composition of carbon and nitrogen is also investigated. By a comparison of the *a* and *b* spectra with the chromospheric lines, it is found that hydrogen exists in a dissociated state in the sun's atmosphere, and that the element *b* is identical with helium  $D_3 = 5874.9$ , whilst the extremely light element *a* forms the corona substance  $\lambda = 5315.9$ , and is named by the author *coronium*.

**Photochromatic Properties of Silver Chloride.** By G. STAATS (*Ber.*, 20, 2322—2323).—When a well-polished plate of silver is dipped into a 5 per cent. solution of iron chloride, it acquires a slate colour. The plate is taken out of the solution after 10 seconds, dried quickly (without heating), and covered with red, emerald, orange, and cornflower-blue glass. In sunshine, the colours appear on the plate after a few minutes; over-exposed plates, especially blue ones, are brownish. The colours dissolve readily in aqueous ammonia. If the plate is heated before exposure, it acquires first a violet and then a red colour, and at the same time partly loses its sensitiveness to yellow and green light. The experiment is suggested as suitable for a lecture experiment.

N. H. M.

**Modification of the Ferric Chloride Cell.** By T. MOORE (*Chem. News*, 56, 64).—Potassium chlorate, hydrochloric acid, and a very small quantity of bromine are recommended in place of bromine alone (Warren, this vol., p. 413), as more economical and equally efficient for the regeneration of the ferric chloride in ferric chloride cells. Cells composed of zinc and carbon immersed in a strong solution of potassium permanganate and ammonium chloride are suggested for use in batteries for electric bells, &c. Exhausted Leclanché cells can be to a great extent revived by pouring a warm, strong, and slightly acid solution of permanganate into the porous cell.

D. A. L.

**Electrical Conductivity of Hot Gases.** By J. BUCHANAN (*Phil. Mag.* [5], 24, 297—302).—In these experiments, small pieces of platinum foil are placed vertically and parallel with a flat gas-flame between them, the platinum discs being connected with the binding screws of a condenser charged from a Leclanché battery, and with the quadrants of an electrometer; one pair of quadrants being connected to earth. The flame being in action, the battery was disconnected, and scale-readings taken at equal intervals of time until zero was nearly reached. From these readings the rate of leakage could be found.

Curves are plotted in which the scale-readings of the electrometer are the ordinates, and the times the abscissæ, and equations are obtained. It was found that the rate of leakage was more rapid when the insulated quadrant was negatively charged than when positive.

**Electromotive Dilution Constants of Silver and Copper Salts.** By J. MIESLER (*Monatsh. Chem.*, 8, 193—196).—Moser (Abstr., 1886, 925) has applied the term electromotive dilution constant to the electromotive force of the current between two solutions of single and double concentration. The values of the constants determined by the present series of experiments are given in the following table:—

|              | Acetate. | Sulphate. | Nitrate. |
|--------------|----------|-----------|----------|
| Copper ..... | 2·3      | 3·6       | —        |
| Lead .....   | 2·6      | —         | 8·3      |
| Zinc .....   | 5·0      | —         | 11·6     |
| Silver ..... | 10·7     | 12·0      | 16·2     |

**Thermochemical Law conjectured by Pebal respecting Non-reversible Electrolytic Actions.** By L. BOLTZMANN (*Monatsh. Chem.*, 8, 230—236).—The present paper has been constructed from a few data in the papers left by Pebal, and from some suggestions made to Boltzmann a few days before Pebal's death.

If a current is produced through an electrolytic cell by a difference of potential infinitely little different from the electromotive force of polarisation  $p$ , an infinitely slow separation of ions takes place. By including a very large resistance in circuit, the process will be reversed and a very feeble current will flow through the cell, whose electromotive force will be infinitely little different from  $p$ . In each case,  $p$  will be independent of the strength of the current provided it is small. From the second law of thermodynamics, Helmholtz finds that in such a cell no secondary heat will be produced as long as  $p$  is independent of the absolute temperature  $\theta$ . If, on the contrary,  $p$  is a function of  $\theta$ , a quantity of heat measured by—

$$\alpha \theta I t \frac{dp}{d\theta} \dots \dots \dots 1,$$

must be supplied to the cell in order to maintain the temperature constant, in the case where the process is reversed. Here the current of strength  $I$  traverses the cell for a time  $t$ , and  $\alpha$  is the thermal equivalent of a unit of work. This result has been tested by the experiments of Czapski, Gokel, and Jahn, and has been found to be correct. In many cases, however, the actions are not reversible. Pebal believes that Helmholtz's result may be extended to non-reversible actions somewhat on the following grounds:—

In the majority of cases to which the second law of thermodynamics is applied, as, for instance, to the theory of the steam-engine, &c., the immediate circumstances are not strictly reversible. Rather they have to be approximated to by an ideal set of conditions, in which every finite difference of temperature and every sudden transformation of energy is avoided. In a similar manner, Helmholtz's result may possibly be made available for all electrolytic actions by replacing sudden transformations of energy by reversible processes.

Taking as an ideal case that of a Grove's gas-battery, the formula  $I$  will give correctly the amount of heat produced by secondary causes. In the actual circumstances when bubbles of gas rise through the

electrolyte or are condensed on the surface of the electrodes, the amount of heat will be smaller, but the diminution will be a quantity which depends only on the nature of the gas evolved, and the substance of the electrodes. In the ideal case, then, the total amount of heat will be  $Q_1$  where—

$$Q_1 = \alpha I p t + \alpha I \theta \frac{dp}{d\theta},$$

and if  $Q$  be the thermal equivalent of the chemical actions in the cell, Pebal's conjecture is that the quantity  $Q_1 - Q$  depends only on the nature of the gas evolved and the substance of the electrodes. A table for eight electrolytes shows that  $Q_1 - Q$  is fairly constant, but its value is somewhat greater than might be at first expected.

**Bunsen's Ice Calorimeter.** By C. V. BOYS (*Phil. Mag.* [5], 24, 214—217).—In order to counteract the evil effect of ordinary ice in unduly cooling the inner ice of a Bunsen's calorimeter, the author adapts a cover to the calorimeter so as to provide a comparatively non-conducting air space between the bulb and the outer ice, and thus reduce the conduction to a minimum, this space being in the first place filled with ice-cold water, which is afterwards removed. In one case a melting = 4 mm. of the scale per hour with the cover, and of 27 mm. without, was observed. With this arrangement, the tubes of the instrument must be made longer, and a good packing of ice placed above the bulb.

H. K. T.

**New Pyrometer.** By E. H. KEISER (*Amer. Chem. J.*, 9, 296—299).—An air bulb made of hard glass or of metal and having a long capillary neck is connected by a narrow bore rubber tube with an inverted burette; this latter is placed in a wider tube containing water, and closed with a cork and stopcock at the bottom. The two halves of the apparatus having acquired the temperature of the room ( $t$ ), the water is adjusted to the zero mark and the apparatus connected together.

The value of a constant ( $c$ ) for the apparatus is determined by heating the bulb to  $100^\circ \text{C}$ ., and noting the increased volume of air ( $V$ ) in the burette, and using the formula  $t' = t + V/c - V/273 + t$ . The bulb being then heated to any other temperature ( $t'$ ) this may be calculated by the above formula.

H. B.

*Note.*—The author makes no correction for the moisture of the measured air, and takes no precautions as to the dryness or moistness of the air in the bulb.

H. B.

**Change in Volume during the Formation of Metallic Oxides.** By N. N. BEKETOFF (*Chem. Centr.*, 1887, 449—450).—The author showed previously that the combination of solid and liquid elements is generally accompanied with decrease of volume and development of heat, the latter being nearly proportional to the former. This relation, which is most striking in the case of the haloïd derivatives of the alkali metals, is also observed in the case of other oxides, the formation of which gives rise to development of heat.

|                              | MgO.    | CaO. | Li <sub>2</sub> O. | Al <sub>2</sub> O <sub>3</sub> . |
|------------------------------|---------|------|--------------------|----------------------------------|
| Atomic weight of metal ..    | 24      | 40   | 7                  | 27                               |
| Sp. gr. of metal .....       | 1·75    | 1·57 | 0·58               | 2·5                              |
| At. vol. of metal .....      | 13·7    | 25·4 | 12·0               | 10·6                             |
| At. wt. of oxygen.....       | 17·5    | 17·5 | 17·5               | 17·5                             |
| Sum of vols. of constituents | 31·2    | 42·9 | 41·5               | 73·3                             |
| Sp. gr. of oxide.....        | 3·2—3·6 | 3·2  | 1·88               | 3·8—4·0                          |
| Mol. vol. of oxide.....      | 11·7    | 17·5 | 16·0               | 26·0                             |
| Decrease of vol. per cent..  | 62·0    | 60·0 | 61·4               | 64·0                             |

The formation of all four oxides corresponds with the heat of formation, 120 to 140 cal. In the case of PbO, a diminution in volume of 31 per cent. was observed, the heat of formation being 55 Cal. When the heat of formation is known, it is possible to calculate the contraction, and from the latter the molecular weight when this is unknown.

N. H. M.

**Action of Acids on Zinc containing Lead.** By W. SPRING and E. VAN AUBEL (*Ann. Chim. Phys.* [6], **11**, 505—554).—The authors have investigated the action of hydrochloric, hydrobromic, hydriodic, and sulphuric acids on zinc containing 0·6 per cent. of lead, prepared by melting zinc with litharge. The metal was cast into cylinders 17 mm. in diameter, covered with wax in such a way that only one of the basal planes was exposed to the action of the acid. The hydrogen evolved was collected in the apparatus previously used in investigations on the action of acids on marble (*Bull. Soc. Chim.*, **47**, 927), and the volume of the gas was read off at regular intervals.

In all cases, the evolution of hydrogen is not the most rapid at the commencement of the reaction, that is, when the acid is strongest, but the velocity of the reaction increases until it reaches a maximum, and then decreases in such a way that the rate of solution is proportional to the concentration of the acid, and the portion of the curve beyond the maximum is a right line which cuts the axis of the abscissæ at a point corresponding with complete solution. The first part of the reaction, during which the rate of solution increases whilst the concentration of the acid diminishes, is abnormal, and represents a *period of induction*. If the second part of the curve is prolonged backwards, it cuts the axis of the ordinates at a point which gives the initial velocity on the assumption that there is no period of induction.

The theoretical initial velocity as thus determined increases with the volume of the acid used, the surface of zinc exposed remaining constant. Experiments show that the temperature of the zinc rises more rapidly than that of the surrounding liquid, the difference being greater the greater the mass of the liquid. This increase in the temperature of the metal of course increases the rate of solution. If the mass of the zinc varies whilst the exposed surface remains constant, the smaller the mass the higher the rate of solution, the greatest velocity being observed with spheres. This result is due to the fact that the temperature rises more rapidly in the case of the smaller masses. In the case of the more concentrated acids, spheres of zinc

were employed, and this introduces a further complication, since the area of the surface is continually diminishing as the action proceeds, and the ratio of the surface to the mass is likewise changing. The correction required is given by the expression—

$$S_1 = S_n (\sqrt[n]{n})^2.$$

Metallic zinc has no action on boiling solutions of zinc chloride.

The experiments were made at three different temperatures, 15°, 35°, and 55°, with hydrochloric acid of 5, 10, and 15 per cent., the strengths of the other acids being adjusted so that they were equivalent to the hydrochloric acid solutions.

With the three different concentrations of hydrochloric acid, the ratio of the rate of solution to the concentration of the acid is not the same in all three series when the whole period of solution is taken into account; but if the period of induction is eliminated in the manner already indicated, then the rate of solution in all cases is proportional to the concentration of the acid. For the same temperature, the theoretical initial velocities are proportional to the concentration of the acid. The slight variations of the curves from right lines are due to the differences between the temperatures of the zinc and the surrounding liquid. Measurements of the electrical resistance show that if electrical conductivity exerts any influence during the period of induction, it is without any sensible effect during the second part of the reaction. In order to ascertain the influence of electrolysis during the period of induction, zinc was immersed in hydrochloric acid of 15 per cent. at a temperature of 35°, the surface of the zinc being first covered with a thin layer of gold, platinum, lead, or copper. If the period of induction is due to electrolysis, the rate of solution during that period should vary with the electromotive force of the couple on the surface of the zinc. Possibly also, thermoelectric currents may be produced by the difference in temperature between the zinc and the surrounding liquid, or by differences between the temperatures of different parts of the metal itself. Under these conditions, the actual initial velocity is very great, but gradually diminishes until it reaches a minimum, then rises and attains a maximum, and becomes a right line, indicating that the rate of solution is proportional to the concentration of the acid. It is evident from this result that the period of induction is the time during which the acid by slow action produces at the surface of the metal an infinite number of minute galvanic couples by exposing the particles of lead which are disseminated throughout the zinc. The great diminution in the rate of solution is probably due to the fact that the liberated hydrogen removes mechanically the particles of the foreign metal which had been precipitated on the surface of the zinc. The actual velocity at the commencement of the reaction increases in the following order:—copper, gold, platinum, lead; whilst the theoretical initial velocity increases in the order, copper, lead, gold, platinum. Neither of these series follows the order of the electromotive force of the couples produced, and hence it is evident that although electrolytic action plays an important part in the solution of a metal in an acid, it is by no means the only determining cause.

No sensible variations in the rate of solution were observed when considerable quantities of sodium or potassium nitrate or sulphates were added to the liquid, and it would therefore seem that the velocity of the reaction is not greatly affected by the internal friction of the solution.

The influence of temperature is shown by a curve the ordinates of which are the initial velocities whilst the abscissæ are the temperatures. These curves seem to be asymptotic to the axis of the temperatures, and the three curves for the three different degrees of concentration of the acid converge at a point which corresponds with a temperature of  $-60^{\circ}$  to  $-70^{\circ}$ . This result seems to indicate that at a temperature below  $-70^{\circ}$  hydrochloric acid will have no action on zinc whatever the concentration of the acid, and it is of interest to recall the well-known fact that liquid hydrogen chloride, which liquefies at about  $-70^{\circ}$ , has no action on this metal.

According to Kohlrausch, the maximum conductivity of hydrochloric acid corresponds with a strength of 21 per cent. Acid of 25, 30, or 34 per cent., however, dissolves zinc more quickly than acid of 21 per cent., and from this and the previous results it is evident that the conclusion of De la Rive and of Kajander, that the rate of solution is intimately connected with the electrical conductivity of the acid, is not confirmed.

With hydrobromic acid, the rate of solution is much higher than with hydrochloric acid of corresponding concentration. Under ordinary conditions the curve is not a right line at any phase of the reaction, a result due to the fact that with an increased rate of solution the difference between the temperature of the liquid and that of the metal is much greater, and the perturbations due to this cause are greatly increased. If the conditions are such that the temperature of the zinc is kept constant, it is found that the period of induction is very short, the velocity of solution rapidly attains a maximum, and then decreases with the concentration of the solution, the latter part of the curve being a right line. It is a general result that the period of induction is shorter the greater the concentration of the acid. With hydrochloric acid of 30 per cent., for example, there is practically no period of induction, and the maximum velocity is attained at once. The theoretical initial velocity with hydrobromic acid is 2.29 times that with hydrochloric acid.

With hydriodic acid, the velocity during the period of induction is less than in the case of hydrochloric acid, and the difference is greater the weaker the acids, but after the maximum velocity is attained the rate of solution is the same for both acids, and if the curves are drawn on a small scale they coincide. It follows, of course, that the theoretical initial velocities are practically the same for both acids.

The results with the three haloïd acids are quite different from those obtained in the case of the action of the same acids on marble (*loc. cit.*), in which case the rate of solution is the same for all three. The velocity of the reaction with zinc has no simple relation to the electrical conductivity of the acids, their heats of neutralisation, or the solubilities of the salts produced.

With sulphuric acid, the action is very slow, and the rate of solu-

tion could not be measured with an acid corresponding with 10 per cent. hydrochloric acid. The period of induction lasts for several hours, and hence the metal was always previously covered with a film of precipitated lead. At 36°, the velocity is only one twenty-seventh of that observed in the case of hydrochloric acid. It is possible that the reaction is not of the same kind as with the haloïd acids. It may be that the formation of zinc sulphate in this way is almost entirely a phenomenon of electrolysis, and that the chemical attraction of the acid for the metal is not the determining cause as with the haloïd acids. In the latter case, there is simple substitution of the metal for the hydrogen of the acid, whilst the formation of zinc sulphate may be the result of a series of reactions, such as  $\text{Zn} + \text{H}_2\text{SO}_4 = \text{ZnO} + \text{H}_2 + \text{SO}_3$ ;  $\text{SO}_3 + \text{H}_2\text{O} + \text{Aq} = \text{H}_2\text{SO}_4 + \text{Aq}$ ;  $\text{ZnO} + \text{H}_2\text{SO}_4 = \text{ZnSO}_4 + \text{H}_2\text{O}$ .

Pure zinc, rubbed on the surface with metallic lead, does not dissolve in acids with a velocity similar to that of zinc alloyed with lead, or zinc covered with lead by precipitation. The black residue left on solution of the zinc containing lead is pure lead. The difference in the electromotive force in these cases may be due to the state of division of the lead, or possibly the black substance is an allotropic modification of the lead. If pure zinc is rubbed with this lead-black by means of a spatula, it becomes more soluble in acids. Mercury amalgamates and dissolves the lead-black, and this is probably the reason why amalgamated zinc is not soluble in acids. d'Almeida's view that amalgamated zinc is as soluble as ordinary zinc, but has the property of condensing on its surface a layer of hydrogen which protects it from the acid, is not supported by any evidence.

C. H. B.

*Note by Abstractor.*—L'Hôte has recently shown that perfectly pure zinc does not decompose water, and is not soluble in acids (Abstr., 1886, 204). According to Osmond and Werth (this vol., p. 894), impure zinc when dissolved in acids leaves graphitoidal residues of complicated composition. In one case the composition of the residue agreed with the formula  $\text{Pb}_2\text{Zn}$ .

C. H. B.

**Integral Weights in Chemistry.** By T. S. HUNT (*Phil. Mag.* [5], 24, 318—324).—The specific gravity of a gaseous body, as compared with hydrogen at normal temperature and pressure, is termed its integral weight. In the same way, the integral weights of liquid and solid substances are represented by the specific gravities of these substances as compared with hydrogen at normal pressure, and at the temperatures at which they are generated from the gaseous or liquid states respectively. Thus the density of water at 100° is 0.95878, hence 1628 vols. of steam at 100° condense to 1 vol. of water at 100°; this value multiplied by 17.9633, gives 29244 as the integral weight of water. From this value, the integral weights of other substances are determined, their specific gravities at their changing point being taken, as compared with water at 100°. The specific gravities so obtained would not deviate much from those obtained at 4°. The coefficient of condensation is obtained by dividing the integral weight of the more complex body by that of the simpler one from which it is derived.

H. K. T.

## Inorganic Chemistry.

**Combustion of Weighed Amounts of Hydrogen ; Atomic Weight of Oxygen.** By E. H. KEISER (*Ber.*, **20**, 2323—2325).—Palladium was weighed with and without occluded hydrogen, it was then heated, and the hydrogen thus expelled passed over heated copper oxide. The water which was formed was also weighed. 1·5935 grams of hydrogen (from three experiments) gave 14·23972 grams of water. The atomic weight of oxygen calculated from these numbers is 15·872. The number obtained from Stas's figures is 15·84 (Ostwald, *Allgem. Chem.*, **1**, 43). The author intends repeating the experiments with large amounts of palladium. N. H. M.

**Composition of Generator-gas and Water-gas.** By F. FISCHER (*Ber.*, **20**, 2551—2553).—The following results are given :—

|                       | Generator-gas from |        | Water-gas from<br>Essen. |
|-----------------------|--------------------|--------|--------------------------|
|                       | Coal.              | Wood.  |                          |
| CO <sub>2</sub> ..... | 5·06               | 6·95   | 2·71                     |
| CO .....              | 21·58              | 28·60  | 43·75                    |
| CH <sub>4</sub> ..... | 2·91               | 2·20   | 0·31                     |
| H .....               | 5·66               | 8·54   | 49·17                    |
| N .....               | 64·79              | 53·71  | 4·06                     |
|                       | 100·00             | 100·00 | 100·00                   |

The analyses were made in a special apparatus, which, however, presents no very novel features. W. P. W.

**Tellurium Dichloride.** By A. MICHAELIS (*Ber.*, **20**, 2488—2492).—Tellurium dichloride melts at about 175°, and boils constantly at 324°. The vapour-density was determined in an atmosphere of nitrogen at the temperature of boiling sulphur, and the following values were obtained: 6·9, 6·6, 7·0, compared with 6·89, the value calculated for TeCl<sub>2</sub>; moreover, there is no indication that the vapour has a greater density at lower temperatures. The vapour of the dichloride is dull red in colour, and gives a characteristic absorption-spectrum (Gernez, this Journal, 1872, 665), in which the bands, whose positions on an arbitrary scale are given, lie between Fraunhofer's lines *b* and *C*. When heated in an open tube, the vapour of the dichloride becomes brighter in colour, and finally assumes a pure yellow. This change in colour is accompanied by the disappearance of the absorption-bands, and is due to the oxidation of the dichloride when heated in air, since the compound when heated in a current of oxygen is converted into a mixture of tellurium tetrachloride and tellurium dioxide, together

with the oxychloride  $\text{TeOCl}_2$ , if the heating is continued for some time. The vapour of the tetrachloride is yellow, and gives no absorption-spectrum, a fact which confirms the point brought out in the vapour-density determinations (this vol., p. 770), that the compound is stable, and does not decompose into chlorine and the dichloride when vaporised.

W. P. W.

**Working-up of Stassfurt Potash Liquors containing a Large Excess of Sodium Chloride.** By H. FISCHER (*J. pr. Chem.* [2], **36**, 222—224).—Boiling water dissolves much more potassium chloride and sulphate but hardly any more sodium chloride than cold water. Potassium sulphate and potassium magnesium sulphate are less soluble in cold water than potassium and sodium chlorides; and finally the presence of magnesium chloride reduces the solubility of all the above salts except potassium chloride.

Advantage is taken of these relationships to isolate potassium chloride from saline solutions containing but little of this substance. End-liquors (rich in magnesium chloride) are added until the solution contains about a quarter as much magnesium chloride as sodium chloride, and the whole is then concentrated. Sodium chloride separates out first, and then potassium sulphate and potassium magnesium sulphate, potassium chloride remaining dissolved.

L. T. T.

**Crystalline Form of Potassium Aurobromide.** By P. SCHOTTLÄNDER (*Annalen*, **240**, 346—348).—Potassium aurobromide crystallises in the monoclinic system.

$$a : b : c = 0.79688 : 1 : 0.3610 \quad \beta = 85^\circ 34' 2''.$$

W. C. W.

**Analysis and Properties of Phosphorised Silver.** By H. N. WARREN (*Chem. News*, **56**, 113).—When phosphorus is added to molten silver, the metal on cooling ejects the phosphorus; it however retains sufficient to give the silver a yellow colour, and to prevent it from spitting. The amount retained seldom exceeds 0.002 per cent. of phosphorus, but this is exceedingly difficult to expel by cupellation.

D. A. L.

**v. d. Pfordten's Silver Suboxide.** By C. FRIEDHEIM (*Ber.*, **20**, 2554—2557).—The composition of the so-called silver suboxide prepared by v. d. Pfordten (this vol., p. 699) was determined by titration with permanganate, which is stated in the paper to be without action on metallic silver. The author, however, finds that when very finely divided ("molecular") silver suspended in water acidified with dilute sulphuric acid (1 : 5) is titrated with permanganate, the colour disappears as in oxalic acid titrations, slowly at first, then more quickly, and silver goes quantitatively into solution. Experiments made simultaneously with similar quantities of materials show that solution of the metal does not occur in the mixture of silver and sulphuric acid, and that the permanganate is not decolorised when added to the sulphuric acid. Moreover, compact silver is also attacked by permanganate acidified with dilute sulphuric acid; thus in an experiment with 1.5 grams of silver foil, 1 gram was dissolved when shaken for

two hours with the acidified permanganate, and brown flocks of what seems to be a compound of silver oxide with a higher oxidation product of manganese were simultaneously formed.

Following v. d. Pfordten's directions in every particular, a substance was prepared which, to judge from the published description, was identical with the so-called silver suboxide. On titration with permanganate, however, the ratio  $\text{Ag} : \text{O} = 2 : 1$  was obtained, and further, the volume of the gas not absorbed by aqueous soda which was given off when the substance, after careful drying in an atmosphere of carbonic anhydride, was slowly heated to bright redness was so small that the preparation must have been silver in an almost pure state; moreover, on dissolving the ignited silver in an acid, a residue of carbon was left. These facts lead the author to the conclusion that v. d. Pfordten's silver suboxide is nothing more than finely divided silver rendered impure by the presence of more or less silver oxide or organic substances.

W. P. W.

**Basic Zinc and Cadmium Nitrates.** By H. L. WELLS (*Amer. Chem. J.*, **9**, 304—308).—By treating zinc or cadmium nitrate in hot solution with the oxides, and allowing it to cool, crystals of the basic salts,  $2\text{ZnO}, \text{N}_2\text{O}_5, 3\text{H}_2\text{O}$  or  $2\text{CdO}, \text{N}_2\text{O}_5, 3\text{H}_2\text{O}$ , separate, the first in thin scales, the second in needles. Both are decomposed by washing with water, and must therefore be purified by washing with absolute alcohol. The basic salts previously described have been prepared by heating the normal nitrates, or by treating them with ammonia; none of these were washed with alcohol.

H. B.

**Basic Lead Nitrates.** By A. J. WAKEMAN and H. L. WELLS (*Amer. Chem. J.*, **9**, 299—303).—Besides the basic lead nitrate  $\text{NO}_3 \cdot \text{Pb} \cdot \text{OH}$ , the following salts have been described:—

$6\text{PbO}, 2\text{N}_2\text{O}_5, 3\text{H}_2\text{O}$ , Berzelius and Meissner;  $6\text{PbO}, 2\text{N}_2\text{O}_5, \text{H}_2\text{O}$ , Meissner, Löwe, and Smolka;  $6\text{PbO}, 2\text{N}_2\text{O}_5, 2\text{H}_2\text{O}$ , Löwe;

Volge;  $10\text{PbO}, 3\text{N}_2\text{O}_5, 5\text{H}_2\text{O}$ , Smolka and Morawski.

The first salt is prepared without difficulty, but the others prove to be incapable of recrystallisation, or to be mixtures, or to have been imperfectly analysed, the only other recrystallisable basic salt being  $10\text{PbO}, 3\text{N}_2\text{O}_5, 4\text{H}_2\text{O}$ . This substance forms flat, tabular crystals of triclinic habit, with an extinction angle of  $35^\circ$ ; it is less soluble than the diplumbic nitrate, and suffers no change by boiling with water or on recrystallisation. All the preparations were examined microscopically, and all mixtures rejected.

H. B.

**Relations of Mercury to other Metals.** By A. C. COUSINS (*Chem. News*, **56**, 113—114).—Attention is drawn to the following coincidences:—The atomic weight of mercury is the mean of the atomic weights of gold and thallium. Its sp. gr. in the liquid state is very nearly the mean of their atomic volumes. Its atomic volume is almost the theoretical sp. gr. of an alloy of equal weights of gold and thallium.

D. A. L.

**Gallium.** By L. DE BOISBAUDRAN (*Ann. Chim. Phys.* [6], **11**, 429—430).—Gallium chloride twice evaporated to dryness and dried at  $100^{\circ}$  loses by volatilisation about 0.6 per cent. of gallium. The amount of volatilisation from a hydrochloric acid solution of gallium chloride heated gradually to redness in presence of sulphuric acid, cannot be recognised with 0.08 gram of the chloride. C. H. B.

**Metallic Manganese.** By T. T. P. B. WARREN (*Chem. News*, **56**, 27).—The author found that a sample of manganese he examined was either non-magnetic or only very slightly magnetic. It contained a small quantity of petroleum, which probably affected its magnetic properties. D. A. L.

**Compound of Manganese Sesquioxide with Cupric Oxide.** By E. A. SCHNEIDER (*Amer. Chem. J.*, **9**, 269—274).—Although many compounds of sesquioxides and protoxides are known, none have been prepared in which manganese sesquioxide plays the part of an acid oxide, and only two have been prepared in which copper oxide plays the part of a basic oxide, namely the compounds  $\text{CuO}, \text{Fe}_2\text{O}_3 + 5\text{H}_2\text{O}$  and  $\text{CuO}, \text{Cr}_2\text{O}_3$ , and none in which silver oxide or mercuric oxide act in a similar manner.

An ammoniacal cupric oxide solution is mixed with aqueous soda, and to the deep blue solution aqueous manganous chloride is added, best drop by drop, with constant stirring. If the copper oxide and manganic oxides are used in the molecular ratio 1 : 1 or 2 : 1, the whole of the copper is at once removed, but with the ratios 3 : 1 or 4 : 1 or 5 : 1 a portion of the copper remains in solution. The black precipitate thrown down in each case seems to have the composition  $\text{Mn}_2\text{O}_3, 3\text{CuO}$ , although when an excess of copper solution is not used the precipitate approximates more towards  $\text{Mn}_2\text{O}_3, 2\text{CuO}$ . The oxidation is effected by atmospheric air. H. B.

**Peculiar Formation in Nickel Regulus.** By T. MOORE (*Chem. News*, **56**, 3).—On allowing a molten nickel regulus to cool slowly, brilliant flakes separated out, of a symmetrical form, and very ductile and malleable. These flakes had the following composition:—(a.) Cu, 160; Ni, 70.30; Fe, 28.30. (b.) Cu, 0.25; Ni, 87.863; Fe, 11.865 per cent. Regulus (a) contained 13.5 per cent. Fe; (b), 15.6. By the exclusion of copper, flakes were obtained composed of 86.40 per cent. Ni with 13.72 Fe, the surrounding regulus containing Ni, 72.10; Fe, 2.32; S, 25.51; whilst the regulus cooled suddenly to prevent formation of flakes had per cent., Ni, 73.80; Fe, 4.27; S, 22.01. It is curious to note the formation of such an alloy, and especially a malleable alloy, in the presence of sulphur. Under favourable conditions, the regulus may contain 10 per cent. of this alloy.

D. A. L.

**Germanium.** By C. WINKLER (*J. pr. Chem.* [2], **36**, 177—209).—In the present communication, the author details the further progress of his researches (Abstr., 1886, 985) on germanium. The investigation of this element is rendered difficult, as the argyrodite vein in the Himmelsfurt Mine is exhausted, and the quantity of

argyrodite in hand is small; this mineral is mainly found as a thin coating over other silver ore, the percentage of germanium in some of the richest ores being only about 0.03 per cent. Slight variations in the mode of extracting the element from the ore from those previously given (*loc. cit.*) are described. The sparing solubility of potassium germaniofluoride may also be employed for this purpose. Powdered argyrodite is mixed with nitre and potassium carbonate, and the mixture introduced in small quantities into a red-hot Hessian crucible. On cooling, two layers are obtained, the lower of silver, the upper of alkali salts. The upper layer, containing all the germanium, is powdered, boiled in water, and the filtered solution treated with excess of sulphuric acid and evaporated to dryness. This acid residue is then dissolved in cold water, when almost all the germanium oxide is gradually deposited from the solution. The remaining germanium is precipitated by hydrogen sulphide, and the sulphide converted into oxide by treatment with nitric acid. The oxides are mixed, dissolved in aqueous hydrofluoric acid, and filtered if necessary; potassium fluoride is added, and the double fluoride separates out. This fluoride is then converted into soluble thio-salt by fusion with potassium carbonate and sulphur, or by digestion with ammonium sulphide, this is decomposed by sulphuric acid, and the germanium precipitated as sulphide with hydrogen sulphide. This sulphide, when mixed with a little sulphuric acid and gently heated, yields a mixture of sulphide and oxide, which is converted into oxide by roasting and treatment with nitric acid. The oxide may be reduced by hydrogen, but if at all in large quantity the following method is preferable:—The powdered oxide is mixed with about 15 to 20 per cent. of starch, and kneaded with a little boiling water into small balls, which are dried at a low heat. These are introduced into crucibles between layers of powdered charcoal, and the whole kept at a bright red heat for about an hour. In this way, a somewhat porous regulus of germanium is obtained, which may be fused with powdered borax glass, and so obtained as a brittle, metallic bead.

When germanium is gently heated in a current of hydrogen chloride, the metal becomes red-hot, hydrogen is evolved, and two liquids of almost identical specific gravity are formed. After some time these separate into two layers. The heavier is the colourless, thin liquid boiling at 72°, previously described (*loc. cit.*) as possibly germanious chloride. Analysis, however, showed it to be *germanium chloroform*,  $\text{GeHCl}_3$ . It is very easily oxidised in contact with air, apparently yielding the oxychloride, and at a high temperature seems to break up according to the equation  $2\text{GeHCl}_3 = \text{Ge} + \text{GeCl}_4 + 2\text{HCl}$ . A vapour-density determination made by Victor Meyer's method at 178° gave 5.55, theory requiring 6.21. The second liquid is *germanium oxychloride*,  $\text{GeOCl}_2$  (?). It is a colourless, non-fuming, oily liquid, which adheres strongly to glass. It boils much above 100°, seemingly without decomposition, but has not yet been obtained quite pure. The author hopes to obtain germanious chloride by heating germanious sulphide in an atmosphere of hydrochloric acid. Germanic chloride (*loc. cit.*) may be obtained by heating a mixture of germanic sulphide and mercuric chloride. It remains liquid at  $-100^\circ$ . *Germanic bromide*,

$\text{GeBr}_4$ , may be prepared either by heating germanium in bromine vapour, or by heating the powdered metal with mercuric bromide. It is a strongly fuming, colourless liquid, which solidifies a little below  $0^\circ$  to a white, crystalline mass. When poured into water, heat is evolved and germanium oxide precipitated.

Germanious oxide dissolves in strong, aqueous hydrofluoric acid to a clear solution; this, on evaporation over sulphuric acid, yields *germanic fluoride*,  $\text{GeF}_4$ , as a colourless liquid, which gradually solidifies to a crystalline mass of the formula  $\text{GeF}_4 + 3\text{H}_2\text{O}$ . It is very deliquescent, and cannot be kept in glass vessels, as it attacks their surfaces. It melts readily in its water of crystallisation, but when more strongly heated hydrogen fluoride and moisture are evolved, and a pellicle of oxide forms. If it is heated to redness, much germanic fluoride is volatilised, about half of the germanium present being left as oxide. Pure anhydrous germanic fluoride has not yet been obtained, but the behaviour of its hydrated compound leaves little doubt that it is a solid, but is also volatilisable. Further experiments as to the action of (1) hydrogen on heated potassium germanium fluoride; (2) of hydrated germanic fluoride heated in a current of carbonic anhydride; (3) of a mixture of germanium oxide, calcium fluoride, and sulphuric acid when heated; and (4) of heat on a mixture of sulphuric acid and potassium germaniofluoride, all point to the same conclusion. The opposite results obtained by Krüss and Wilson (this vol., p. 704) are probably due to the smallness of the quantities of fluoride with which they experimented, being especially favourable to the decomposition into oxide. When the vapours of germanic fluoride are passed into water, a solution of germanic oxide (or acid) and of *hydrofluogermanic acid*,  $\text{H}_2\text{GeF}_6$ , is formed; the latter appears to be volatile at ordinary temperatures, but its boiling point seems to lie slightly above that of water. The acid has not, however, yet been obtained in the pure state. The potassium salt has already been described by Krüss and Nilson. It is best obtained by treating a solution of the oxide in hydrofluoric acid with potassium chloride. One part of this salt requires about 180 parts of water at  $18^\circ$ , or about 36 at  $100^\circ$ , for its solution. The salt stands a dull red heat without change, but melts at a bright red heat, and at a still higher temperature loses weight considerably. These results differ from those obtained by Krüss and Nilson (*loc. cit.*).

*Germanic ethide*,  $\text{GeEt}_4$ , was prepared by mixing together zinc ethide and germanic chloride. The reaction took place with violence, and cooling was necessary. This compound forms a colourless liquid of slightly alliaceous odour. It is very slightly lighter than water, with which it is not miscible; it boils at  $160^\circ$ , but is slowly volatile even at ordinary temperatures. Germanic ethide is not affected by oxygen at ordinary temperatures, but inflames easily, and then burns with a yellowish-red flame and formation of white fumes of oxide. Its vapour-density, as determined in Victor Meyer's apparatus, is 8.50, theory requiring 6.51. The author is unable to explain the discrepancy. No hydrogen-derivative of germanium has yet been obtained.

Germanium appears to be capable of replacing silicon in ultra-

marine. If a mixture of soda and sulphur is heated in a crucible used for roasting germanium sulphide, a blue colour is produced, but the author has not yet succeeded in obtaining a true germanium ultramarine.

The above results agree very closely with the properties predicted by Mendelejeff for ekasilicon, especially those for the ethide, for which he predicted a sp. gr. of 0.96 and boiling point of 160°. L. T. T.

**Separation of Gold from the Platinum Metals.** By W. BETTEL (*Chem. News*, 56, 133—134). The author severely criticises Hoffmann and Krüss's paper on this subject. With regard to the sulphurous acid method, it answers well but, on account of the sulphuric acid produced, only for moderate quantities of gold. The results are affected by dilution, temperature, and especially acidity; if too acid, the gold is not completely precipitated, if too neutral traces of platinum come down, but at the proper stage all the gold present is precipitated of a purity of 999.9 to 1000. It is, however, customary to remove platinum as double chloride, and estimate gold in the solution. It is noted that tests made with solutions of gold and platinum are not of much practical use, since the commercial alloys as a rule contain many other substances besides gold and platinum. The author finds the oxalic acid method excellent, and has also used formic acid and formates with success. Hoffmann and Krüss neglected to neutralise the gold solution, and did not provide against loss by the evolution of carbonic anhydride; consequently they obtained low results with the oxalic acid method. These two experimenters, moreover, found that gold precipitated by ferrous chloride was platiniferous, a statement characterised by the author as grossly misleading and inaccurate; he moreover, from considerable experience, confidently affirms the contrary to be the case. D. A. L.

---

## Mineralogical Chemistry.

---

**Antimonite from Valdagno.** By E. LUZZATTO (*Zeit. Kryst. Min.*, 13, 303—304).—The antimonite from S. Quirico, near Valdagno, occurs in fibrous, laminated masses between quartz and dolomite. It is associated with kermesite, volgerite, and cervantite (?), products of its alteration. Analysis gave the following results:—

| S.    | Sb.   | Pb.  | Fe.  | Total. |
|-------|-------|------|------|--------|
| 27.63 | 69.61 | 1.84 | 0.30 | 99.38  |

B. H. B.

**Tellurium-silver-bismuth from Jalisco, Mexico.** By C. F. DE LANDERO (*Zeit. Kryst. Min.*, 13, 320).—The author deals with the ore introduced by A. del Castillo as tapalpite and described by Rammelsberg as tellurium-bismuth-silver, from the mines of the Sierra de Tapalpa, Jalisco, Mexico. At the San Antonio mines, the

mineral occurs in association with quartz grains and iron pyrites crystals, cemented together by talc. No crystals were observed, the ore forming irregular, finely granular masses with a splintery fracture. It is of a silver-white to steel-grey colour. On fresh fractures, a brilliant, metallic lustre is exhibited. The hardness of the ore is from 2 to 3, and its specific gravity 7.395. Qualitative analysis gave bismuth, silver, sulphur, and tellurium. B. H. B.

**Minerals from the Stassfurt Salt Mines.** By O. LUEDEKE (*Zeit. Kryst. Min.*, **13**, 289—293).—*Picromerite*. This mineral was first discovered in 1855 by Scacchi at Vesuvius. It has subsequently been found in the Ascherleben and Leopoldshall salt mines near Stassfurt. In chemical composition, it corresponds with the formula  $\text{MgSO}_4, \text{K}_2\text{SO}_4 + 6\text{H}_2\text{O}$ . It crystallises in the monoclinic system, the axial ratio being  $a : b : c = 0.7425 : 1 : 0.4965$ ;  $\beta = 74^\circ 52'$ .

*Bloedite*.—Crystals of bloedite have recently been discovered at the von der Heydt and Leopoldshall mines. Analysis of this mineral from the latter locality gave:—

| $\text{MgSO}_4$ . | $\text{Na}_2\text{SO}_4$ . | $\text{H}_2\text{O}$ . |
|-------------------|----------------------------|------------------------|
| 36.13             | 42.90                      | 21.07                  |

These results correspond with the formula  $\text{MgSO}_4, \text{Na}_2\text{SO}_4 + 4\text{H}_2\text{O}$ .

The author also gives descriptions of crystals of rock salt, of kainite, and of pinnoite (*Abstr.*, 1884, 1271; 1885, 1117) from the Stassfurt mines. B. H. B.

**Ignatieffite, a New Variety of Aluminite.** By K. K. FLUG (*Zeit. Kryst. Min.*, **13**, 306—307).—This mineral was sent by Count N. P. Ignatieff for analysis in the Russian Government Laboratory. It was found in the Bachmut district of the Government of Ekaterinoslav, South Russia, occurring in the form of white, reniform concretions lying in white sand. Analysis gave the following results:—

| $\text{H}_2\text{O}$ . | $\text{SiO}_2$ .        | $\text{Al}_2\text{O}_3$ . | $\text{SO}_3$ .        | $\text{P}_2\text{O}_5$ . | $\text{FeO}$ . | $\text{CaO}$ . | $\text{MgO}$ . |
|------------------------|-------------------------|---------------------------|------------------------|--------------------------|----------------|----------------|----------------|
| 0.45                   | 3.33                    | 36.39                     | 30.57                  | 3.83                     | 0.32           | 1.40           | 0.23           |
|                        |                         |                           |                        |                          |                |                |                |
| $\text{K}_2\text{O}$ . | $\text{Na}_2\text{O}$ . | C.                        | $\text{H}_2\text{O}$ . | Total.                   |                |                |                |
| 6.37                   | 2.89                    | 1.50                      | 12.72                  | 100.00                   |                |                |                |

These results show that the new mineral resembles aluminite or loewigite. The author is of opinion that the mineral may be of practical importance, as, on account of its low percentage of iron, it is adapted, like bauxite, for the preparation of aluminium sulphate.

B. H. B.

**A Mineral associated with the Columbite of the Val Vigizzo.** By A. PICCINI (*Zeit. Kryst. Min.*, **13**, 302).—The crystallised substance examined, resembles externally the columbite of the same locality, Craveggia in the Val Vigizzo (*Abstr.*, 1885, 732). The powder is brown with a specific gravity of 5.7. On ignition, it does not change in colour, and loses but little weight. The proportion of

metallic anhydrides is much less in this mineral than in columbite, and consists for the most part of tantalic anhydride, with a considerable quantity of titanitic anhydride and a small quantity of niobic anhydride. The bases are principally the cerite and gadolinite earths, a small quantity of ferrous oxide, less manganous oxide, with appreciable quantities of thorium. In columbite, on the other hand, large amounts of ferrous and manganous oxides are found, with traces only of the rare earths. The mineral examined is consequently not columbite, but rather a tantalate of the rare earths, of which the composition would be the same as that of samarskite were the niobic acid not replaced by tantalic acid. B. H. B.

**The Peridote of Schaelinger Matten.** By A. KNOP (*Zeit. Kryst. Min.*, **13**, 236—241).—A yellow mineral occurring in the limestone of Schelinger Matten in the Kaiserstuhl was described by H. Fischer in 1865 as monticellite. The mineral, which may be termed peridote, occurs in association with magnoferrite, koppite, apatite, and barytobiotite. On the crystals, the forms  $\infty P_2$ ,  $\infty P$ ,  $\bar{P}_2$  were observed. An analysis of carefully purified mineral gave the following results (I):—

|     | SiO <sub>2</sub> . | MgO.  | FeO. | MnO. | CaO. | Total. |
|-----|--------------------|-------|------|------|------|--------|
| I.  | 41·88              | 49·83 | 4·56 | 1·73 | 0·00 | 98·00  |
| II. | 42·41              | 53·30 | 2·33 | —    | —    | 98·04  |

In the analysis (I), a small quantity of alumina was found, but not weighed. The results of the analysis and of the crystallographical examination indicate that this variety of peridote is forsterite. An analysis (II) of that mineral from Monte Somma is added for comparison. B. H. B.

**Glaucophane.** By B. KOTO (*Chem. Centr.*, 1887, 391—392).—Lavender-coloured glaucophane occurs in large amount in the Island of Shikotu, together with iron epidote, yellowish-green garnet, and manganese epidote. Analysis gave following numbers:—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | FeO. | CaO. | MgO. | Na <sub>2</sub> O. | K <sub>2</sub> O. |
|--------------------|----------------------------------|----------------------------------|------|------|------|--------------------|-------------------|
| 56·71              | 15·14                            | 7·98                             | 4·31 | 4·80 | 4·33 | 4·83               | 0·25              |

Sp. gr. = 2·991. Secondary glaucophane from augite minerals is more frequent. The transformation of pyroxene into blue hornblende and the formation of glaucophane is seen in various stages with formation of more or less glaucophane asbestos. N. H. M.

**Altered Cordierite from Rocca Federighi in Tuscany.** By E. SCACCHI (*Zeit. Kryst. Min.*, **13**, 297).—This altered product is found in liparite in the form of opaque, greyish-green columns 3 to 5 mm. in length. The axial ratio is  $a : b : c = 0·58007 : 1 : 0·55890$ . Analysis gave the following results:—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | CaO. | MgO. | H <sub>2</sub> O. | Total. |
|--------------------|----------------------------------|----------------------------------|------|------|-------------------|--------|
| 49·62              | 27·41                            | 8·89                             | 3·95 | 1·25 | 8·43              | 99·55  |

The specific gravity is 1·616. This product of the alteration of cordierite is evidently pinite. B. H. B.

**Composition of Rocks and Minerals from Vulture and Melfi.** By L. RICCIARDI (*Gazzetta*, 17, 214—225).—The Vulture is an extinct volcano forming the principal centre of eruptions, probably prehistoric, situated in Apulia; subsidiary craters are Braida and Melfi, the latter of which has been the centre of several disastrous earthquakes. In the paper, a series of analyses are given of the rocks and minerals from the Vulture as also of Melfi. The eruptive material of the former consists principally of cinerea and augite, beside which are found crystals of black mica, leucite, and magnetite, and titaniferous ironstone; on the summit oolite is found. The volcano of Melfi is in all probability a centre of eruption independent of that of the Vulture; the minerals are somewhat similar, although the analyses of the lava and tufa show marked differences. The author agrees with the conclusions of Palmieri and Scacchi, in considering that the three volcanic regions of the Campania, namely, of the Monte di Somna, together with Vesuvius, the region of the Flogrea, and the Roccamontine district, in which the above volcanos are situated, form distinct centres, each with their peculiar characteristics.

**Meteorite from Angra dos Reis.** By E. LUDWIG and G. TSCHERMAK (*Chem. Centr.*, 1887, 647).—The meteorite which fell at Angra dos Reis, a town on the coast in the province of Rio, Brazil, belongs to a small group of meteorites rich (93·28 per cent.) in augite; small quantities of olivine and of magnetic oxide of iron are also present. The specimen was of sp. gr. 3·43, but not very coherent. The augite had the following composition:—

| SiO <sub>2</sub> . | Al <sub>2</sub> O <sub>3</sub> . | Fe <sub>2</sub> O <sub>3</sub> . | FeO. | MgO. | CaO.  | Na <sub>2</sub> O. | K <sub>2</sub> O. |
|--------------------|----------------------------------|----------------------------------|------|------|-------|--------------------|-------------------|
| 42·72              | 8·84                             | 2·47                             | 6·88 | 8·95 | 22·37 | 0·26               | 0·19              |

According to Rose's classification of meteorites, the specimen is akin to howardite and eukrite, differing, however, from both by the chemical and physical properties of the augite, as also from the former by the presence of olivine, and from the latter by the absence of plagioclase.

V. H. V.

**Flitwick Water.** By W. JOHNSTONE (*Analyst*, 12, 90—92).—This water rises through a bed of ferruginous peat on Flitwick Moor. It appears to result from the percolation of rain-water through the ferruginous sands and peat of the district, until stopped by the Oxford clay forming the floor of the valley. A sample collected in May, 1885, contained in 1000 parts:—

|   |        |
|---|--------|
| Ammonium oxide .....                    | 0·1144 |
| Calcium oxide .....                     | 0·0640 |
| Magnesium oxide.....                    | 0·0511 |
| Ferric oxide.....                       | 1·2212 |
| Alumina .....                           | 0·0044 |
| Cupric oxide.....                       | 0·0075 |
| Manganous oxide.....                    | 0·0014 |
| Potassium oxide .....                   | 0·0024 |
| Sodium oxide .....                      | 0·0211 |
| Chlorine .....                          | 0·0340 |
| Sulphuric acid (SO <sub>3</sub> ) ..... | 1·7328 |
| Silica.....                             | 0·2328 |
| Organic matter .....                    | 1·2753 |
|   | <hr/>  |
|   | 4·7624 |

Specific gravity at 15·5° = 1·0041.

About two-thirds of the iron is as ferric sulphate; the remainder is in combination with organic acids. The composition is not constant, ferrous as well as ferric salts being sometimes present. When exposed to the air, it deposits a tufaceous bog-iron ore. M. J. S.

## Organic Chemistry.

**Detection of certain Hydrocarbons in Alcohols.** By H. N. WARREN (*Chem. News*, 56, 64).—A sample of wood-naphtha saturated with calcium chloride and fractionated, yielded a fraction boiling at 160—180°, which assumed a fine blood-red colour on the addition of an alkali, baryta with soda being the best for the purpose. This substance was also detected in several samples of light petroleum, methyl amyl and other alcohols, and amongst the products of the action of chlorine on coal-gas. It has not been further examined.

D. A. L.

**Ethyl Isobutyl Ether.** By A. MEISSLER (*Chem. Centr.*, 1887, 479).—Ethyl isobutyl ether is contained in that fraction of the product of the action of alcoholic potash on isobutyl bromide which boils at 60—115°. Sodium dissolved in ethyl alcohol also acts on isobutyl chloride, but much more slowly than in the case of the bromide.

N. H. M.

**So-called Allyl Trisulphide.** By R. NASINI and A. SCALA (*Gazzetta*, 17, 236—240).—In the course of the action of sodium amalgam on a mixture of ethyl iodide and carbon bisulphide, Löwig and Scholz (*J. pr. Chem.*, 79, 441) obtained a liquid of disagreeable odour, to which they ascribed the formula C<sub>6</sub>H<sub>10</sub>S<sub>3</sub>, or (C<sub>3</sub>H<sub>5</sub>)<sub>2</sub>S<sub>3</sub>, regarding it as an allyl-derivative. Their results have not at present been controverted, although several writers of manuals have doubted

the validity of their conclusions. Accordingly, the authors have repeated the experiments, and find that provided all the materials and containing vessels are dry, the only reaction occurring is that between the sodium amalgam and the ethyl iodide; in the presence of moisture, however, a product is obtained similar to that obtained by Löwig and Scholz. Analysis points to a formula,  $C_5H_{10}S_3$ , or that of diethyl trithiocarbonate,  $CS(SEt)_2$ ; this substance when heated slowly is decomposed into ethyl sulphide and carbon bisulphide; but if heated more rapidly it turns brown at  $180^\circ$ , beginning to distil with decomposition; the greater part, however, distils at  $240^\circ$ , as noted by Schweizer, Debus, and other observers.

V. H. V.

**Ethereal Oil of Allium Ursinum.** By F. W. SEMMLER (*Annalen*, **241**, 90—150).—The ethereal oil of *Allium ursinum* consists essentially of vinyl sulphide, but it also contains polysulphides of vinyl and minute quantities of a mercaptan and aldehyde. Vinyl sulphide is freed from admixture with these substances by the action of metallic potassium. It is a volatile liquid boiling at  $101^\circ$ . Its sp. gr. is 0.9125. Its odour resembles that of allyl sulphide. By the action of dry oxide of silver on the sulphide, vinyl oxide,  $(C_2H_3)_2O$ , is obtained, but it could not be completely separated from unaltered sulphide. The oxide boils at  $39^\circ$ . If moist oxide of silver is substituted, vinyl alcohol,  $C_2H_3 \cdot OH$ , is formed, which at once changes into acetaldehyde.

On oxidation with nitric acid, potassium permanganate, or chromic acid, vinyl sulphide splits up, yielding sulphuric and oxalic acids and carbonic anhydride. When a concentrated alcoholic solution of mercuric chloride is cautiously added to an alcoholic solution of vinyl sulphide, crystals are suddenly deposited. If the mercuric chloride is added too rapidly and in excess, the crystals will only separate after diluting the solution with water. If too much water is added, a voluminous, amorphous precipitate will be produced. The crystalline compound is soluble in absolute alcohol. Its formation is represented by the following equation:  $2(C_2H_3)_2S + 2HgCl_2 = 2C_2H_3Cl, HgCl_2, (C_2H_3)_2S, HgS$ . Allyl sulphide forms an analogous compound with mercuric chloride. If these mercury compounds are heated with potassium thiocyanate, the thiocarbimides of allyl and vinyl respectively are produced.

The precipitate deposited on mixing alcoholic solutions of vinyl sulphide and platinum chloride is analogous in composition to the allyl compound described by Wertheim. Its formation is represented thus:  $3(C_2H_3)_2S + 2PtCl_4 = 4C_2H_3Cl, PtCl_4, (C_2H_3)_2S, PtS_2$ . With silver nitrate, vinyl sulphide forms a double salt,  $(C_2H_3)_2S, 2AgNO_3$ , analogous to the allyl sulphide compound. It melts about  $87^\circ$ , and turns yellow when treated with water. Vinyl sulphide absorbs bromine, forming the compound  $(C_2H_3Br_2)_2SBr_2$ , which boils with decomposition at  $195^\circ$ .

W. C. W.

**Formation and Properties of Inosite and its Occurrence in the Vegetable Kingdom.** By R. FICK (*Chem. Centr.*, 1887, 452—453).—Inosite is prepared by treating the fresh plant material with hot alcohol, and keeping the whole in a closed vessel in a warm

place for several days. The alcoholic solution is then separated, distilled, and the small aqueous residue purified by means of lead acetate, precipitated with basic lead acetate, and this precipitate, after being washed, is decomposed with hydrogen sulphide. The filtrate is evaporated down, mixed with alcohol and left to crystallise. The presence of inosite is detected by means of Seidel's reaction (evaporating the solution to dryness with nitric acid, dissolving the residue in water, and adding a few drops of a solution of strontium acetate), a distinct violet coloration with a slight green lustre is obtained, when only 0.3 mgrm. of inosite is present. A large number of plants were found to contain inosite, but only in small amount.

Inosite melts at  $225^{\circ}$  (corr.), dissolves in 7.5 parts of water at  $17-21^{\circ}$ ; it does not ferment, and cannot be converted into a fermentable sugar by acids. The *acetyl-compound*,  $C_6H_7O_6Ac_5$ , melts at  $215.68^{\circ}$  (corr.), distils without change, and is soluble in alcohol, insoluble in water. N. H. M.

**Alcoholic Fermentation of Milk-sugar.** By P. VIETH (*Analyst*, 12, 2—6).—The addition of yeast to milk or to a solution of milk-sugar does not set up alcoholic fermentation readily. Under the influence, however, of a special ferment known as kefir grains, milk undergoes a somewhat rapid alcoholic as well as lactic fermentation. These grains contain a bacillus, named *Diospora caucasica* by Kern, and a modified form of *Saccharomyces cerevisiae* (Abstr., 1883, 226; compare also Struve, Abstr., 1884, 1235). Alcohol is slowly developed when whey or milk is kept in closed vessels, and the marked diminution in the amount of solid residue which occurs when small quantities of milk are exposed to the air for a few days in a warm place, seems also to be due to alcoholic fermentation. M. J. S.

**Aldehyde Resin.** By E. PUCHOT (*Ann. Chem. Phys.* [6], 9, 422—432).—Aldehyde resin washed two or three times with warm water and exposed to air becomes hard and friable. It dissolves in alcohol and is reprecipitated by water. Analysis of two preparations gave the formula  $C_{48}H_{64}O_{10} \pm nH_2O$ ,  $n$  being equal to 4, but the amount of water is variable. When exposed to dry air, the resin gives off water, and its weight gradually reaches a minimum at which it remains constant for some time, and then increases. When the weight is at the minimum, the substance has the composition  $C_{48}H_{64}O_{10} = 8(C_6H_8O) + O_2$ , which varies slightly with the rate of drying. When the increase in weight has become constant, the composition is  $C_{48}H_{64}O_{12} = 8C_6H_8O + O_4$ . If the resin is exposed to moist air, its weight increases, and becomes constant after some weeks; if it is then exposed to dry air, the weight diminishes until it reaches a new limit. The composition at this last stage is not constant, but approximates to  $C_{48}H_{64}O_{12}$ . The substance formed in contact with moist air is probably a hydrate, but its composition was not determined.

In some cases, the crude resin was first placed in dry air, then before the loss of weight was complete, in moist air, and finally in dry air again. After this treatment, it had the composition  $C_{48}H_{66}O_{13} = C_{48}H_{64}O_{12} + H_2O$ , but this result was not constant. In another case,

the composition was  $C_{48}H_{64}O_{12}$ . The change of weight which the resin undergoes shows that the increase of weight is not due to simple combination with oxygen, but there is simultaneous loss of carbon, increased weight being always less than corresponds with the increased percentage of oxygen. Either of the resins first mentioned increases in weight in moist air, but regains its original weight in dry air, the hydrate formed under the first conditions being decomposed in the dry air. Hydrates are obtained containing 2, 3, 5, or 7 mols.  $H_2O$ .

The resin was placed alternately several times in dry air and in air saturated with the vapour from a saturated solution of sodium chloride. The dry substance had the composition  $C_{48}H_{68}O_{14}$ . In the moist atmosphere, there is an increase in the percentage of oxygen, but a decrease in the percentage of carbon, which may be due either to formation of a hydrate or to oxidation with simultaneous loss of carbon.

From these results, it follows that crude aldehyde resin loses water, and forms the compound  $C_{48}H_{64}O_{12}$  or  $8(C_6H_8O) + O_2$ , which may be regarded as an oxidised polymeride of trialdane. This substance yields more highly oxidised products which may be regarded as hydrated oxides of the same aldane. Members of the latter series absorb water from a moist atmosphere, and form hydrates which decompose in dry air. When aldehyde resin is gradually heated from  $120^\circ$  to the boiling point of sulphur, it undergoes condensation. Water and an oily liquid are given off, and a non-volatile residue containing a high percentage of carbon is left in the retort. C. H. B.

**Chloracetones.** By C. CLOEZ (*Ann. Chim. Phys.* [6], 9, 145—221).—The author has prepared and examined all the chlorine-derivatives of acetone which are theoretically possible if the generally accepted formula is correct. A short history of the derivatives previously known is given, together with full bibliographical references.

The material employed was commercial acetone purified by fractionation and conversion into the hydrogen sodium sulphite compound. The author investigated the action of chlorine: (1) on cold acetone; (2) on acetone which at first was cold but afterwards was heated to  $100^\circ$ ; (3) on well-cooled acetone containing iodine; and (4) on boiling acetone containing iodine. No advantage is gained by the presence of iodine, and in fact the iodo-products which are formed in small quantity decompose during distillation and render purification very difficult. The iodine cannot be removed by means of iron or mercury. All fractions boiling above  $125$ — $130^\circ$  should be distilled under reduced pressure. The final product in all four cases is tetrachloracetone.

*Monochloracetone* is most readily prepared by Barbaglia's method (*Ber.*, 7, 467) of passing chlorine into well-cooled acetone for several days; a current of water is sufficient for this purpose, a freezing mixture is not necessary. It boils at  $117$ — $118^\circ$ ; sp. gr. at  $13^\circ = 1.158$ . It is very slightly soluble in water, but dissolves in all proportions in alcohol, ether, and chloroform. It does not form a crystalline hydrate, and volatilises readily in water-vapour. When freshly prepared, it has no irritating odour, but after exposure to air for some days it gives off

irritating vapours. It can, however, be purified by washing with a very dilute solution of an alkali.

Monochloracetone is readily attacked by chlorine in the cold. Bromine has little effect in the cold, but at 100° energetic reaction takes place with formation of chlorotribromacetone. With potassium, it forms potassium chloride, together with red and brown products which probably contain the acetyl carbinol obtained by Emmerling by the action of potassium or potassium carbonate on bromacetone. Ammonia produces ammonium chloride and the amido-derivative,  $\text{COMe}\cdot\text{CH}_2\cdot\text{NH}_2$ , which when distilled with potash yields methylamine. It follows that monochloracetone has the constitution  $\text{COMe}\cdot\text{CH}_2\text{Cl}$ .

The action of a warm concentrated solution of potash on dichlorhydrin yields a liquid closely resembling monochloracetone in its physical properties. It boils at 118—119°; sp. gr. at 11° = 1.194. It combines with hydrochloric and acetic acids, forming derivatives of glycerol, and it also combines with water. With alcoholic ammonia, it yields the badly defined compound hemichlorhydramine,  $\text{C}_3\text{H}_{12}\text{ClNO}_2$ ; this is evidently not an acetone-derivative, and it most probably has the constitution  $\text{CH}_2\text{Cl}\cdot\text{CH}<\begin{smallmatrix} \text{CH}_2 \\ \text{O} \end{smallmatrix}>$ .

*Dichloracetone* is best prepared by the prolonged action of chlorine on well-cooled acetone. It boils at 120°, whilst the monochloro-derivative boils at 117°, but the two compounds may be separated by taking advantage of the fact observed by Mulder and by Barbaglia, that the product obtained under these conditions has the composition of the dichloracetone even in the fraction boiling at 170°. The fraction boiling at 125—170° is collected separately and purified by further fractionation. The pure compound boils at 120°; sp. gr. at 15° = 1.234. It combines readily with sodium hydrogen sulphite, and the compound crystallises with 3 mols.  $\text{H}_2\text{O}$ . Even when carefully purified, the vapour acts energetically on the eyes, &c., but after some time the organs become insensitive to its action. Ammonia acts rapidly on dichloracetone, with formation of ammonium chloride and the base  $\text{COMe}\cdot\text{CHCl}\cdot\text{NH}_2$ , which yields methylamine when distilled with potash.

The product of the action of chlorine on cooled acetone has the composition of the dichloro-derivative even in the fraction boiling at 170°, but on redistillation the boiling point is reduced to 120°. Barbaglia obtained a liquid which boiled at 165—170°, and when cooled solidified to a mass of bulky, prismatic crystals melting at 44°. In its physical properties, this product resembles symmetrical dichloracetone, but with bromine it yields a dichlorodibromacetone identical with that obtained from unsymmetrical dichloracetone, and very different from the corresponding compound obtained from the symmetrical derivative. This high boiling fraction may be a polymeride.

Symmetrical dichloracetone is obtained by the action of silver chloride on the symmetrical diiodoacetone prepared by the action of iodine chloride on acetone in presence of water. It has a pungent odour, forms crystals which melt at 44°, and boils at 170° without decomposition.

When dichlorhydrin is oxidised by means of a well-cooled mixture of sulphuric acid and potassium dichromate, in the manner described by Grimaux and Adam, it yields a liquid which has the composition of dichloracetone. When this product is cooled, it crystallises in large needles melting at  $43-44^{\circ}$ , which change spontaneously, especially in presence of ether, into short prisms with the same melting point. It boils at  $170^{\circ}$ , has a very pungent odour, and in ethereal or alcoholic solution is a most powerful caustic, producing very severe burns. With ammonia, it forms an unstable compound which crystallises in large plates.

In diffused daylight, chlorine acts somewhat slowly on epichlorhydrin. When the product is distilled and the fraction boiling at  $160-180^{\circ}$  is purified, it yields a liquid which boils at  $170^{\circ}$  and has the composition  $\text{CHCl}_2\cdot\text{CH}<\begin{smallmatrix}\text{CH}_2\\-\text{O}-\end{smallmatrix}>$ , and is therefore an isomeride of dichloracetone. With ammonia at a low temperature, it yields a white, amorphous, unstable substance, almost insoluble in water, alcohol, and ether; this has the formula  $\text{C}_6\text{H}_4\text{Cl}_2\text{NO}_2$ , but its constitution could not be determined.

The dichloracetone obtained from diiodoacetone is not identical with the so-called symmetrical dichloracetone obtained by the oxidation of dichlorhydrin. The action of bromine, potash, or oxidising agents on dichlorhydrin yields derivatives which closely resemble derivatives of the acetones, but are never identical with them. Potash yields epichlorhydrin, which closely resembles monochloracetone in its physical properties. Bromine yields a derivative to which the constitution  $\text{CO}(\text{CHClBr})_2$  has been assigned. A compound,  $\text{CHCl}_2\cdot\text{CO}\cdot\text{CHBr}_2$ , can also be obtained from acetone. If the two compounds are treated with mercuric chloride the latter yields tetrachloracetone, whilst the former yields a compound containing a lower percentage of chlorine.

If ordinary dichloracetone and the symmetrical dichloracetone from the iodo-derivative are treated with bromine, they both yield dichlorodibromacetones, and when the latter are treated with mercuric chloride the same symmetrical tetrachloracetone is obtained in both cases. When the pseudodichloracetone from dichlorhydrin is treated in the same way, the product is an isomeride of tetrachloracetone, very distinct from either of the compounds  $\text{CO}(\text{CHCl}_2)_2$  and  $\text{CCl}_3\cdot\text{CO}\cdot\text{CHCl}$ . Since only two tetrachloracetones can exist, it follows that the derivative from dichlorhydrin is not an acetone-derivative. Again, when dichloracetone and the pseudodichloracetone are subjected to the action of chlorine in sunlight, the products are very different, although both have the composition of pentachloracetone. Only one pentachloracetone is, however, possible. The pseudodichloracetone is a derivative of dichlorhydrin,  $\text{CH}_2\text{Cl}\cdot\text{CH}(\text{OH})\cdot\text{CH}_2\text{Cl}$ , and has the constitution  $\text{CH}_2\text{Cl}\cdot\text{CH}<\begin{smallmatrix}\text{CHCl}\\-\text{O}-\end{smallmatrix}>$ , analogous to that of epichlorhydrin. Pseudodichlorhydrin does not combine with acetic acid. It reacts violently with concentrated hydrochloric acid, but when the product is evaporated over sulphuric acid the original compound is obtained.

*Trichloracetones.*—When a limited quantity of bromine is allowed

to act on dichloroacetone, the product  $\text{CHCl}_2 \cdot \text{CO} \cdot \text{CH}_2\text{Br}$  is obtained, which boils at  $111^\circ$  under a pressure of 25 mm., and when this is heated with mercuric chloride in presence of alcohol, trichloroacetone boiling at  $172^\circ$  is obtained. This trichloroacetone yields no chloroform with aqueous or alcoholic ammonia, and no phenylcarbylamine with aniline and potash. It therefore does not contain the group  $\text{CCl}_3$ , and must have the constitution  $\text{CHCl}_2 \cdot \text{CO} \cdot \text{CH}_2\text{Cl}$ . Only a very small quantity was obtained.

Trichloroacetone,  $\text{CCl}_3 \cdot \text{CO} \cdot \text{CH}_3$ , is readily obtained by the action of chlorine on an aqueous solution of sodium citraconate heated at  $100^\circ$  (Gottlieb and Morawsky, *J. pr. Chem.* [2], 12, 369). With ammonia, it yields chloroform and a small quantity of ammonium chloride, together with a large quantity of acetamide if the liquid has been kept cool and excess of ammonia has been avoided.

The action of chlorine on impure methyl alcohol (Bouis) or on acetone (Bischoff) yields a liquid which has the composition of trichloroacetone and boils at  $172^\circ$ ; sp. gr. 1.418. It solidifies incompletely in long needles at  $-14^\circ$ , the temperature rising suddenly to  $-5^\circ$ . The crystals melt between  $-5^\circ$  and  $+2^\circ$ . It combines with 2 mols.  $\text{H}_2\text{O}$ , forming a hydrate which melts at  $43-44^\circ$ . It also combines with sodium hydrogen sulphite, but the product crystallises with great difficulty. With aniline and potash, it yields phenylcarbylamine; but with ammonia it yields very little if any chloroform or acetamide, ammonium chloride, however, is formed in large quantities, and if the liquid is distilled with potash, it yields dichloromethylamine, which is doubtless derived from the compound  $\text{CHCl}_2 \cdot \text{CO} \cdot \text{CH}_2\text{NH}_2$ . It would follow that the trichloroacetone has the constitution  $\text{CHCl}_2 \cdot \text{CO} \cdot \text{CH}_2\text{Cl}$ , but the formation of chloroform and phenylcarbylamine, and the variable boiling and melting points of the compound, show clearly that it is a mixture of a solid trichloro-derivative which melts about  $-5^\circ$ , with an isomeride which is liquid even at low temperatures.

*Unsymmetrical tetrachloroacetone* was obtained by Bouis by the action of chlorine on wood-spirit in diffused daylight (*Ann. Chim. Phys.* [3], 21—111), and by Bischoff by the action of chlorine on a mixture of acetone and methyl alcohol (this Journal, 1876, i, 558). It is most readily obtained by passing chlorine into commercial acetone, the temperature being allowed to rise. Tetrachloroacetone is a colourless liquid which boils at  $180-182^\circ$ , and becomes brown when exposed to air and light; sp. gr. at  $17^\circ = 1.482$ . When distilled under the ordinary pressure, it undergoes partial decomposition. It is very hygroscopic, and forms a tetrahydrate which melts without decomposition at  $30^\circ$ . With aniline and potash, it yields phenylcarbylamine, and with aqueous ammonia at a low temperature it yields chloroform and monochloroacetamide. It therefore has the constitution  $\text{CCl}_3 \cdot \text{CO} \cdot \text{CH}_2\text{Cl}$ .

By the prolonged action of chlorine on pure acetone at first cooled and afterwards heated on a water-bath, Grabowsky (this Journal, 1876, i, 557) has obtained trichloromethyl propyl ketone, boiling at  $186^\circ$ . The author has been unable to obtain this result. Probably the nature of the reaction depends on the purity of the acetone.

*Symmetrical tetrachloroacetone*.—Dichlorodibromoacetone prepared by the action of bromine on unsymmetrical dichloroacetone is heated

with alcohol and mercuric chloride in sealed tubes at 100°. The product is distilled, and is purified from mercury by conversion into a hydrate which is repeatedly recrystallised, and then decomposed by hydrochloric acid. The product is dried over calcium chloride, and boils at 179—181°; its sp. gr. is the same as that of the preceding compound. With water, it forms a hydrate crystallising in needles which melt at 47—48°. With ammonia or aniline, it yields no distinct result, but neither chloroform nor phenylcarbylamine is formed. The compound therefore does not contain the group  $\text{CCl}_3$ , and must have the constitution  $\text{CHCl}_2 \cdot \text{CO} \cdot \text{CHCl}_2$ .

The dichlorodibrom-derivative obtained by the action of bromine on dichlorhydrin yields with mercuric chloride an oily liquid which has no fixed boiling point, and is not attacked by ammonia at the ordinary temperature. It is not a tetrachloracetone.

When the product of the oxidation of dichlorhydrin is treated with bromine, it yields an isomeride of dichlorodibromacetone, which, according to Markownikoff, has the constitution  $\text{CHClBr} \cdot \text{CO} \cdot \text{CHClBr}$ . When this compound is treated with mercuric chloride, however, it yields a liquid which fumes in the air, boils at about 180°, has a disagreeable odour, and does not combine with alkaline hydrogen sulphites. With ammonia or aniline, it yields neither chloroform nor phenylcarbylamine, but dichloracetamide and dichloracetanilide respectively. It follows that either there are two isomeric symmetrical tetrachloracetones, or that the product of the oxidation of dichlorhydrin is not an acetone-derivative, as already indicated.

When symmetrical iodacetone is treated with silver chloride, and the product is treated with bromine and afterwards with mercuric chloride, a liquid is obtained which boils at 180°, and is identical with symmetrical tetrachloracetone. The dichloracetone from iodacetone has always been regarded as identical with Markownikoff's products, but these results show that they are very different, and the latter is most probably a derivative of epichlorhydrin—

*Pentachloracetone* was obtained by Staedeler by adding hydrochloric acid to a boiling solution of quinic acid and potassium chlorate. The yield is very small, and great care is required to avoid explosions. Much better results are obtained by the following method. A solution of citric acid in 1.5 parts of water is allowed to fall drop by drop down a tube packed with punice, up which passes a current of dry chlorine, the tube being heated at 100° by means of a water-jacket. The product is purified by washing and redistillation. If the water used for washing is evaporated at a low temperature, it deposits crystals of citric acid which contain 2 mols.  $\text{H}_2\text{O}$ , and are quite different in appearance from the ordinary crystals. They form flattened prisms with four of the faces abnormally developed. The cleavage planes and the angles at the edges are, however, identical with those of the ordinary crystals.

The pentachloracetone obtained is identical with that prepared by Staedeler and by Cloez, sen., by the action of chlorine on alkaline

citrates. With ammonia, it yields chloroform and dichloroacetamide, and with aniline it yields phenylcarbylamine and dichloroacetanilide. It may also be prepared in large quantity by the action of dry chlorine on dry commercial acetone in direct sunlight. Pure acetone seems to give a different result, since Fittig, and Dumas and Kane, obtained no derivative higher than the dichloroacetone by the action of chlorine on acetone at  $100^{\circ}$  or in sunlight. Under the conditions given, however, the acetone is converted into a mixture of pentachloroacetone and hexachloroacetone which are separated by fractionation.

*Pentachloroacetone* is a colourless liquid with an odour resembling that of chloral, which, however, is only observed after the liquid has been exposed to air. It boils at  $192^{\circ}$ , and is readily volatile in water vapour; sp. gr. at  $14^{\circ} = 1.576$ . It dissolves in 10 parts of water, from which it separates completely at  $50-60^{\circ}$ . At low temperatures, the solution deposits a tetrahydrate in small, rhomboidal plates melting at  $15^{\circ}$  with decomposition. With ammonia, it yields chloroform and dichloroacetamide.

The action of chlorine in sunlight on the pseudodichloroacetone from dichlorohydrin yields a liquid which has a pungent smell, and boils at  $185^{\circ}$ ; sp. gr. at  $8^{\circ} = 1.617$ . With ammonia, it yields trichloroacetamide but no chloroform, and hence it is not a derivative of acetone. The action of chlorine on dichloropropylene oxide yields a strongly fuming liquid which boils at about  $178^{\circ}$ . Its composition does not agree very well with that of pentachloropropylene oxide, and when treated with ammonia, it yields trichloroacetamide but no chloroform. It therefore has the constitution  $\text{CHCl}_2\cdot\text{CCl}<\overset{\text{CCl}_2}{\underset{\text{O}}{\text{O}}}>$ . From these results, it is evident that there are three isomeric compounds having the composition of pentachloroacetone, but only one of these is really a derivative of acetone.

*Hexachloroacetone* was obtained by Plantamour by the action of chlorine on a solution of citric acid in sunlight, and has been described under different names by Laurent, Staedeler, and Cloez, sen. A solution of citric acid is treated with chlorine in sunlight until the gas is no longer absorbed. Carbon dioxide is given off, especially in the later stages of the reaction. The yield is about one-fourth of the weight of the citric acid taken. Hexachloroacetone can readily be obtained by the action of chlorine on acetone in sunlight. The fraction of the product which boils at  $185-220^{\circ}$  is collected and purified. The fraction boiling at  $290^{\circ}$  contains a considerable quantity of hexachlorobenzene, which is probably formed by pyrogenic decomposition, and does not exist in the product before distillation. It is not always formed.

Hexachloroacetone is a very limpid liquid with an odour which is feeble at a low temperature, but becomes very pungent and irritating when the liquid is warmed. It boils without decomposition at  $202-204^{\circ}$ , and when cooled solidifies in large, white plates melting at  $-2^{\circ}$ ; sp. gr. at  $12^{\circ} = 1.744$ ; vapour-density 9.615. It is slightly soluble in water, and forms a crystalline monohydrate which is almost insoluble in water. With aqueous ammonia it yields chloroform and trichloro-

acetamide, and with aniline it yields chloroform and trichloroacetanilide. When heated with water in sealed tubes at  $120^{\circ}$ , it splits up into chloroform and trichloroacetic acid. The action of chlorine on epichlorhydrin in sunlight yields crystals which seem to be hexachlorobenzene, and a small quantity of a liquid which boils at  $200\text{--}210^{\circ}$  and yields chloroform and trichloroacetamide with ammonia. Most probably the product has the constitution  $\text{CCl}_3\cdot\text{CCl}\langle\begin{smallmatrix}\text{CCl}_2\\-\text{O}-\end{smallmatrix}\rangle$ .

*Chlorobromacetones*.—Theegarten (this Journal, 1874, 242) treated epichlorhydrin with bromine, and oxidised the product. In this way, he obtained crystals which have an irritating odour, melt at  $34\text{--}35^{\circ}$ , and boil at  $177\text{--}180^{\circ}$ . This compound is only slightly soluble in water, but dissolves readily in alcohol and ether. It does not combine with bisulphites, and doubtless has the constitution

A compound with the composition of monochlorotribromacetone was obtained by Claus and Lindhorst (Abstr., 1880, 862) by the action of bromine and water on dichlorhydrin, and by Grimaux and Adam (*ibid.*, 457) by the action of bromine on epichlorhydrin at  $100^{\circ}$ . With equal molecular proportions of bromine and epichlorhydrin, the reaction is complete in a few hours. The product is a colourless, pungent liquid, heavier than water, with which it forms a hydrate melting at  $55^{\circ}$ , soluble in alcohol, and stable when exposed to air. The compound itself decomposes when boiled even under reduced pressure. It is not a true derivative of acetone, but is derived from epichlorhydrin.

When monochloroacetone is heated with bromine at  $100^{\circ}$  and the product dissolved in water, a tetrahydrate is formed which can be recrystallised. It is decomposed by hydrochloric acid, and when the liquid thus obtained is dried, it boils at  $130^{\circ}$  under a pressure of 25 mm., and at  $215^{\circ}$  under normal pressure; sp. gr. = 2.270. It has a pungent, irritating odour. The hydrate is only slightly soluble in water, but dissolves more readily in alcohol of  $80^{\circ}$ , from which it crystallises in large, hexagonal tables containing 1 mol.  $\text{H}_2\text{O}$ ; this is readily given off even on exposure to the air. With aqueous ammonia at a low temperature, chlorotribromacetone yields bromoform and chloroacetamide, and therefore has the constitution  $\text{CBr}_3\cdot\text{CO}\cdot\text{CH}_2\text{Cl}$ . So-called dichlorodibromacetone, obtained by the action of bromine on pseudodichloroacetone, is a liquid which solidifies at  $-14^{\circ}$ , melts at  $-8^{\circ}$ , and boils at  $135^{\circ}$  under a pressure of 40 mm. It does not combine with alkaline hydrogen sulphites. It forms a tetrahydrate, which crystallises in long prisms melting at  $53\text{--}54^{\circ}$  with partial decomposition. The action of ammonia shows that this compound contains neither  $\text{CCl}_2\text{Br}$  nor  $\text{CBr}_2\text{Cl}$ , and hence its constitution must be  $\text{CHBrCl}\cdot\text{CH}\langle\begin{smallmatrix}\text{CBrCl}\\-\text{O}-\end{smallmatrix}\rangle$ .

The action of bromine on dichlorhydrin yields a compound which boils at  $140\text{--}141^{\circ}$  under a pressure of 20 mm. It forms a crystalline tetrahydrate which melts at  $55\text{--}56^{\circ}$ , and boils with partial decompo-

sition at 140—150° under a pressure of 20 mm. It is not identical with the preceding compound, and may have the constitution

The action of bromine on ordinary dichloroacetone yields a liquid which boils at 120° under a pressure of 25 mm., and does not solidify at a low temperature. It forms a tetrahydrate which crystallises in hexagonal tables with a very disagreeable odour; these readily lose their water. Barbaglia's dichloroacetone boiling at 170° yields the same derivative with bromine, and is therefore a polymeride of ordinary dichloroacetone. Dibromodichloroacetone reacts energetically with ammonia, but no chlorobromoform is produced, and hence the compound must have the constitution  $\text{CHCl}_2\cdot\text{CO}\cdot\text{CHBr}_2$ . With mercuric chloride, it yields a tetrachloroacetone which does not contain the group  $\text{CCl}_3$ .

When trichloroacetone is treated with bromine at 100°, it yields a trichlorobromoacetone, which boils at 107° under a pressure of 25 mm., and at 190° under the ordinary pressure. It is very hygroscopic, and forms a tetrahydrate which crystallises in hexagonal tables melting at 48°. With ammonia, it yields chloroform and bromoacetamide, and therefore must have the constitution  $\text{CCl}_3\cdot\text{CO}\cdot\text{CH}_2\text{Br}$ .

Tetrabromoacetone forms a tetrahydrate, which, although unstable, crystallises readily. With ammonia, it yields bromoform and bromoacetamide.

All the chlorobromoacetones described are tetra-substitution-derivatives. Starting from tetrachloroacetone, each substitution of bromine for chlorine produces a rise of about 10° in the boiling point. There is also a gradual increase in the specific gravity.

*Action of Ammonia and Amines on Chloroacetones.*—The action of orthotoluidine on hexachloroacetone yields orthocresyltrichloroacetamide,  $\text{C}_6\text{H}_4\text{Me}\cdot\text{NH}\cdot\text{C}_2\text{Cl}_3\text{O}$ , which crystallises in large needles only slightly soluble in cold alcohol. It melts at 66—67°, readily remains in superfusion, and volatilises at 215°. Paratoluidine yields the corresponding para-derivative, which crystallises in very short rectangular prisms, melting at 79—80°, and volatilising with partial decomposition at 185°. It is only slightly soluble in cold alcohol.

With diethylamine, hexachloroacetone yields diethyltrichloroacetamide, which is very soluble in alcohol, and crystallises in prisms which melt at 90° and volatilise almost immediately with partial decomposition. With trimethylamine, dimethyltrichloroacetamide is formed; this is very soluble in boiling alcohol, and crystallises in radiating needles which melt at 104°, and sublime at 195°. With dimethylaniline, the reaction takes place only on warming, and the product is a mixture of a violet colouring matter, soluble in boiling water but almost insoluble in ether, and very soluble in chloroform, with another badly defined colouring matter. Allylamine yields allyltrichloroacetamide, soluble in alcohol and in chloroform, and crystallising in large tables which melt at 45° and volatilise without decomposition at 190°. With hexachloroacetone and pentachloroacetone respectively, ethylenediamine yields the two derivatives,  $\text{C}_2\text{H}_4\cdot\text{N}_2\text{H}_3\cdot\text{C}_2\text{Cl}_3\text{O}$

and  $C_2H_4 : N_2H_3 \cdot C_2HCl_2O$ . The first is soluble in alcohol, and crystallises in elongated rhomboidal plates which melt at  $200^\circ$  and sublime at the same temperature. The second is soluble in warm alcohol, and very soluble in ether. It crystallises from alcohol in elongated parallelograms, and from ether in fan-shaped plates.

When one molecular proportion of urea is heated at  $150^\circ$  with two molecular proportions of hexachloracetone, the amide—

is readily obtained. It crystallises from its alcoholic solution in yellowish, hexagonal plates.

**Chlorinated Methyl Formates.** By W. HENTSCHEL (*J. pr. Chem.* [2], 36, 209—215).—Continuing his previous work (this vol., p. 1027) the author has repeated Cahours' investigation (*Ann. Chim. Phys.* [3], 19, 342) on the chlorination of methyl formate, but with totally different results.

The chlorination takes place very slowly in the dark, very rapidly in bright daylight, and care must be taken to prevent an accumulation of the two reacting substances, or violent explosions occur. The author obtained the trichloromethyl chloroformate,  $C_2Cl_4O_2$ , previously described by him (*loc. cit.*), but could obtain no such stable compound,  $C_2Cl_4O_2$ , boiling at  $180$ — $185^\circ$ , as is described by Cahours, and usually given in text-books. He believes that such a compound does not exist, and that Cahours must have been mistaken in his results.

L. T. T.

**Action of Sodium on Ethyl Salts of the Higher Fatty Acids.** By O. WOHLBRÜCK (*Ber.*, 20, 2332—2340; comp. this vol., p. 717).—*Ethyl dimethylisobutyrylacetate*,  $CHMe_2 \cdot CH \cdot CO \cdot CMe_2 \cdot COOEt$ , is obtained by adding 30 grams of sodium to 100 grams of ethyl isobutyrate diluted with an equal weight of absolute ether, the whole being kept cool. Afterwards it is heated in a water-bath for some hours. The product is poured into water, and the oil so obtained is treated with dilute aqueous soda, dried and distilled. It is a lemon-yellow liquid of a strong aromatic odour, boiling at  $186$ — $189^\circ$  under 716 mm. pressure.

*$\alpha$ -Dimethyl- $\beta$ -hydroxyisocaproic acid,*

is contained as sodium salt in the soda used in purifying the above ethyl salt, and crystallises in prisms melting at  $108^\circ$ . It is soluble in water, readily in ether. The *barium salt* with 3 mols.  $H_2O$  forms readily soluble, microscopic plates; the *silver salt* blackens when exposed to light, and gives a mirror when heated in water. The acid is also formed by the reduction with sodium of ethyl dimethylisobutyrylacetate diluted with alcohol.

*Ethyl isopropylisovalerylacetate,*

is prepared by the action of sodium (38 grams) on ethyl isovalerate (100 grams) diluted with dry ether. The product is purified in a manner similar to ethyl dimethylisobutyrylacetate. It is a bright

yellow oil boiling at 204—207 under 722° mm. pressure. When treated with bromine, and the product decomposed by an alkali, an acid melting at 185—187° (probably  $C_{10}H_{16}O_3$ ) is obtained.

*α-Isopropyl-β-isobutylhydracrylic acid,*

is contained in the aqueous alkaline extract from ethyl isopropylisovalerylacetate. It is an oil which solidifies after some days to long, slender needles of a silky lustre. It melts at 120°, and dissolves readily in alcohol, ether, and hot water. When heated above its melting point, it sublimes in lustrous needles. The *barium salt* crystallises in hard, colourless prisms. The acid can also be obtained by reducing ethyl isopropylisovalerylacetate with sodium.

N. H. M.

**Transformation of Fumaric and Maleic Acids into Aspartic Acid and Asparagine.** By G. KOERNER and A. MENOZZI (*Gazzetta*, **17**, 226—231).—The authors have shown that paraffinoid amido-acids can be converted into olefinoid acids by the introduction of the methyl-group into the amido-residue, and subsequent removal of the elements of the amine. A case of the converse change is here investigated, in that it is shown that ethyl fumarate, when heated with alcoholic ammonia in sealed tubes, yields an oil, ethyl aspartate, and a substance of the composition  $C_4H_6N_2O_2$ . The ethyl aspartate is a colourless oil, which boils at 150—154° under a pressure of 25 mm., but is decomposed when distilled at the ordinary pressure. The compound  $C_4H_6N_2O_2$  crystallises in glistening leaflets melting at about 250° with decomposition; it may be regarded probably as the imide of aspartic acid; on protracted heating with alcoholic ammonia, it is converted into asparagine. The above-mentioned oil when treated with aqueous ammonia yields asparagine in abundance, the crystals formed showing hemihedric modifications.

In like manner, ethyl maleate yields identical products, and practically in the same proportion.

V. H. V.

**Oxidising Action of Alloxan.** By G. PELLIZZARI (*Gazzetta*, **17**, 254—259).—When a concentrated aqueous solution of alloxan is added to phenylhydrazine hydrochloride in presence of sodium acetate, nitrogen and benzene vapour are evolved, and alloxantin is formed thus:  $2C_4H_2N_2O_4 + NHPh \cdot NH_2 = C_8H_4N_4O_7 + C_6H_6 + N_2 + H_2O$ . It is supposed that in the first phase of the reaction two atoms of hydrogen are eliminated in the form of water, with formation of a hypothetical diazobenzene, which decomposes into benzene and nitrogen. If this view were correct, then hydrazobenzene under similar conditions should yield azobenzene, a result confirmed by experiment.

An analogous result was obtained with indigo-white, the alloxan being reduced to alloxantin, whilst simultaneously the white is oxidised to indigo-blue, thus:  $2C_4H_2N_2O_4 + C_{16}H_{12}N_2O_2 = C_8H_4N_4O_7 + C_{16}H_{10}N_2O_2 + H_2O$ .

Ceresole (Abstr., 1883, 913) has shown that hydroxylamine hydrochloride acts on alloxan in a manner similar to the usual reaction with ketones, leading to the formation of violuric acid. In the paper,

this result is confirmed, and the identity of the product formed with violuric acid is established by crystallographic measurements.

**1 : 3 Methylphenylthiophen and 1 : 2 Thioxen.** By C. PAAL and A. PÜSCHEL (*Ber.*, 20, 2557—2560).—1 : 3 *Methylphenylthiophen*,  $C_4SH_2MePh$ , is obtained when phenyllevulinic acid, or preferably its sodium salt, is heated with phosphorus trisulphide or pentasulphide; the sodium salt must contain water, otherwise carbonisation is the sole result. It crystallises in large, nacreous laminæ, melts at  $72-73^\circ$ , distils without decomposition, and is readily soluble in alcohol, benzene, &c. It is less volatile with steam than its isomerides, has an odour resembling that of diphenyl, and gives the indophenine reaction, but does not show Laubenheimer's reaction distinctly. The *tetrabromo-derivative*,  $C_{11}SH_4Br_4$ , formed by the action of methylphenylthiophen on an excess of bromine in the cold, crystallises in slender needles or scales, melts at  $136-137^\circ$ , and is readily soluble in ether, benzene, and light petroleum, less so in alcohol and acetic acid.

1 : 2 *Thioxen*,  $C_4SH_2Me_2$ , is prepared by distilling  $\beta$ -methyllevulinic acid with phosphorus trisulphide, and washing the distillate with ice-cold, dilute, aqueous soda. It is a colourless liquid, which boils at  $134-138^\circ$ , and shows the indophenine and Laubenheimer reactions. The alkaline solution employed for washing the distillate contains 1 : 2 : 4 thioxenol.

W. P. W.

**Action of Methyl Chloride on Orthodichlorobenzene in Presence of Aluminium Chloride.** By C. FRIEDEL and J. M. CRAFTS (*Ann. Chim. Phys.* [6], 10, 411—424).—The action of methyl chloride on dibromortho-xylene in presence of aluminium chloride is very complicated, and no definite products were obtained.

Orthodichlorobenzene, prepared by Istrati, was purified by crystallising out the less fusible para-derivative, and dissolving the orthodichlorobenzene in a mixture of equal vols. of ordinary sulphuric acid and the fuming acid, which leaves the greater part of the still admixed para-derivative undissolved. The sulphonic acid thus obtained was recrystallised and decomposed by heating in a retort into which a current of steam was passed. Some paradichlorobenzene distils over at  $100^\circ$ , and the ortho-derivative passes over in an almost pure condition at about  $200^\circ$ . It boils at  $178^\circ$ ; sp. gr. at  $0^\circ = 1.3254$ . During distillation, crystals of the sulphone  $(C_6H_3Cl_2)_2SO_2$  condense in the upper part of the condenser; they melt at  $173^\circ$ , and boil at  $360^\circ$  with partial decomposition.

The orthodichlorobenzene was mixed with 20 per-cent. of aluminium chloride, heated on a water-bath, and treated with a current of dry methyl chloride for about 10 hours. The chief products are hexamethylbenzene and trichloromesitylene.

Hexamethylbenzene thus obtained crystallises in long needles which melt at  $164^\circ$  and boil at  $264^\circ$ . With an excess of picric acid, it forms a compound containing the two substances in equal molecular proportions, and which crystallises in golden-yellow lamellæ melting at  $168-169^\circ$ .

Trichloromesitylene contains more chlorine than the original com-

pound, although some of the latter always remains unaltered. Its formation is not due to the presence of any trichlorobenzene. It crystallises from alcohol in slender needles, which melt at  $205^{\circ}$  and boil at  $280^{\circ}$  without decomposition. When heated in sealed tubes with 16 times its weight of hydriodic acid of sp. gr. 1.9, in the vapour of diphenylmethane, it yields mesitylene. Under the same conditions, hexamethylbenzene yields mesitylene and methane.

The formation of hexamethylbenzene is doubtless due to the reducing action which has been observed in similar reactions. Probably the organo-metallic compound is produced from the dichlorobenzene, with displacement of chlorine and not of hydrogen, and this chlorine produces the trichloromesitylene. Analogous phenomena have been observed by L. Roux in the action of aluminium chloride on the haloid derivatives of naphthalene.

In addition to hexamethylbenzene, a small quantity of a compound which seems to be a chloromethyl-derivative of diphenyl, is formed.

Aluminium chloride alone has no action on orthodichlorobenzene at  $160^{\circ}$ . C. H. B.

**Action of Methylene Chloride on Methylbenzenes in Presence of Aluminium Chloride.** By C. FRIEDEL and J. M. CRAFTS (*Ann. Chim. Phys.* [6], **11**, 263—277).—Benzene yields toluene, diphenylmethane melting at  $25^{\circ}$  and boiling at  $260$ — $265^{\circ}$ , and anthracene. The absence of hydranthracene is due to its reduction to anthracene and methyl chloride by the action of the methylene chloride, the methyl chloride then producing the toluene. The relative quantities of diphenylmethane and anthracene obtained depend on the proportions of methylene chloride and benzene.

Toluene yields a mixture of meta- and para-xylene boiling at  $130$ — $150^{\circ}$ , ditolylmethane boiling at  $280$ — $290^{\circ}$ , and dimethylantracene melting at  $231$ — $232^{\circ}$ .

Metaxylylene, in addition to liquid products, yields tetramethylantracene melting at  $162$ — $163^{\circ}$ ; this unites with picric acid in equal molecular proportions to form a deep red compound crystallising in stellate groups. Oxidised with chromic acid in presence of acetic acid, it yields yellowish-white prisms which melt at  $206^{\circ}$ , and have the composition  $C_{18}H_{16}O_2$ . From its mode of formation this tetramethylantracene must have the constitution  $1' : 3' : 1 : 3$  or  $1' : 3' : 2 : 4$ .

Pseudocumene yields durene and solid products, which melt respectively at about  $165^{\circ}$ ,  $220^{\circ}$ , and  $290^{\circ}$ . The first is a small quantity of tetramethylantracene identical with that obtained from metaxylylene. The second consists of hexamethylantracene, which from its mode of formation must have the constitution  $1' : 2' : 4' : 1 : 2 : 4$  or  $1' : 3' : 4' : 1 : 2 : 4$ . If it is mixed in alcoholic solution with picric acid, the two substances unite in equal molecular proportions, and the compound separates in small, golden-brown needles which melt at about  $203^{\circ}$ . The hydrocarbon dissolves in sulphuric acid, forming a red solution, which becomes colourless as the acid absorbs moisture from the air. The third product might be expected to be a hepta- or octamethylantracene. It has the composition  $C_{18}H_{18}$ , forms no compound

with picric acid, and yields a dibromo-derivative which has the composition  $C_{18}H_{16}Br_2$  or  $C_{18}H_{14}Br_2$ . When oxidised with chromic acid and acetic acid, it yields yellowish or white needles, which melt at  $325^\circ$  and sublime completely without decomposition at a higher temperature. The composition of this product agrees more nearly with the formula  $C_{18}H_{16}O_2$  than  $C_{18}H_{14}O_2$ . With bromine, a mixture of a mono- and dibromo-derivative is obtained. Most probably the hydrocarbon is an isomeride of tetramethylantracene, although it differs markedly from it and the other methylantracenes. C. H. B.

### Decomposition of Mixed Ethers by Heat and Nitric Acid.

By G. ERRERA (*Gazzetta*, 17, 193—209).—In former investigations it has been shown that when the mixed ethers containing a paraffinoid and aromatic grouping are heated with nitric acid, they yield the corresponding aromatic aldehyde or its nitro-derivative, and the nitrate of the paraffin. Also Liebig, Cannizzaro, and others have shown that when heated, the ethers decompose into an aldehyde and hydrocarbon.

In this paper, the reactions are studied in the case of benzyl isobutyl ether and benzyl isoamyl ether, and halogen-derivatives of benzyl ethyl ether. When benzyl isobutyl ether is heated with concentrated nitric acid, it forms benzaldehyde and isobutyl nitrate, whilst benzyl isoamyl ether yields the same aldehyde and isoamyl nitrate.

Considerable difficulty was experienced in the preparation of parabromobenzyl chloride, whether by the bromination of benzylic chloride or the chlorination of benzylic bromide; the product was invariably a mixture nearly in molecular proportion of parabromobenzylic chloride and bromide. This mixture, however, serves for the preparation of *parabromobenzyl ethyl ether*,  $C_6H_4Br \cdot CH_2 \cdot OEt$ , which is a colourless liquid of fruity odour boiling at  $243^\circ$ , but with appreciable decomposition into parabromobenzaldehyde and ethane; this change is instantaneous at the temperature of boiling sulphur. The bromobenzyl ethyl ether is converted into parabromobenzaldehyde by the action of nitric acid.

*Parachlorobenzyl ethyl ether*,  $C_6H_4Cl \cdot CH_2 \cdot OEt$ , from parachlorobenzylic bromide, is a liquid of properties similar to those of the bromo-compounds; it boils at  $225$ — $227^\circ$ , and is decomposed at a higher temperature into the corresponding aldehyde and ethane; it also yields the same aldehyde when treated with nitric acid.

V. H. V.

**Isonitroso-derivatives.** By H. v. PECHMANN (*Ber.*, 20, 2539—2544).—When pure benzaldoxime is shaken with 10 times its volume of a 30 per cent. solution of sodium hydrogen sulphite, a crystalline compound is obtained, which after removal of the mother-liquor and washing with alcohol and ether, crystallises from water in small, white needles of the composition  $SO_3Na \cdot CHPh \cdot NH \cdot SO_3Na + 3H_2O$ . This compound is insoluble in alcohol but very soluble in water; its aqueous solution is decomposed on boiling. When heated with dilute acids or alkaline carbonates, or when treated with alkalis in the cold, it decomposes quantitatively into benzaldehyde, sodium sulphate, and ammonium hydrogen sulphite.

Acetoxime dissolves in a solution of sodium hydrogen sulphite with

development of heat, and yields a clear liquid from which, on addition of alcohol and some acetic acid, a crystalline compound slowly separates. Dilute acids decompose this compound into acetone, sodium sulphate, and ammonium hydrogen sulphite.

With sodium hydrogen sulphite, under similar conditions, nitrosoacetone forms a compound which most probably has the composition  $\text{SO}_3\text{Na} \cdot \text{CMe}(\text{OH}) \cdot \text{CH}(\text{SO}_3\text{Na}) \cdot \text{NH} \cdot \text{SO}_3\text{Na} + 3\text{H}_2\text{O}$ . This separates from dilute alcohol as a powder consisting of colourless needles, and is extremely soluble in water but insoluble in alcohol. When heated with dilute acids, it is decomposed into methylglyoxal, sodium sulphate, sodium hydrogen sulphite, and ammonium hydrogen sulphite. The methylglyoxal was recognised by subjecting the product to steam distillation and treating the distillate firstly with phenylhydrazine acetate, when the *phenylhydrazide*,  $\text{N}_2\text{HPh} : \text{CH} \cdot \text{CMe} : \text{N}_2\text{HPh}$ , which crystallises in slender, yellow needles melting at  $145^\circ$ , was obtained; and secondly with toluylenediamine, when methyltoluinoxaline, identical with that described by Hinsberg (Abstr., 1886, 561), was formed. These derivatives are also formed by the action of these reagents on nitrosoacetone, but their formation in the absence of this compound may be regarded as affording evidence of the presence of methylglyoxal.

W. P. W.

**Unsymmetrical Secondary Hydrazines.** By B. PHILIPS (*Ber.*, 20, 2485—2488).—Sodium phenylhydrazine suspended in benzene is treated with an alkyl bromide, and the mixture after the lapse of some hours is heated on a water-bath to complete the reaction. The product, after filtration from the sodium bromide, is purified by saturating the benzene solution with hydrogen chloride and filtering from the insoluble hydrochlorides; the benzene is then removed by distillation, the residue dissolved in ether, the solution again distilled, and the base obtained by precipitating the aqueous solution of the hydrochloride with an alkali. The secondary hydrazines when freshly distilled are colourless liquids which become brown in the air, dissolve to clear solutions in concentrated hydrochloric acid, and show all the characteristic properties of Fischer's methyl- and ethyl-phenylhydrazine.

*α-Isopropylphenylhydrazine*,  $\text{NPrPh} \cdot \text{NH}_2$ , boils at  $185^\circ$  under 172 mm. and at  $233^\circ$  under the ordinary pressure; the *hydrochloride* crystallises well from benzene and melts at  $135^\circ$ . The *tetrazone* forms colourless crystals and melts at  $85^\circ$ , the *thiosemicarbazide*,  $\text{NPrPh} \cdot \text{NH} \cdot \text{CS} \cdot \text{NHPh}$ , crystallises from alcohol in large, well formed crystals and melts at  $116^\circ$ , and the *acetyl*-derivative,  $\text{NPrPh} \cdot \text{NHAc}$ , melts at  $97^\circ$ .

*α-Isobutylphenylhydrazine*,  $\text{C}_4\text{H}_9 \cdot \text{NPh} \cdot \text{NH}_2$ , boils at  $193$ — $195^\circ$  under 179 mm., and at  $240$ — $245^\circ$  under the ordinary pressure, in the latter case with partial decomposition and formation of small quantities of ammonia. The hydrogen sulphate forms nacreous scales.

*α-Isoamylphenylhydrazine*,  $\text{C}_5\text{H}_{11} \cdot \text{NPh} \cdot \text{NH}_2$ , boils at  $210^\circ$  under 57 mm., and at  $260^\circ$  under the ordinary pressure.

*α-Benzylphenylhydrazine* (Abstr., 1886, 1025) is a thick, colourless liquid which cannot be distilled without decomposition in a partial vacuum, and when cooled in open vessels gradually solidifies to a

crystalline mass; this melts at  $21^{\circ}$  and seems to contain 1 mol.  $\text{H}_2\text{O}$ . The anhydrous base does not solidify in dry air. The *acetyl*-derivative melts at  $121^{\circ}$ , and the *tetrazone* at  $109^{\circ}$ . When treated with benzaldehyde, *benzylidenebenzylphenylhydrazine*,  $\text{C}_7\text{H}_7\cdot\text{NPh}\cdot\text{N}:\text{CHPh}$ , is obtained; this crystallises in needles, melts at  $109^{\circ}$ , and is readily soluble in alcohol, ether, and benzene. This base could not be prepared by the direct action of benzyl chloride on benzylidenephénylhydrazine; if, however, the sodium compound of the base, obtained by the addition of finely divided sodium to benzylidenephénylhydrazine in benzene solution, is treated with benzyl chloride, a compound is obtained which shows all the properties of benzylidenebenzylphenylhydrazine. The author regards this result as affording experimental evidence in favour of the formula  $\text{NPh}\cdot\text{N}:\text{CHPh}$  for benzylidenephénylhydrazine.

W. P. W.

**Azophenines and Indulines.** By O. FISCHER and E. HEPP (*Ber.*, 20, 2479—2484).—Azophenine can be obtained by heating nitrosomethylaniline and nitrosoethylaniline with aniline hydrochloride (1 part) and aniline (4 to 5 parts) at  $80^{\circ}$ . The best method of preparation, however, consists in digesting paranitrosodiphenylamine (1 part) with aniline hydrochloride (1 part) and aniline (5 parts) at  $100^{\circ}$  for 8 to 10 hours; the product, which contains induline and paramidodiphenylamine (m. p. =  $66$ — $67^{\circ}$ ), is washed with water and alcohol, and crystallised from toluene: the yield amounts to 1.5 part of pure azophenine. The azophenine of paratoluidine can also be prepared from nitrosodiphenylamine and paratoluidine, and is identical with Kimich's compound (this Journal, 1876, i, 268).

*Chlorazophenine*,  $\text{C}_{36}\text{H}_{25}\text{ClN}_5$ , is obtained from parachloronitrosodiphenylamine by a similar method; it melts at  $230^{\circ}$ , and closely resembles azophenine in its properties, but is somewhat more soluble in benzene and toluene. *Tetrabromazophenine*,  $\text{C}_{36}\text{H}_{25}\text{Br}_4\text{N}_5$ , results from the action of nitrosodiphenylamine (1 part) on parabromaniline (4 parts) and parabromaniline hydrochloride (1 part) at  $100^{\circ}$ ; it melts at  $243^{\circ}$ . If metahydroxynitrosodiphenylamine is substituted for nitrosodiphenylamine in the preparation of azophenine, *hydroxyazophenine* is obtained. Dibromonitrosophenol also yields a brominated azophenine when heated at  $90^{\circ}$  with aniline and aniline hydrochloride. From these results, it is evident that nitrosodiphenylamine enters in some way into the molecule of azophenine, and that the views advanced by Witt with regard to the constitution of this compound (this vol., p. 821) must be abandoned in favour of those originally put forward by Kimich. If paranitrosodiphenylamine be represented as a quinoneoxime-derivative of the formula  $\text{C}_6\text{H}_4\langle\begin{smallmatrix} \text{NPh} \\ | \\ \text{N} \end{smallmatrix}\rangle\text{O}$ ,

the authors regard the formation of azophenine as analogous to that of quinone-anilide, and attribute to azophenine the formula

[N : NHPh : N : NHPh = 1 : 2 : 4 : 6]. This view may be considered as being confirmed in the following way:—Azophenine when heated with alcoholic ammonium sulphide and toluene at 130—140° for some hours is converted into *dihydrazophenine*,  $C_{36}H_{31}N_5$ ; this crystallises in white needles, melts at 173—174°, and is soluble in alcohol, readily soluble in chloroform and toluene, and insoluble in hydrochloric acid. Moreover, if azophenine is digested with alcohol and concentrated sulphuric acid at 100° in a reflux apparatus, it is converted into a compound,  $C_{24}H_{19}N_3O_2$ , which crystallises from aniline in silver-grey scales, red by reflected light, dissolves in concentrated sulphuric acid with a magenta colour, and yields with tin and hydrochloric acid, a colourless crystalline reduction compound; aniline and a blue dye are also produced in this reaction.

When nitrosodiphenylamine, aniline, and aniline hydrochloride in alcoholic solution are heated at 120°, two indulines are formed, one of which yields a hydrochloride readily soluble, and the second a hydrochloride sparingly soluble in hot alcohol. The latter is identical with the blue-shade induline obtained from azobenzene and aniline hydrochloride, and is formed in larger proportion by heating at 135—140°, whilst pure azophenine heated with aniline and aniline hydrochloride at 140° is almost wholly converted into it. W. P. W.

**Action of Heat on Triethylbenzylphosphonium Salts.** By N. COLLIE (*Phil. Mag.*, 24, 27—37).—A continuation of the author's researches on the decomposition of phosphonium salts by heat (*Proc.*, 1886, 164). Triethylbenzylphosphonium chloride, prepared by treating triethylphosphine with excess of benzyl chloride, first fuses when heated, and eventually decomposes without charring into ethylene and diethylbenzylphosphine. Triethylbenzylphosphonium bromide decomposes with charring into hydrogen bromide, triethylphosphonium and diethylbenzylphosphonium bromides, acetylene, and other hydrocarbons. Triethylbenzylphosphonium hydroxide gives triethylphosphine oxide and toluene. The hydrogen carbonate when heated decomposes into toluene, carbonic anhydride, and triethylphosphine oxide. The normal carbonate could not be obtained, thus showing the decrease in alkalinity produced by introducing the benzyl-group, the tetrethyl compound forming a normal compound, whilst the tetrabenzyl compound will not fix carbonic anhydride at all. Triethylbenzylphosphonium sulphate decomposes into triethylphosphine oxide, dibenzyl, and sulphurous anhydride, whilst the acetate decomposes partly into triethylphosphonium oxide and methyl benzyl ketone, partly into triethylphosphine and benzyl acetate. The oxalate gave triethylphosphonium oxide, toluene, carbonic anhydride, and carbonic oxide. It is supposed that water took part in this reaction, as no triethylphosphine was produced. These experiments show that when triethylbenzylphosphonium oxy-salts are heated, the benzyl-group is invariably separated from the phosphorus. In the cases of the chloride and bromide, the ethyl-group separates as ethylene. H. K. T.

**Action of Bromine on Bromanilic and Chloranilic Acids.** By S. LEVY and K. JEDLIČKA (*Ber.*, 20, 2318—2321).—Experiments

made by the authors confirm the result obtained by Hantzsch and Schniter (this vol., p. 925), showing that the product of the reaction between bromine and bromanilic acid is perbromacetone (Stenhouse, *Annalen*, Suppl. 8, 17). Phenylhydrazine acts on perbromacetone so vigorously that ether has to be used as a diluent; the products of the reaction are phenylhydrazine hydrobromide and bromobenzene. Bromine acts on chloranilic acid with formation of the compound  $C_6Br_8Cl_3 \cdot OH$  (Stenhouse, *loc. cit.*). When 10 grams of the latter is treated with 8 grams of barium hydroxide and 500 c.c. of water and heated to boiling, chlorodibromomethane (6 grams) and barium carbonate, bromide, and chloride are formed. When dry ammonia is passed through a solution of the compound  $C_6Br_8Cl_3 \cdot OH$  in anhydrous ether, chlorodibromomethane and dibromochloracetamide are formed.

The mother liquor obtained in the action of bromine on chloranilic and bromanilic acids contained, besides oxalic acid, chlorodibromomethane and bromoform respectively.

N. H. M.

**Galloflavin.** By R. BOHN and C. GRAEBE (*Ber.*, 20, 2327—2331).—*Galloflavin*,  $C_{13}H_6O_9$  (?), is obtained by dissolving 50 grams of gallic acid in 875 c.c. of alcohol and 1 litre of water, cooling to  $-5^\circ$  to  $+5^\circ$ , and adding 135 c.c. of 28 per cent. aqueous potash. Air is passed through for five hours. The potassium salt which separates is dissolved in hot water (at  $90^\circ$ ), and treated with acid with exclusion of air. Galloflavin separates in greenish-yellow, crystalline plates. When heated, it carbonises without melting. It dissolves sparingly in water, alcohol, and ether; alkalis and alkaline carbonates dissolve it with yellow colour; sulphuric acid dissolves it unchanged. The potassium salt,  $C_{13}H_4O_9K_2$ , is a greenish-yellow, crystalline substance, very sparingly soluble in cold water, insoluble in alcohol; when boiled with water, free galloflavin is formed. Galloflavin yields coloured insoluble salts with the oxides of aluminium and chromium. The *acetyl-derivative*,  $C_{13}H_2O_9Ac_4$ , crystallises from benzene in white needles melting at  $230^\circ$ ; it dissolves readily in glacial acetic acid and in chloroform, but is insoluble in alkaline carbonates. When galloflavin is heated with chloroacetic chloride at  $100-110^\circ$  for 15 hours, the compound  $C_{13}H_2O_9(CH_2Cl \cdot CO)_4$  is formed. This crystallises in white needles, soluble in ethyl acetate and acetic acid, very sparingly soluble in alcohol, ether, chloroform and benzene; it melts at  $210-212^\circ$ .

N. H. M.

**Ethyl Parabromobenzoate and Parabromobenzoic Acid.** By G. ERRERA (*Gazzetta*, 17, 209—213).—According to the results described previously (p. 1103), ethyl parabromobenzyl ether is obtained by the action of alcoholic potash on parabromobenzyl chloride or bromide.

In a recent paper, Elbs (this vol., p. 151) has stated that ethyl parabromobenzoate is formed in the above reaction, together with parabromobenzyl alcohol and parabromobenzoic acid as subsidiary products; the view is supported by the formation of parabromobenzoic acid by the prolonged action of boiling alcoholic potash on the supposed ethereal salt.

To decide as to the correctness of Elbs' result, ethyl parabromobenzoate was prepared by the etherification of the corresponding acid; the compound obtained differs in boiling point ( $262^\circ$ ) from parabromobenzyl ethyl ether ( $243^\circ$ ), and is saponified immediately in the cold by alcoholic potash. The formation of parabromobenzoic acid from the ether is due to oxidation.

As a further point of difference, it is noted that parabromobenzyl ethyl ether on nitration forms parabromobenzaldehyde, whilst ethyl parabromobenzoate under the same conditions yields ethyl nitrobromobenzoate,  $\text{COH}_3\text{Br}(\text{NO}_2)\cdot\text{COOEt}$  [ $\text{COOEt} : \text{NO}_2 : \text{Br} = 1 : 3 : 4$ ].

In conclusion, some details are given as to the best method of preparing parabromobenzoic acid by the oxidation of the corresponding bromotoluene.

V. H. V.

**Derivatives of Phenylamidoacetic Acid.** By O. REBUFFAT (*Gazzetta*, 17, 231—236).—*Acetylphenylamidoacetic acid*,

obtained by heating phenylamidoacetic acid with acetic anhydride in presence of benzene, crystallises in micaceous laminæ, melting at  $190\text{--}191^\circ$ , very soluble in water and alcohol, sparingly soluble in benzene.

*Benzoylphenylamidoacetic acid*,  $\text{NPhBz}\cdot\text{CH}_2\cdot\text{COOH}$ , is prepared in like manner to the above, and may be purified by means of its sodium salt, which crystallises on slow evaporation in large, tabular crystals. The acid is a white, amorphous precipitate, melting at  $63^\circ$ ; the *copper* salt is an amorphous, green precipitate.

In the course of the preparation of phenylamidoacetic acid from aniline and monochloroacetic acid, the formation of a black, resinous substance is observed, the quantity of which increases with the quantity of water in excess of a certain proportion, and the time employed in evaporating the solution for crystallising the amido-acid. Thus if one molecular proportion of monochloroacetic acid and two of aniline are heated together, this black resin is the sole product. If this substance is purified from the accompanying aniline hydrochloride and phenylamidoacetanilide residue, dissolved in hydrochloric acid, and then reprecipitated with water, an acid is obtained crystallising in micaceous scales which decompose at  $190\text{--}195^\circ$ . Analysis points to *phenylglycinephenylamidoacetic acid*,

When impure, the acid rapidly turns black; it is sparingly soluble in water, but soluble in alcohol; it readily decomposes carbonates.

V. H. V.

**Derivatives of Hydrothiocinnamic Acid.** By S. BONDZYNSKI (*Monatsh. Chem.*, 8, 349—364; compare Abstr., 1886, 325).—*Hydrothiocinnamic acid*,  $\text{CHPh} : \text{C}(\text{SH})\cdot\text{COOH}$ , obtained by heating "benzylidene-rhodanic acid,"  $\text{C}_6\text{H}_5\cdot\text{CH} : \text{C}(\text{SH})\cdot\text{CO}\cdot\text{SCN}$ , with baryta-water, forms a yellowish, crystalline powder, and melts at  $119^\circ$ . It is easily soluble in alcohol, ether, benzene, &c., almost insoluble in water. The alkaline salts are easily soluble in alcohol and water, the salts of the

heavy metals are insoluble. When treated with iodine in carbon bisulphide solution, *bisulphid-cinnamic acid*,

is obtained; this crystallises in slender, yellow needles melting at  $179^{\circ}$ . The *sodium* salt of this acid is an orange-yellow, amorphous substance easily soluble in water, quite insoluble in alcohol. The *potassium* salt is soluble in both alcohol and water. The *barium* and *magnesium* salts are easily soluble in water; the salts of the heavy metals are quite insoluble in water. Bromine acts on hydrothiocinnamic acid in the same manner as iodine. Hydriodic and hydrobromic acids do not combine with the acid.

When benzylidene-rhodanic acid is treated with a mixture of nitric and sulphuric acids, a violent action takes place, and two substances are obtained, one readily soluble in alcohol, the other sparingly soluble. The former, which crystallises in bright-yellow, rhombic prisms, is *nitrohydrothiocinnamic acid*; when purified by means of the barium salt and recrystallised from alcohol, it melts at  $240^{\circ}$ . The second, nearly insoluble substance appears to be a *nitrobenzylidene-rhodanic acid*; it melts at  $263\text{--}265^{\circ}$ . This method, however, does not give a good yield; the author therefore prepares *orthonitrohydrothiocinnamic acid* by heating together in alcoholic solution orthonitrobenzaldehyde and thiocyanic acid. The resulting orthonitrobenzylidene-rhodanic acid is a white, crystalline powder, insoluble in water, soluble in alcohol; it melts at  $188\text{--}189^{\circ}$ . When this substance is treated with baryta-water, an acid barium salt of the acid is obtained in orange crystals; it is therefore necessary to saponify the acid by heating it with excess of crystallised barium hydroxide.

When the nitro-compound is reduced with alcoholic ammonium sulphide, a small quantity of *amidohydrothiocinnamic acid* is formed. When reduced with ferrous sulphate, it yields *orthamidobenzylidene-rhodanic acid*,  $\text{C}_6\text{H}_4(\text{NH}_2) \cdot \text{CH} : \text{C}(\text{SH}) \cdot \text{CO} \cdot \text{SCN}$ ; this forms brilliant, blood-red crystals, which are completely decomposed on heating at  $265\text{--}269^{\circ}$ . The substance still retains acid properties; it is soluble in alkalis and reprecipitated by dilute acids. When heated with acetic anhydride, it gives the *diacetate*, which crystallises in yellow needles and melts at  $189^{\circ}$ . A little *monacetate* is also produced; this forms long, citron-yellow needles melting at  $280\text{--}285^{\circ}$ . Attempts to obtain orthohydrothiocinnamic acid from orthamidobenzylidene-rhodanic acid by treatment with baryta were unsuccessful, as also were endeavours to diazotise the latter substance. G. H. M.

**Paracoumaric Acid.** By G. EIGEL (*Ber.*, 20, 2527—2539).—Paracoumaric acid was prepared by the three known methods: from aloes (*Annalen*, 136, 31), from parahydroxybenzaldehyde (this Journal, 1877, ii, 893), and from paradiazocinnamic acid, and modifications are described by which the yield may be much increased. Methyl-paracoumaric acid was also prepared by Perkin's reaction from anisaldehyde (*Abstr.*, 1877, i, 40), and by the methylation of paracoumaric acid. A comparison of these acids with naringenic and methylnaringenic acids respectively establishes their identity (this vol., p. 497).

Hydromethylnaringenic acid, formed by the reduction of methyl-naringenic acid with sodium, is identical with hydromethylparacoumaric acid; it crystallises in feather-like forms, but after conversion into the sodium salt and treatment with an acid is obtained in long, colourless needles; the crystals of both forms are anhydrous. The *silver* salt,  $C_{10}H_{11}AgO_3$ , crystallises in small needles, is sparingly soluble in hot water, and when dry is unaffected by light; the *barium* salt,  $(C_{10}H_{11}O_3)_2Ba + 2H_2O$ , crystallises in cubic forms. The *methyl* salt,  $C_{11}H_{14}O_3$ , obtained in small quantity only by saturating a solution of the acid in methyl alcohol with hydrogen chloride, is readily prepared by heating the acid (1 mol.), with potassium hydroxide (2 mols.), methyl iodide (2 mols.), and some methyl alcohol at  $140^\circ$  for an hour; it boils at  $265-270^\circ$ , solidifies at  $0^\circ$  to a crystalline mass which melts at  $38^\circ$ , and is identical with methyl hydromethylparacoumarate.

When dry paracoumaric acid in ethereal solution is treated with bromine (1 mol.), and the solvent is removed by evaporation in a current of air, colourless crystals of what is perhaps a paracoumaric acid dibromide are obtained; these melt at  $97-101^\circ$  and decompose on drying. *Bromoparacoumaric acid dibromide*,

is formed when paracoumaric acid dissolved in acetic acid or absolute ether is treated with an excess of bromine; it crystallises from chloroform in needles and melts at  $188^\circ$ . On treatment with alcoholic potash, it yields *bromoparavinyphenol dibromide*,

This compound is crystalline, melts at  $108^\circ$ , and yields an *acetyl*-derivative,  $C_8H_6Br_3OAc$ , melting at  $94^\circ$ .

*Methylparacoumaric acid dibromide*,  $OMe \cdot C_6H_4 \cdot CHBr \cdot CHBr \cdot COOH$ , is prepared by the action of bromine on methylparacoumaric acid in equimolecular proportions; chloroform is used as a solvent, and must be removed by evaporation at the ordinary temperature. It forms colourless crystals, which melt at  $149^\circ$  when heated rapidly, and at  $168^\circ$  when slowly heated; heat readily decomposes it. The *methyl* salt has been already described (this vol., p. 488); when treated with alcoholic potash, it yields two acids crystallising in needles, one of which is soluble in hot water, and melts at  $158-168^\circ$ , whilst the second is soluble in hot alcohol, and melts at  $127-132^\circ$ . If methylparacoumaric acid dibromide is heated with aqueous potash, *bromoparavinylianisoil*,  $OMe \cdot C_6H_4 \cdot CH : CHBr$ , is obtained; this crystallises from alcohol in scales, melts at  $54.5^\circ$ , is volatile with steam, and has an odour and taste resembling that of anise and fennel.

On treatment with an excess of bromine in chloroform solution, methylparacoumaric acid yields *bromomethylparacoumaric acid dibromide*,  $OMe \cdot C_6H_3Br \cdot CHBr \cdot CHBr \cdot COOH$ , which crystallises from ether or chloroform in needles, melts at  $162^\circ$ , and is decomposed by alcohol and water. When heated with 30 per cent. aqueous potash, it is converted into *bromoparacetyleneanisoil*,  $OMe \cdot C_6H_3Br \cdot C : CH$ . This compound crystallises from alcohol in scales, melts at  $75^\circ$ , is volatile with steam, and yields a greenish-yellow, feebly explosive precipitate with ammoniacal cuprous chloride solution.

W. P. W.

**Homo-orthophthalimide.** By G. PULVERMACHER (*Ber.*, **20**, 2492—2499; compare this vol., pp. 50, 725).—When a solution of homo-orthophthalimide (1 mol.) and sodium (2 mols.) in alcohol is digested with ethyl iodide (2 mols.) at 100°, *α*-diethylhomo-orthophthalimide,  $C_9H_5Et_2NO_2$ , is obtained; this crystallises from alcohol in white scales, melts at 144°, and is soluble in alkalis. By the further action of ethyl iodide and alcoholic potash on this compound at 100°, triethylhomo-orthophthalimide,  $C_9H_4Et_3NO_2$ , is formed; this is a glistening, white, crystalline mass, which melts at 50°, and is extremely soluble in all ordinary solvents, but is insoluble in alkalis.

*Homo-orthophthalethylimide*,  $C_6H_4\langle\begin{smallmatrix} CH_2\cdot CO \\ CO\cdot NEt \end{smallmatrix}\rangle$ , is prepared by distilling a solution of homo-orthophthalic acid in ethylamine. It crystallises in yellowish needles, melts at 105°, and is readily soluble in all ordinary solvents and in alkalis. When ethylated, it yields triethylhomo-orthophthalimide, whose constitution therefore is probably represented by the formula  $C_9H_4\langle\begin{smallmatrix} CEt_2\cdot CO \\ CO\cdot NEt \end{smallmatrix}\rangle$ . Diazobenzene chloride and benzaldehyde react with the ethylimide, and form compounds analogous to those obtained by the action of these substances on homo-orthophthalimide (*loc. cit.*); *homo-orthophthalethylimidazobenzene*,  $C_{11}H_{10}NO_2\cdot N_2Ph$ , crystallises from alcohol in yellow needles melting at 139°, and *benzalthomo-orthophthalethylimide*,

crystallises from acetic acid in stellate groups of yellow needles, melting at 97°.

*α*-Diethylhomo-orthophthalic anhydride,  $C_9H_4Et_2O_3$ , is obtained when diethylhomo-orthophthalimide is heated with fuming hydrochloric acid at 230°. It crystallises in colourless scales, melts at 53°, and is sparingly soluble in ammonia, but soluble in warm aqueous alkalis. The *barium* salt,  $C_9H_4Et_2O_4Ba$ , crystallises in white, silky scales; the *silver* salt,  $C_9H_4Et_2O_4Ag_2$ , was also prepared. When mixed with soda-lime and distilled over lime, the anhydride yields a red oil, from which diethyltoluene,  $C_6H_5\cdot CHEt_2$  (b. p. = 178°), can be separated by fractionating between 170—180°. If the solution of the anhydride in aqueous potash is treated in the cold with hydrochloric acid, *α*-diethylhomo-orthophthalic acid,  $COOH\cdot C_6H_4\cdot CEt_2\cdot COOH$ , separates as a crystalline precipitate, which after crystallisation from alcohol, melts at 148° and is converted into the anhydride.

*α*-Dibenzylhomo-orthophthalimide,  $C_9H_5(C_6H_5)_2NO_2$ , obtained by digesting homo-orthophthalimide with sodium and benzyl chloride in alcoholic solution, crystallises in yellow scales and melts at 174°. Unlike the diethylimide, it is insoluble in alkalis, and is only attacked by hydrochloric acid with difficulty even at 300°, when it yields a compound which seems to be the *anhydride* of *α*-dibenzylhomo-orthophthalic acid; this crystallises in yellow needles, melts at 191°, and is sparingly soluble in alkalis.

*Homo-orthophthalbenzylimide*,  $C_{16}H_{13}NO_2$ , obtained by distilling homo-orthophthalimide with benzylamine, forms yellowish-green crystals which melt at 127°, and are soluble in alkalis. When heated with

benzyl chloride and an alkali, it yields  $\alpha$ -dibenzylhomo-orthophthalbenzyl-imide (tribenzylhomo-orthophthalimide),  $C_9H_4(C_7H_7)_3NO_2$ , identical with that prepared in a similar manner from dibenzylhomo-orthophthalimide; this crystallises in yellowish-white scales, and melts at  $109^\circ$ .

W. P. W.

**Homo-orthophthalimide and the Homologues of Isoquinoline.** By S. GABRIEL (*Ber.*, **20**, 2499—2506).—*Ethyl homo-orthophthalate*,  $COOEt \cdot C_6H_4 \cdot CH_2 \cdot COOEt$ , is obtained either by treating the silver salt of the acid with ethyl iodide, or by saturating an alcoholic solution of the acid with hydrogen chloride. It is a thick oil with a faint, aromatic odour, boils at  $291.5$ — $292.5^\circ$ , and is not acted on when treated with sodium in alcoholic solution and then digested with ethyl iodide.

$\alpha$ -Methylhomo-orthophthalonitrile,  $CN \cdot C_6H_4 \cdot CHMe \cdot CN$ , is prepared by treating a lukewarm alcoholic solution of orthocyanobenzyl cyanide (5.7 grams) with methyl iodide (3 c.c.) and an alcoholic solution of potassium hydroxide (2.25 grams), cooling the mixture when necessary, and finally heating at  $100^\circ$  to complete the reaction; the residue left on distilling off the alcohol is then treated with water, extracted with ether, and the oil remaining after the evaporation of the ether is purified by distillation. It crystallises in large triclinic forms,  $a : b : c = 0.9449 : 1 : 1.0809$ ;  $\alpha = 97^\circ 2'$ ;  $\beta = 103^\circ 12'$ ;  $\gamma = 87^\circ 11'$ ; melts at  $36$ — $37^\circ$ , boils at  $284$ — $286^\circ$ , is only slightly volatile with steam, and is readily soluble in the ordinary solvents, sparingly soluble in light petroleum. When the nitrile is dissolved in sulphuric acid, heated at  $100^\circ$  until the reaction is complete, and the product poured into water—

$\alpha$ -Methylhomo-orthophthalimide,  $C_6H_4 \left\langle \begin{smallmatrix} CHMe \cdot CO \\ CO - NH \end{smallmatrix} \right\rangle$ , is obtained; this crystallises in compact, glistening prisms, melts at  $145^\circ$ , distils without decomposition, and dissolves in alkalis. On digestion with methyl iodide and alcoholic potash, this compound is converted into trimethylhomo-orthophthalimide (this vol., p. 50). When the methyl-imide is heated with fuming hydrochloric acid at  $190$ — $200^\circ$  for two hours, it yields  $\alpha$ -methylhomo-orthophthalic acid; this is a crystalline powder, which melts at  $146$ — $147^\circ$  and dissolves in ammonia and alkalis. The silver salt,  $C_{10}H_8Ag_2O_4$ , was analysed.

Methyldichlorisoquinoline,  $C_6H_4 \left\langle \begin{smallmatrix} CMe : CCl \\ -CCl : N- \end{smallmatrix} \right\rangle$ , is prepared by heating  $\alpha$ -methylhomo-orthophthalimide (5 grams) with phosphorus oxychloride (15 c.c.) at  $190$ — $200^\circ$  for four hours, extracting the product with water, and heating the crystalline residue with very dilute aqueous soda; the insoluble methyldichlorisoquinoline is then purified by distillation and crystallised from alcohol. It crystallises in long, white needles, and melts at  $101$ — $102^\circ$ . On treating the alkaline filtrate with an acid, it yields methylchloroxyisoquinoline,  $C_6H_4 \left\langle \begin{smallmatrix} CMe : C(OH) \\ -CCl : N- \end{smallmatrix} \right\rangle$  or  $C_6H_4 \left\langle \begin{smallmatrix} CHMe \cdot CO \\ -CCl : N- \end{smallmatrix} \right\rangle$ , which crystallises from acetic acid in needles, and melts at  $224^\circ$  with frothing.

Homo-orthophthalonitrile, when ethylated under conditions similar

to those detailed for the methyl-derivative, yields  $\alpha$ -ethylhomo-orthophthalonitrile,  $\text{CN} \cdot \text{C}_6\text{H}_4 \cdot \text{CHEt} \cdot \text{CN}$ , which crystallises in short, compact prisms, melts at  $39\text{--}40^\circ$ , and distils at  $293\text{--}295^\circ$ . On treatment with sulphuric acid, the ethyl nitrile is converted into  $\alpha$ -ethylhomo-orthophthalimide,  $\text{C}_{11}\text{H}_{11}\text{NO}_2$ ; this crystallises in colourless needles, melts at  $97\text{--}99^\circ$ , dissolves in alkalis, and when heated with phosphorus oxychloride yields ethyldichlorisoquinoline,

Orthocyanobenzyl cyanide, when heated at  $80^\circ$  with concentrated sulphuric acid, or at  $100^\circ$  with fuming hydrochloric acid, is converted into homo-orthophthalimide. W. P. W.

**Transformation of Homologues of Indole into those of Quinoline.** By G. MAGNANINI (*Gazzetta*, 17, 246—254).—Though indole and pyrroline are regarded as possessing an analogous constitution, yet this view has not as yet been confirmed by experimental evidence. Ciamician and Dennstedt have shown that derivatives of pyrroline are readily converted by chloroform or bromoform into those of pyridine; by the same reaction, derivatives of indole should be converted into those of quinoline. In this paper, it is shown that methylketole and skatole yield substances which are in all probability halogen-derivatives of quinoline. For example, methylketole when heated with chloroform in presence of alcoholic soda is converted by a violent reaction into a chloroquinaldine thus:  $\text{C}_9\text{H}_9\text{N} + 2\text{NaOH} + \text{CHCl}_3 = \text{C}_{10}\text{H}_8\text{ClN} + 2\text{NaCl} + 2\text{H}_2\text{O}$ ; the product is best purified by means of the picrate, and subsequent decomposition of the salt formed by potash.

*Chloroquinaldine*,  $\text{C}_9\text{H}_8\text{NMeCl}$ , crystallises in delicate, white needles, melting at  $71\text{--}72^\circ$ , insoluble in water, very soluble in alcohol and ether; the *picrate* forms sparingly soluble, yellow needles melting at  $223^\circ$  with decomposition.

*Bromoquinaldine*,  $\text{C}_9\text{H}_8\text{NMeBr}$ , obtained from bromoform under identical conditions, crystallises in white needles melting at  $78^\circ$ : system, monoclinic;  $a : b : c = 0.91 : 1 : 0.624$ ;  $\beta = 64^\circ 31' 33''$ . The *picrate* melts at  $224\text{--}225^\circ$ .

In like manner, skatole yields a *chloro-* and *bromo-lepidine*; the former crystallises in delicate needles melting at  $54\text{--}55^\circ$ , and the *picrate* melts at  $208^\circ$ ; the latter melts at  $58.5\text{--}59.5^\circ$ , and its *picrate* at  $214\text{--}215^\circ$  with decomposition.

The above derivatives are not identical with the methyl halogen-derivatives previously described; the author considers that the chloroquinaldine from methylketole has the constitution  $\text{Me} : \text{Cl} = 2' : 3'$ , while the chlorolepidine from skatole has the constitution  $\text{Cl} : \text{Me} = 3' : 4'$ . V. H. V.

**Chlorobromonaphthalene.** By J. GUARESCHI and P. BIGINELLI (*Chem. Centr.*, 1887, 518—519).—By the action of bromine (1 mol.) on  $\alpha$ -monochloronaphthalene (1 mol.), and by the action of chlorine on  $\alpha$ -monobromonaphthalene, the same dihalogen-naphthalenes are

obtained; in both cases two chlorobromonaphthalenes,  $C_{10}H_6ClBr$ , melting at  $66-67^\circ$  and at  $119-119.5^\circ$  are formed. *Parachlorobromonaphthalene* melts at  $66-67^\circ$ , boils at  $303^\circ$  (uncorr.), dissolves in ether and acetic acid, and sublimes in needles; when oxidised with chromic acid (two parts) in acetic acid solution, chlorobromonaphthaquinone and parachlorobromophthalide are formed. The quinone (probably *parachlorobromo- $\alpha$ -naphthaquinone*) crystallises from alcohol in yellow needles of a silky lustre melting at  $166.5-167^\circ$ . *Parachlorobromophthalide* crystallises in tabular, rhombohedral crystals melting at  $179.5-180^\circ$ .

The derivative melting at  $119-119.5^\circ$  forms thin, lustrous plates, more sparingly soluble in alcohol and glacial acetic acid than its isomeride; when oxidised with chromic acid,  $\alpha$ -chlorophthalic acid, melting at  $183-184^\circ$ , is formed (Guareschi, Abstr., 1886, 353). In the compound melting at  $119^\circ$ , the halogen is therefore contained in both benzene nuclei.

N. H. M.

**Nitrosamines.** By O. FISCHER and E. HEPP (*Ber.*, 20, 2471—2478).—When an alcoholic solution of  $\beta$ -naphthylethyl nitrosamine, cooled in ice, is treated with alcoholic hydrogen chloride,  $\alpha$ -nitroso- $\beta$ -ethylnaphthylamine,  $[NO : NH_2 = 1 : 2]$ , is obtained; this crystallises from benzene in well-formed, flat tables, melts at  $120-121^\circ$ , and yields salts readily soluble in water. On the addition of potassium nitrite to the solution of the base in dilute sulphuric acid, a nitrosamine is formed, and crystallises in long, hair-like needles, whilst on reduction with tin and hydrochloric acid, or allowing a solution of the base in alcoholic hydrogen chloride to remain at  $10-15^\circ$  for some time, or on treating  $\beta$ -naphthylethyl nitrosamine with alcoholic hydrogen chloride at the ordinary temperature, ethenyl- $\alpha$ - $\beta$ -naphthylenediamine,  $C_{12}H_{10}N_2$  (this vol., p. 729), is obtained. The *hydrochloride* of the anhydro-base,  $C_{12}H_{10}N_2 \cdot HCl + 2H_2O$ , crystallises in slender, colourless needles, and is sparingly soluble in water, and the base itself is identical with that prepared by Liebermann and Jacobson (Abstr., 1882, 521).

The base obtained from  $\beta$ -phenylnaphthyl nitrosamine by treating its alcoholic solution in the cold with alcoholic hydrogen chloride, is identical with naphthaphenazine (this vol., p. 591); the yield amounts to 10 per cent.

*Nitrosoaniline*,  $C_6H_6N_2O$ , is formed when nitrosophenol (1 part) is heated with ammonium chloride (5 parts) and ammonium acetate (10 parts) at  $100^\circ$  for half an hour; the product is then poured into water, and the dark-green, crystalline precipitate is purified by crystallisation from benzene. It forms steel-blue, curved needles, and melts at  $173-174^\circ$ . Like nitrosodimethylaniline, it yields sodium nitrosophenol and ammonia, when boiled with aqueous soda. Although nitrosoaniline could not be obtained by the action of ammonia on nitrosophenol, it is possible to prepare  $\alpha$ -nitroso- $\beta$ -ethylnaphthylamine by heating  $\alpha$ -nitroso-naphthol with ethylamine at  $100^\circ$ , and the authors suggest that Ilinski's orthonaphthalene- $\alpha$ -oxime- $\beta$ -imide (Abstr., 1886, 474) should be regarded as  $\alpha$ -nitroso- $\beta$ -naphthylamine.

When nitrosophenylglycocine (Abstr., 1878, 795) is dissolved in 2 parts of alcohol, treated with 3 parts of alcoholic hydrogen chloride, and allowed to remain for 12 hours, a crystalline mass is obtained which is precipitated from cold alcoholic solution by ether in yellow scales of the composition  $C_6H_6N_3OCl$ . The compound explodes when heated, is decomposed by water with the evolution of two-thirds of its nitrogen, and dissolves in concentrated hydrochloric acid without decomposition. Its *platinochloride*,  $(C_6H_6N_3OCl)_2 \cdot PtCl_4$ , crystallises in yellow scales, and decomposes on boiling with water with a separation of platinum. The compound is regarded as the diazo-salt of phenylhydroxylamine, since the aqueous solution after boiling reduces silver and cupric salts, and the compound when added to boiling absolute alcohol decomposes with evolution of nitrogen and an odour of aldehyde, and after distilling off the alcohol it yields a residue from which a pale-yellow oil can be separated by steam distillation. The oil,  $C_{12}H_{12}N_2O_2$ , has all the properties of a feeble base, and forms a *hydrochloride* crystallising in white prisms. This compound also reduces an ammoniacal silver solution, slowly reduces Fehling's solution, and is wholly converted into benzidine on treatment with tin and hydrochloric acid. It is regarded as diphenyldihydroxylamine,  $OH \cdot NH \cdot C_6H_4 \cdot C_6H_4 \cdot NH \cdot OH$  [ $NH \cdot OH : C_6H_4 = 1 : 4$ ].

**Derivatives of Camphor.** By L. BALBIANO (*Gazzetta*, 17, 240—245).—It has recently been shown by the author (this vol., p. 1049) that the reaction of phenylhydrazine on camphor is essentially different from that of the same reagent on substances formed on the ethylenic oxide type, such as epichlorhydrin. In continuation of experiments on the derivatives of camphor, it is shown that chloro- and bromo-camphor, on oxidation with alkaline permanganate, yield camphoric acid, thus confirming the results of Armstrong (*Ber.*, 12, 1358) and Schiff (*Gazzetta*, 9, 324) in opposition to those of Cazeneuve. The inertness of derivatives of camphor towards hydroxylamine affords no evidence as to the absence of the carbonyl-group in these compounds, inasmuch as the reaction will not proceed in the presence of solvents, and even phenylhydrazine under these conditions will not always react, and, secondly, some compounds containing two carbonyl-groups, such as benzoylacetone and phenanthraquinone, react only with partial substitution of the isonitroso-residue.

V. H. V.

**Strophanthin.** By T. R. FRASER (*Pharm. J. Trans.* [3], 18, 69).—It has been found that the substance obtained by the former process for the preparation of strophanthin, is resolved by lead acetate into at least two others—one an extremely active glucoside, and the other an acid for which the name *kombic acid* is suggested. To obtain pure strophanthin, the following is the process ultimately adopted. The product obtained in the earlier process is dissolved in water, tannic acid is added, and the tannate digested with recently precipitated lead oxide. The alcoholic extract from this is precipitated with ether, the precipitate dissolved in weak alcohol, and carbonic anhydride is passed through the liquid for several hours to remove lead. The solution is then evaporated at a low temperature and dried in a

vacuum. Strophanthin thus obtained is imperfectly crystalline, neutral, intensely bitter, freely soluble in water, less so in rectified spirit, and nearly insoluble in ether and chloroform. It burns without residue, and the results of analysis agree fairly with the formula  $C_{20}H_{34}O_{10}$ . Nearly all acid reagents cause its solutions to become turbid, and the liquid is then found to contain glucose. This decomposition is also produced by hydrogen sulphide, especially when heated. Many organic acids, and all mineral acids, except carbonic, resolve strophanthin, even in the cold, into glucose and a substance which the author names *strophanthidin*. Therefore, neither hydrogen sulphide nor acids (especially mineral acids) should be used in the preparation of strophanthin. The crystalline product obtained by Hardy and Gallois in 1877, by extracting the seeds with rectified spirit acidified with hydrochloric acid, was supposed by them to be strophanthin; and as it failed to yield glucose when heated with dilute sulphuric acid, they inferred that strophanthin is not a glucoside. But there can be little doubt, both from the mode of its preparation and also from its reactions, that their product was strophanthidin. R. R.

**Strophanthus and Strophanthin.** By E. MERK (*Pharm. J. Trans.* [3], 18, 72).—When the fatty oil in the seeds of *Strophanthus* is extracted by ether previously to treating them with alcohol, the ethereal solution will also contain a certain amount of strophanthin, and to this circumstance the small activity of the alcoholic tincture of strophanthus of commerce is in part due. The author obtains strophanthin as a white, crystalline powder which melts at  $185^{\circ}$  and volatilises without residue. R. R.

**Strophanthus and Strophanthin.** By W. ELBORNE (*Pharm. J. Trans.* [3], 18, 219).—The following process for preparing strophanthin obviates certain objections to which Gerrard's process is open. The seed in fine powder is mixed into a thin paste with water to which 10 per cent. of alcohol has been added; this is set aside for 12 hours, then agitated with six times its volume of absolute alcohol, and, after six hours, is filtered. The residue is washed with rectified spirit, and the washings added to the filtrate, and from the whole four-fifths of the alcohol is removed by distillation. To the remainder, solution of lead subacetate is added, and the mixture is heated to  $100^{\circ}$ , filtered, and allowed to cool. The lead is then removed from the cold filtrate by precipitation with hydrogen sulphide; the filtrate is agitated with amyl alcohol, which dissolves out the strophanthin and yields it on evaporation as a colourless film that crumbles on removal into a non-deliquescent, white powder. R. R.

**Chlorophyll.** By A. TSCHIRCH (*Chem. Centr.*, 1887, 669).—Phyllocyanic acid is obtained by dissolving crude chlorophyllan in concentrated hydrochloric acid, and precipitating with excess of water. This substance can also be obtained in minute crystals from solutions in alcohol and ether. Its spectrum agrees with that of chlorophyllan; it also gives a zinc compound containing 11.07 per cent. of the metal; with alkalis it forms very soluble combinations. The formula

$C_{25}H_{47}N_2O_6$  is provisionally assigned to this compound. The proportion of phyllocyanic acid present, which appears in leaves in the form of chlorophyll, can be estimated by the chemical or spectroscopical methods. In the dark-brown leaves of the *Fuchsia ovata*, the proportion of the absorbing chlorophyll matter varied from 2.5 to 5 per cent. of the dried substance, apart from the ash of the leaves; the presence of copper diminishes the fluorescence. V. H. V.

**Preparation of Picrocarmine.** By L. GEDÖLST (*Chem. Centr.*, 1887, 599).—In order to prepare picrocarmin for microscopical purposes the following method is proposed. About half a gram of carmine is dissolved in 100 c.c. of water containing 5 c.c. of a 1 per cent. solution of soda; the solution is then boiled, filtered, and made up again to 100 c.c. To neutralise the liquid, it is mixed with an equal volume of water; a 1 per cent. solution of picric acid is then added, which causes at first a turbidity which subsequently disappears; the non-disappearance of the turbidity serves as an indication that the point of neutralisation has been passed. V. H. V.

**Diastase.** By L. SCHÄRTLER (*Chem. Centr.*, 1887, 534).—Pure diastase is prepared as follows:—10 kilos. of light, ground malt, 50 grams of sodium hydrogen carbonate, and 12 to 14 litres of water are heated at 40°, digested for two hours, the liquid drawn off, and 6 to 8 litres more water added. After some time, the second supply of water is drawn off, added to the first liquor, heated at 65°, and passed through a sieve; twice the volume of alcohol is added and the clear solution drawn off; the residue containing the diastase is treated with a little warm distilled water, the solution separated from the undissolved albuminoids, and precipitated with alcohol. It is dried at 50° and then powdered. The yield is 1 to 1½ per cent. N. H. M.

**Pyridinepolycarboxylic Acids.** By J. WEBER (*Annalen*, 241, 1—32).—Carbodinicotinic acid, or 2:3:5-pyridinetricarboxylic acid, cannot be obtained directly from pyridinetetracarboxylic acid, but it can be prepared by starting from symmetrical lutidinedicarboxylic acid. On oxidation with the theoretical quantity of potassium permanganate, *α*-methylcarbodinicotinic acid (2:3:5 *α*-picolinetricarboxylic acid),  $C_5NHMe(COOH)_3$ , is formed. It is isolated by acidifying the crude product with acetic acid and adding barium chloride. The precipitate is washed and decomposed by a slight excess of dilute sulphuric acid. On evaporating the filtrate, *α*-methylcarbodinicotinic acid is deposited in crystalline masses. The acid crystallises with 1 mol.  $H_2O$ . It turns yellow at 170°, and melts with decomposition at 226°, forming a crystalline sublimate; if kept at a temperature of 150° for some time, it is converted into *α*-methylidinicotinic acid. The free acid forms precipitates in solutions of silver, lead, mercurous, cadmium, and zinc salts, also with barium and calcium salts in the presence of ammonia. The copper and silver salts, and the acid potassium salt,  $C_5NHMe(COOH)_3 + C_5NHMe(COOH)_2 \cdot COOK + 6H_2O$ , are crystalline.

*α*-Methylidinicotinic acid,  $C_5NH_2Me(COOH)_2 + H_2O$  [Me : (COOH)<sub>2</sub>

= 2:3:5], is soluble in hot water, and is deposited on slowly cooling the solution in needle-shaped crystals. The acid melts between 245° and 250° with decomposition. The neutral solution gives crystalline precipitates with lead ( $C_5H_5NO_4Pb + 2H_2O$ ) and cadmium salts, and amorphous precipitates with the salts of silver and mercury.

The *hydrochloride*,  $C_5H_7NO_4 \cdot HCl + 1$  or  $1\frac{1}{2}H_2O$ , forms transparent crystals which rapidly become opaque on exposure to the air.

*Carbodinicotinic acid*,  $C_5NH_2(COOH)_3 + 1\frac{1}{2}H_2O$ , is formed by the oxidation of the preceding acid with potassium permanganate. Nitrate of silver is added to the crude solution, the precipitate is dissolved in the minimum quantity of boiling nitric acid, and on cooling, the acid silver salt crystallises out. The free acid is liberated by the action of hydrogen sulphide on the silver salt. It dissolves freely in hot water, and forms colourless crystals. Prolonged heating at 150° completely converts the acid into dinicotinic acid which melts at 323° with decomposition.

*β-Carbocinchomeric acid* (3:4:5-pyridinetricarboxylic acid),  $C_5NH_2(COOH)_3 + 3H_2O$ , can be prepared by converting 4-phenylpyridinetetracarboxylic acid into 4-phenyldinicotinic acid and oxidising the phenyl in this acid to carboxyl. A much better yield is obtained by heating pyridinepentacarboxylic acid or its acid potassium salt,  $C_5N(COOH)_3(COOK)_2 + 3\frac{1}{2}H_2O$ . The crude product is converted into the silver salt, which is decomposed by hydrochloric acid yielding a mixture of cinchomeric and β-carbocinchomeric acids. The former is sparingly soluble in water. β-Carbocinchomeric acid crystallises in plates and melts with decomposition at 261°. The silver salt,  $C_5NH_2(COOAg)_3 + 2H_2O$ , and the calcium and barium salts are crystalline.

*Berberonic acid* is neither identical with β-carbocinchomeric acid nor with carbodinicotinic acid. It must therefore be regarded as α'-carbocinchomeric acid.

Symmetrical and unsymmetrical pyridinetetracarboxylic acids have been prepared, but not the "consecutive" isomeride 2:3:4:5-pyridinetetracarboxylic acid. Lutidinetricarboxylic acid is converted into 2:4-dimethyldinicotinic acid [ $Me_2:(COOH)_2 = 2:4:3:5$ ] at 175°; this crystallises in yellow needles containing 2 mols.  $H_2O$ . The acid loses its water of crystallisation at 130° and melts at 255° with decomposition. The *hydrochloride* crystallises with 1 or  $\frac{1}{2}$  mol.  $H_2O$ . The *platinohchloride*,  $(C_5NH_9O_4)_2 \cdot H_2PtCl_6$ , forms orange-coloured plates, and is decomposed by water. On oxidation with potassium permanganate, 2:4-dimethyldinicotinic acid yields a mixture of pyridinetetracarboxylic and 4-methylcarbodinicotinic acids. The tetracarboxylic acid [ $(COOH)_4 = 2:3:4:5$ ] crystallises in prisms containing 2 or 3 mols.  $H_2O$ . At 120° it begins to lose carbonic anhydride, yielding β-carbocinchomeric acid. The *barium salt*,  $C_5NHO_8Ba_2 + 4H_2O$ , is precipitated on adding barium chloride to a solution of ammonium pyridinetetracarboxylate. The *acid silver salt*,

is precipitated on the addition of silver nitrate to the acid in the presence of a small quantity of nitric acid.

**4-Methylcarbodinicotinic acid** or **2:3:5-picolinetricarboxylic acid**,  $[\text{Me} : (\text{COOH})_3 = 4 : 2 : 3 : 5]$ , is less soluble in water than the tetracarboxylic acid. It crystallises with 1 mol.  $\text{H}_2\text{O}$  in needles and with 2 mols.  $\text{H}_2\text{O}$  in prisms. When the acid is heated at  $205^\circ$ , it turns yellow and slowly loses carbonic anhydride, forming a black porous mass; at  $258\text{--}260^\circ$  a rapid evolution of gas takes place, and the mass swells up to three or four times its original volume. The free acid produces in silver, lead, copper, and mercurous salts precipitates which become crystalline after a time. In presence of ammonia, the acid gives crystalline precipitates with calcium and barium salts. In hot solutions, cadmium sulphate produces a crystalline precipitate which redissolves on cooling. Ferrous sulphate gives rise to a deep-red coloration. The constitution of the acid is verified by the fact that the calcium salt on dry distillation yields the  $\gamma$ -picoline described by Lange (Abstr., 1886, 256). W. C. W.

**New Dimethoxyquinoline.** By G. GOLDSCHMIEDT (*Monatsh. Chem.*, **8**, 342—348).—In the course of experiments made to ascertain the position of the methoxy-groups in papaverine, the author prepared a dimethoxyquinoline from the nitro-compound of veratric acid,  $\text{COOH} \cdot \text{C}_6\text{H}_3(\text{OMe})_2 = (1 : 3 : 4)$ , by reducing this with tin and hydrochloric acid, and directly condensing the stannochloride of amidoveratric acid with glycerol, according to Skraup's method.

The dimethoxyquinoline so obtained was an oil, the boiling point of which was not determined. The *hydrochloride* obtained by dissolving the base in dilute hydrochloric acid forms large, white needles, easily soluble in water, sparingly in alcohol. The *platinochloride* is a bright yellow, crystalline powder. The *picrate* is obtained in slender, yellow needles, which melt at  $257^\circ$  with violent decomposition. The *chromate* consists of a bright yellow, crystalline powder.

The position of the nitrogen to the methoxy-groups in this compound is not certain, since the position of the nitro-group in the nitroveratric acid is not definitely known, but the most probable position is  $[\text{OMe} : \text{OMe} : \text{NO}_2 = 2 : 3 : 4]$ . G. H. M.

**Synthesis of Hydroxyquinolinecarboxylic Acid.** By E. LIPPMANN and F. FLEISSNER (*Monatsh. Chem.*, **8**, 311—326).—The preparation and properties of this acid have been previously described (this vol., p. 63); the authors, however, find that a larger yield is obtained when a smaller quantity of potassium hydroxide is used than was previously recommended. The pyridinedicarboxylic acid obtained by oxidation with alkaline permanganate has now been identified with Hoogewerff and van Dorp's quinolinic acid, since when heated it loses carbonic anhydride, and is converted into nicotinic acid. This acid must therefore be orthohydroxyquinolinecarboxylic acid. When brominated, the acid yields dibromhydroxyquinoline.

When *o*-hydroxyquinolinecarboxylic acid is treated with nascent hydrogen in acid solution, it yields *tetrahydrohydroxyquinolinecarboxylic acid*. This forms brilliant, quadratic crystals, which melt at  $265^\circ$  with decomposition; it is sparingly soluble in water and alcohol,

insoluble in benzene, ether, or chloroform. The aqueous solution has an acid reaction, reduces silver nitrate, and gives precipitates with salts of the heavy metals. Iron salts give a characteristic cherry-red coloration with the acid solution. Dilute nitric acid gives the nitrate, which forms brownish-yellow needles.

The *sulphate* and *acetate* are sparingly soluble in water. The *nitroso*-compound forms a white crystalline precipitate melting at  $195^{\circ}$ , which is slightly soluble in water or dilute acid, with a cherry-red coloration. When treated with ethyl iodide and alcohol, the tetrahydro-acid gives the *hydriodide* of *ethyltrihydrohydroxyquinolinecarboxylic acid*, which forms large white needles, easily soluble in hot water, more sparingly in cold. *Ethyltrihydrohydroxyquinolinecarboxylic acid* is obtained in beautiful prisms, when the hydriodide is decomposed with ammonia; it melts at  $220^{\circ}$ , and is very sparingly soluble in all solvents. Measurement of the crystals gave  $a : b : c = 1 : 1.510 : ?$ .

*Parahydroxyquinolinecarboxylic acid* is obtained when parahydroxyquinoline, soda, and carbon tetrachloride are mixed in alcoholic solution, and the whole boiled for 2 to 3 hours. When purified, the acid separates as a white, flocculent precipitate, which melts at  $220^{\circ}$ , and gives a blood-red coloration with iron chloride. The *barium* salt forms slightly soluble, stellate prisms; the *copper*, *silver*, and *lead* salts are almost absolutely insoluble. The *hydrochloride* obtained by dissolving the acid in dilute hydrochloric acid is easily soluble in hot water, sparingly in cold; when dried over lime, it does not lose hydrochloric acid, thus differing from the analogous ortho-compound. The *platinochloride* is a dark-yellow, crystalline powder. Attempts to form a *hydro-acid* were unsuccessful. When oxidised with alkaline potassium permanganate, the acid yields quinolinic acid, so that this acid must also be regarded as a parahydroxyquinolinecarboxylic acid.

G. H. M.

**Tetramethyldiquinolyline from Benzidine.** By C. SCHESTOPAL (*Ber.*, 20, 2506—2510).—*Tetramethyldiquinolyline*,  $C_{22}H_{20}N_2$ , is obtained by heating benzidine (1 mol.) with acetone (4 mols.) and concentrated hydrochloric acid at  $180^{\circ}$  for two days, and subsequently precipitating the base with an alkali; methane is formed during the reaction. A second method of preparation consists in saturating a mixture of acetone and paraldehyde in molecular proportions with hydrogen chloride, and after some hours heating the product with benzidine and concentrated hydrochloric acid in a reflux apparatus. The base crystallises in nacreous scales, melts at  $232^{\circ}$ , and is insoluble in water, sparingly soluble in ether, and readily soluble in alcohol. The *hydrochloride*,  $C_{22}H_{20}N_2 \cdot 2HCl$ , crystallises in white, glistening needles, and is readily soluble in water, sparingly soluble in alcohol; the *sulphate*,  $C_{22}H_{20}N_2 \cdot H_2SO_4$ , crystallises from water in small, white needles, and from alcohol in large, rhombic prisms; the *dichromate*,  $C_{22}H_{20}N_2 \cdot H_2Cr_2O_7$ , crystallises in small, orange-yellow needles, which become brown on exposure to light, and are sparingly soluble in water; the *platinochloride*,  $C_{22}H_{20}N_2 \cdot H_2PtCl_6$ , crystallises in flat, reddish-yellow needles, and the *picrate* is insoluble in water and cold alcohol. The *methioidide*,  $C_{22}H_{20}N_2 \cdot 2MeI$ , crystallises in yellow needles, melts at about  $270^{\circ}$  with decomposition, and is readily soluble in water and alcohol,

insoluble in ether; the *ethiodide*,  $C_{22}H_{20}N_2 \cdot 2EtI$ , crystallises in large, flat, straw-coloured needles, melts at  $158^\circ$  with decomposition, and is soluble in alcohol and water, insoluble in ether; the hydrochloride of the *chloriodide*,  $C_{22}H_{20}N_2 \cdot 2ICl \cdot 2HCl$ , forms slender, flesh-coloured needles. When the base is heated with benzaldehyde in the presence of zinc chloride at  $180^\circ$  for 4 to 5 hours, a compound is obtained, which crystallises from alcohol in large, yellow needles. The constitution of this tetramethyldiquinolyline is probably represented by the formula  $\begin{matrix} <CH : CMe \\ CMe : N > \end{matrix} C_6H_3 \cdot C_6H_3 \begin{matrix} <CMe : CH \\ N : CMe > \end{matrix}$ .

W. P. W.

**Pyrazolone-derivatives from Ethyl Benzoylacetate.** By L. KNORR and C. KLOTZ (*Ber.*, 20, 2545—2550).—Ethyl benzoylacetate, like ethyl acetoacetate, reacts with phenylhydrazine, and yields diphenylpyrazolone, and inasmuch as ethyl succinosuccinate (*Abstr.*, 1884, 1380) and ethyl oxalacetate (this vol., p. 234) also form pyrazolone-derivatives under similar conditions, this reaction seems to be characteristic for ethyl salts of ketonic acids of the general formula  $R \cdot CO \cdot CH_2 \cdot COOEt$ .

*Diphenylpyrazolone*,  $NPh \begin{matrix} <CO \cdot CH_2 \\ N : CPh > \end{matrix}$ , obtained by the action of phenylhydrazine on ethyl benzoylacetate, melts at  $137^\circ$ , and is very sparingly soluble in water, sparingly soluble in ether and light petroleum, readily soluble in alcohol, chloroform, benzene, and acetic acid. The *hydrochloride*,  $C_{15}H_{12}N_2O \cdot HCl$ , crystallises in small, white needles, and is readily soluble in alcohol; the *sulphate*,  $C_{15}H_{12}N_2O \cdot H_2SO_4$ , melts at  $237^\circ$ . On treatment of its alkaline solution with sodium nitrite, *isonitrosodiphenylpyrazolone*,  $C_3N_2Ph_2O : NOH$  is formed; this melts at  $197$ — $200^\circ$ . *Diphenylpyrazoloneazobenzene*,  $C_3HN_2Ph_2O \cdot N_2Ph$ , is obtained when diazobenzene chloride is added to a cooled solution of diphenylpyrazolone in acetic acid; it crystallises in matted needles, and melts at  $170$ — $171^\circ$ .

Diphenylpyrazolone, when heated with an excess of benzaldehyde, is converted into *benzylidenediphenylpyrazolone*,  $C_3N_2Ph_2O : CHPh$ , which crystallises in slender needles, and melts at  $147^\circ$ ; when, however, an excess of diphenylpyrazolone is employed, *benzylidene-bis-diphenylpyrazolone*,  $C_3HN_2Ph_2O \cdot CHPh \cdot C_3HN_2Ph_2O$ , is also obtained; this forms colourless crystals, melting at about  $220^\circ$ . *Bis-diphenylpyrazolone*,  $C_{30}H_{22}N_4O_2$ , is formed by the oxidation of diphenylpyrazolone with phenylhydrazine at the boiling point; it melts above  $330^\circ$ .

On treatment with methyl alcohol and methyl iodide at  $100^\circ$  in a sealed tube, diphenylpyrazolone yields *diphenylmethylpyrazolone*,  $NPh \begin{matrix} <CO - CH \\ NMe \cdot CPh > \end{matrix}$ . This compound crystallises in white needles, melts at  $150^\circ$ , and is sparingly soluble in hot water, ether, and light petroleum, readily soluble in alcohol and acetic acid. The *hydrochloride*,  $C_{16}H_{14}N_2O \cdot HCl$ , crystallises in satiny needles, and is decomposed by water; the *ferrocyanide*,  $(C_{16}H_{14}N_2O)_2 \cdot H_4Fe(CN)_6$ , is a white, crystalline precipitate; the *picrate*,  $C_{16}H_{14}N_2O \cdot C_6H_2(NO_2)_3OH$ , melts at  $170^\circ$ . With bromine, diphenylmethylpyrazolone yields an additive product, which on treatment with water is converted into the substi-

tution derivative  $C_{16}H_{13}N_2OBr$ ; this melts at  $110-120^\circ$ , and is soluble in water. W. P. W.

**Weyl's Reaction for Creatinine.** By J. GUARESCHI (*Chem. Centr.*, 1887, 580).—Weyl has shown that a red coloration is produced on the addition of a few drops of sodium nitroprusside and soda to a solution of creatinine; Salkowsky has further shown that the addition of acetic acid causes a bluish-green coloration. According to the author, this reaction is not restricted to creatinine, but is common also to substances allied to it, such as thio- and methyl-hydantoïn, and compounds derived from them. Thus if carbamide or thiocarbamide is melted with an amido-acid, the product gives the above reaction. It is apparently characteristic of compounds containing the glycollyl-group  $CH_2CO$ , associated with two nitrogen-atoms. V. H. V.

**Cryptopine and its Salts.** By E. KAUDER (*Pharm. J. Trans.* [3], 18, 250).—To the mother-liquor from which codeïne, narceïne, thebaïne, and papaverine have been separated in the usual way, sodium hydroxide is added in excess, and the resulting precipitate is washed with hot water, and redissolved by hydrochloric acid. The solution on cooling forms a gelatinous mass, which changes in two or three days into soft crystals. These are collected, redissolved in hot water, the hot solution filtered through charcoal, and allowed to cool, when it gelatinises and crystallises. The dried crystals are finally dissolved in hot alcohol, from which on cooling pure white crystals of cryptopine hydrochloride are obtained in soft masses, but without any gelatinous character. From a warm aqueous solution of this salt, ammonia precipitates the alkaloid in minute crystals. Cryptopine undergoes little or no decomposition when treated with hydrochloric acid, thus differing from other opium alkaloids. The normal sulphate of cryptopine does not crystallise; the acid sulphate gelatinises as the solution cools, and the jelly shows but slight signs of crystallisation after remaining for weeks. Normal cryptopine meconate is not soluble in cold, but is slightly so in boiling water. The analytical results correspond with the formula  $(C_{21}H_{23}NO_5)_2C_7H_4O_7 + 10H_2O$ . Probably it is in this form that cryptopine exists in opium, all kinds of which contain it in varying amounts. Its physiological effects have not yet been examined. R. R.

**Cinchona Alkaloids.** By W. J. COMSTOCK and W. KOENIGS (*Ber.*, 20, 2510—2527).—The action of bromine on cinchine in chloroform solution (this vol., p. 282) gives rise to two cinchine dibromides in about equal proportions; that already described is now termed  $\alpha$ - and its isomeride  $\beta$ -cinchine dibromide. The two compounds can readily be separated by treatment with hot, dilute hydrobromic acid, since the  $\alpha$ -dibromide crystallises out in concentrically-grouped needles, whilst the  $\beta$ -dibromide remains in solution.  $\alpha$ -Cinchine dibromide crystallises in monoclinic forms;  $a:b:c = 0.95699:1:0.86861$ ;  $\beta = 65^\circ 52'$ ; observed faces,  $\infty P_\infty$ ,  $\infty P$ ,  $R_\infty$ , and  $+P$ .  $\beta$ -Cinchine dibromide melts at  $133-134^\circ$ , and crystallises in rhombic forms;  $a:b:c = 0.55524:1:1.2017$ ; observed

faces,  $\check{P}\infty$ ,  $\bar{P}\infty$ ,  $0P$ , and  $+\frac{2P^2}{2}$ . The  $\alpha$ -dibromide is not converted into the  $\beta$ -compound or *vice versa* by prolonged heating at  $130^\circ$ , and it is somewhat more soluble in alcohol and ether than its isomeride. Hot dilute nitric acid dissolves the  $\alpha$ -dibromide, and the nitrate on cooling separates in colourless crystals; whilst the  $\beta$ -derivative, when similarly treated, is obtained in a form resembling that of recently precipitated silica. Both compounds yield zincchlorides, which crystallise in colourless needles, and melt almost simultaneously at about  $250^\circ$ . The dibromides separated from the nitrates or zinc salts melt at their original temperatures, although both are converted into the same dehydrocinchone on treatment with alcoholic potash.

Cinchonine, on bromination in a mixture of alcohol and chloroform at the ordinary temperature, also yields two dibromides, and these can be separated by the method employed with the  $\alpha$ -cinchine-derivatives. The  $\alpha$ -dibromide, the isomeride already described (*loc. cit.*), crystallises with 1 mol.  $H_2O$ , whilst the  $\beta$ -compound crystallised under similar conditions is always anhydrous. Both derivatives yield sparingly soluble salts, which seem to crystallise differently, and the hydrobromide of the  $\beta$ -compound is more readily soluble in hot, dilute hydrobromic acid.

*Chinine dibromide*,  $C_{20}H_{22}Br_2N_2O$ , is obtained by the action of bromine dissolved in chloroform on a chloroform solution of cinchine. The *hydrobromide*,  $C_{20}H_{22}Br_2N_2O \cdot 2HBr + 2H_2O$ , is a citron-yellow, crystalline mass, sparingly soluble in cold water, alcohol, and excess of hydrobromic acid. When the base is heated with alcoholic potash for seven to eight hours, it yields *dehydrochinine*,  $C_{20}H_{20}N_2O$ , which, after repeated recrystallisation of its tartrate, is obtained as a thick oil, slowly solidifying to a mass of long needles. It crystallises with at least 3 mols.  $H_2O$ , melts above  $40^\circ$ , and is almost insoluble in water, readily soluble in alcohol, wood-spirit, and ether. The solution in sulphuric acid has an intense greenish-blue fluorescence, and on the addition of chlorine and ammonia becomes green. The *hydrobromide* forms yellow crystals, and is readily soluble in water, less so in alcohol.

*Hydrochloroquinine*,  $C_{20}H_{25}ClN_2O_2$ , is formed when quinine hydrochloride is treated with 10 times its weight of hydrochloric acid saturated at  $-17^\circ$ , and allowed to remain for a week at the ordinary temperature; the base is precipitated by ammonia and purified by conversion into its nitrate, which is then repeatedly crystallised from very dilute nitric acid. It melts at  $186-187^\circ$ , and is insoluble in water, but crystallises well from ether and alcohol. The *nitrate* forms colourless crystals, is very sparingly soluble in dilute nitric acid, and its aqueous solution fluoresces an intense blue, and gives the green coloration on treatment with chlorine-water and ammonia. *Hydrobromoquinine*,  $C_{20}H_{25}BrN_2O_2$ , obtained by the action of hydrobromic acid saturated at  $-17^\circ$ , on quinine dihydrobromide in the cold, yields a well-crystallised acid hydrochloride and hydrobromide; the latter has the composition  $C_{20}H_{25}BrN_2O_2 \cdot 2HBr$ . Neither the hydrochloro- nor the hydrobromo-quinine are soluble in aqueous potash, but on treatment for 50 days at the ordinary temperature with 10 times

its weight of hydrobromic acid saturated at  $-17^{\circ}$ , acid quinine hydrobromide yields a compound,  $C_{20}H_{27}Br_3N_2O_3$ , which dissolves completely in dilute aqueous potash, and is precipitated from the solution by carbonic anhydride. It is soluble in ether, and its solution in sulphuric acid shows no fluorescence.

*Hydrochlorocinchonine*,  $C_{19}H_{23}ClN_2O$ , obtained in a similar manner from cinchonine hydrochloride, melts at  $212-213^{\circ}$ . The *dihydrochloride* crystallises in well-formed prisms. When the base is heated with alcoholic potash for 10 to 12 hours, it loses chlorine and seems to be converted, like the hydrobromo-derivative, into isocinchonine and a small quantity of cinchonine. Hydrobromocinchonine,  $C_{19}H_{23}BrN_2O$ , prepared similarly from cinchonine dihydrobromide, is identical with the base obtained by Skraup (*Annalen*, **201**, 324), and when heated with silver oxide, yields as stated by him silver bromide and an organic base of peculiar odour recalling that of acetamide and piperidine; this change, however, does not occur in the cold. The same odour is produced when hydrobromocinchonine is heated with dilute sulphuric acid and lead dioxide or manganese dioxide with the addition of some silver sulphate, and the product afterwards saturated with an alkali; cinchonic acid is also formed during the oxidation with manganese dioxide.

*Isocinchonine*,  $C_{19}H_{22}N_2O$ , is formed when hydrobromocinchonine (1 part) is heated in a reflux apparatus with potassium hydroxide (2 parts), and alcohol (30 parts), until the base is free from bromine. At the same time, cinchonine is also obtained, and the two bases are separated by treatment with ether; the small quantity of cinchonine is then removed by converting the residue obtained from the ethereal solution into the zincochloride, and crystallising from aqueous zinc chloride, in which solvent the isocinchonine compound is sparingly soluble in the cold. Isocinchonine melts at  $125-127^{\circ}$ , and, unlike cinchonine, is extremely soluble in alcohol, ether, benzene, carbon bisulphide, chloroform, and ethyl acetate. With acids, it yields for the most part soluble salts, and when carefully heated in small quantity volatilises without decomposition. The *zincochloride*,  $C_{19}H_{22}N_2O \cdot 2HCl \cdot ZnCl_2$ , crystallises in small, colourless needles and melts at  $260-262^{\circ}$ .

*Hydrobromocinchine*,  $C_{19}H_{21}BrN_2$ , obtained by dissolving cinchine in 10 times its weight of hydrobromic acid saturated in a freezing mixture of ice and salt, and allowing the solution to remain for two days, crystallises from ether in monoclinic forms;  $a : b : c = 0.85412 : 1 : 0.82801$ ;  $\beta = 63^{\circ} 7'$ ; and is isomorphous with  $\alpha$ -cinchine dibromide (m. p.  $= 113^{\circ}$ ). It melts between  $105^{\circ}$  and  $116^{\circ}$ , and dissolves readily in alcohol, ether, &c., but only sparingly in light petroleum. The zincochloride crystallises well. Cinchine does not seem to form addition compounds with 2 mols. of a haloïd acid or 2 mols. of bromine.  $\beta$ -Cinchine dibromide, for example, when treated with bromine in chloroform solution, yields a perbromide, which is converted into the unaltered base on the addition of sodium hydrogen sulphite; whilst cinchine, when heated with concentrated hydrobromic acid at  $100^{\circ}$ , yields a base which could not be crystallised, and which seems to contain somewhat less bromine than hydrobromocinchine.

*Hydrobromodehydrocinchonine*,  $C_{19}H_{21}BrN_2O$ , is prepared by allowing a solution of dehydrocinchonine in concentrated hydrobromic acid to remain for eight days. It forms anhydrous crystals, and melts at about  $235^\circ$ . The corresponding dehydrocinchonine dibromide could not be prepared by the action of bromine on dehydrocinchonine in chloroform solution, but under these conditions a crystalline base melting at  $228^\circ$  is obtained, whose composition approximates to that of a monobromodehydrocinchonine,  $C_{19}H_{19}BrN_2O$ .

Pyridine-derivatives do not seem to form halogenated compounds when treated with hydrobromic acid saturated at  $-17^\circ$ ; thus pyridine and quinoline are unaltered in the cold or when heated at  $140^\circ$  with the acid; tetrahydroquinoline is unaffected in the cold, and the tertiary base,  $C_{11}H_{13}N$ , obtained by Fischer and Steche (this vol., pp. 588 and 976), which is probably a partially hydrogenated quinoline-derivative, and methylepidone are similarly unattacked. From considerations based on the oxidation of cinchonine and quinine with chromic acid, the authors regard it as improbable that the quinoline-group in the molecule is hydrogenated, and since these alkaloids, together with cinchine and dehydrocinchonine, readily combine with a molecule of hydrogen bromide or chloride, it is evident that the addition must occur in the complex  $C_{10}H_{16}NO$ , which seems to have the same constitution for both alkaloids.

W. P. W.

**Preparation of Aconitine.** By J. WILLIAMS (*Pharm. J. Trans.* [3], 18, 238—240).—The dried, coarsely ground root of *Aconitum napellus* is exhausted with amyl alcohol, the solution is agitated with very dilute sulphuric acid (1 : 600), the alkaloïd is precipitated from the acid by sodium carbonate, and then dissolved either in alcohol or in ether, and allowed to crystallise. The necessary precautions are detailed in the original.

R. R.

**Curare.** By R. BOEHM (*Chem. Centr.*, 1887, 520).—Besides the active principle, curarine, contained in curare, the author has found a second base, *curine*, which has no action on the organism. This is a white, microcrystalline substance, soluble in water, readily soluble in alcohol, chloroform, and in dilute acids. The solutions give a thick, white precipitate with metaphosphoric acid.

The separation of curarine is effected by means of platinic chloride; it is a yellow substance. 0.35 mgrm. is sufficient to kill a rabbit weighing 1 kilo.; 0.003—0.005 mgrm. will kill a frog.

N. H. M.

**The Alkaloids of Coca Leaves.** By O. HESSE (*Pharm. J. Trans.* [3], 18, 71).—The author dissents from Stockman's opinion that amorphous cocaïne is a solution of true cocaïne in hygrine. Coca leaves finely divided, and extracted by ether, give on agitation of the ethereal solution with hydrochloric acid, a liquid which although at first non-fluorescent, after a time becomes distinctly fluorescent, thus showing that hygrine is a product of subsequent decomposition. The amorphous bases easily separated from cocaïne, give a platinum salt containing 18.44 per cent. platinum; but these are not homogeneous, for the author has been able to separate by fractional precipitation a

well-defined base, which he has called *cocamine*. This has the same composition as cocaine,  $C_{17}H_{21}NO_4$ ; it dissolves readily in ether, alcohol, or chloroform, and on evaporation remains in an amorphous condition. Its hydrochloride,  $C_{17}H_{21}NO_4 \cdot HCl$ , is amorphous, neutral, and soluble in water and alcohol; when dried at  $120^\circ$  it loses weight, and eventually becomes insoluble in cold water. R. R.

**Separation of Hygrine from Cocaine.** By W. C. HOWARD *Pharm. J. Trans.* [3], 18, 71).—In a liquor containing cocaine, hygrine, &c., neutralised by hydrochloric acid, platinum chloride produces a doubtfully semi-crystalline precipitate, part of which was insoluble in water at  $80^\circ$ . The base of the soluble part, the author identified as cocaine. The insoluble platinum salt was found by two experiments to contain platinum, 18.48 per cent. and 18.6 per cent., and when decomposed in the usual way, it yielded a base that gave no crystallisable chloride, did not smell of trimethylamine, had a bitter taste, and was not decomposed by hot water; in which characters it differs from hygrine as described by Lossen (*Annalen*, 121, 374). Therefore, either Lossen's base was impure, or the author's is a different one, and amorphous cocaine may have no existence, but may be merely a solution of cocaine in the base above described.

R. R.

**Higher Homologues of Cocaine.** By F. G. NOVY (*Pharm. J. Trans.* [3], 18, 233—234).—These substances were prepared by heating benzoylcegonine with the homologues of methyl iodide.

*Ethylbenzoylcegonine*,  $C_{16}H_{18}EtNO_4$ , forms white, silky crystals or large monoclinic prisms, melts at  $107-108^\circ$ , and resolidifies at  $90^\circ$ . The hydrochloride crystallises in colourless needles or prisms; the platinochloride,  $(C_{16}H_{18}NO_4)_2 \cdot H_2PtCl_6$ , forms yellow, rhombic plates; the aurochloride is obtained as a voluminous, yellowish-white precipitate. Bromethylbenzoylcegonine, prepared from benzoylcegonine and ethylene bromide,  $C_2H_4Br \cdot C_{16}H_{18}NO_4$ , could only be obtained as a colourless syrup.

*Propylbenzoylcegonine*,  $C_{16}H_{18}PrNO_4$ , crystallises in silky needles or colourless prisms, melts at  $78-79.5^\circ$ , and resolidifies at  $65^\circ$ ; it has a very bitter taste and is a powerful anæsthetic.

*Isobutylbenzoylcegonine*,  $C_4H_9 \cdot C_{16}H_{18}NO_4$ , crystallises in short, colourless prisms, melts at  $61-62^\circ$ , has an intensely bitter taste and powerfully anæsthetic properties. The hydrochloride forms a hard, vitreous, yellow mass.

A. J. G.

**Absorption of Light by Oxyhæmoglobin.** By F. KRÜGER (*Zeit. Biol.*, 24, 47—66).—The results of the present investigation corroborate Kupffer's statement that the absorption coefficient of oxyhæmoglobin increases each time the oxyhæmoglobin is recrystallised.

In determining the absolute amount of hæmoglobin in blood by means of the spectrophotometer, it is best only to recrystallise once, as each recrystallisation increases the error of observation.

The use of dilute ammonia in the preparation of hæmoglobin

crystals as recommended by Schmidt increases their solubility in water.

J. P. L.

**Action of Reducing Agents on Hæmatin and Occurrence of the Products of Reduction in Pathological Urine.** By C. LE NOBEL (*Chem. Centr.*, 1887, 538).—When hæmatin is reduced in acid or alkaline solution, iron is eliminated and *hæmatoporphyrin* is formed. Afterwards *hæmatoporphyröidin* (differing from hæmatoporphyrin in solubility but nearly identical in its spectroscopic properties) is formed. The hæmatoporphyröidin is then transformed into MacMunn's urohæmatin, to which the author gives the name *isohæmatoporphyrin* and lastly *urobilinoïdin* is formed. This resembles urobilin in some of its properties; it can readily be converted into isohæmatoporphyrin and hexahydrohæmatoporphyrin. Maly's hydrobilirubin is not identical with Jaffe's urobilin. There is no connection between the colouring matter of blood and Jaffe's urobilin. In some pathological conditions, in which it may be assumed the colouring matter of blood has decomposed, the above products of reduction occur in urine.

N. H. M.

**Hemialbumose.** By AXENFELD (*Arch. Pharm.* [3], 25, 696—697).—Pyrogallol is a better precipitant for this albuminoid than either ammonium sulphate, or nitric or picric acids, as more dilute solutions can be employed. Its sensibility is 10 times that of nitric acid. The author has detected hemialbumose in meal, bread, leguminous seeds, milk, and cheese. The usual method of detection consists in the precipitation of hemialbumose at the ordinary temperature by nitric acid, and solution of this precipitate on warming, but the pyrogallol test succeeds where this test fails. In milk after precipitating the casein by acetic acid, and the albumin and paraglobulin by magnesium sulphate, 0.13 per cent. of hemialbumose was found in cow's milk and 0.29 per cent. in human milk. All animal tissues excepting nerve and muscle substance contain hemialbumose.

## Physiological Chemistry.

---

**Glycogen.** By A. CRAMER (*Zeit. Biol.*, 24, 67—104).—The potash process for estimating glycogen recommended by Külz, has enabled the author to make an exhaustive study of the occurrence and relative distribution of glycogen in various tissues and organs. The following are some of the chief conclusions arrived at:—

From the result of many determinations, the process leaves little to be desired from the point of accuracy.

The glycogen in the muscular structure of both halves of the body is found, as would be supposed from theoretical considerations, to be equal. In the liver, the glycogen is equally distributed throughout: for the estimation of the glycogen therefore it is only necessary to

use a small portion. In the muscles of the heart, glycogen is unequally distributed, therefore the whole organ must be taken for the determination.

Different groups of muscles vary in the amount of glycogen they contain, but symmetrical or corresponding muscles contain the same amount.

Absolutely pure glycogen can be obtained from the skin of the human foetus or the cartilage of the foetus of an animal.

In the estimation of the total amount of glycogen in the body, it is only necessary, as Böhn and Hoffmann have already pointed out, to take into consideration the glycogen in the muscular mass and liver, for the amount existing in other organs is not of sufficient importance.

Lastly, the optical method proposed by Kulz is not so accurate as the method of weighing.

J. P. L.

**Chemical Studies on the Torpedo.** By T. WAYL (*Zeit. physiol. Chem.*, **11**, 525—528).—From the electrical organ of the torpedo, a substance, *torpedo-mucin*, can be separated in the following way:—The organ is first extracted with cold, then with hot alcohol and ether; the residue is then cut into small pieces and extracted with dilute sodium hydroxide (0.1 per cent.). A solution is obtained of a faint-yellow colour, which is filtered and diluted with distilled water. On adding very dilute acetic acid to this, a white, flocculent precipitate is obtained; this is washed by decantation, redissolved in sodium and hydroxide, reprecipitated by acetic acid. After this process has been repeated five times, the precipitate is washed with alcohol, and dried, first in a vacuum over sulphuric acid, and then at 110°. An elementary analysis gave the following results:—

I. Containing ash : II. Free from ash.

|     | C.    | H.   | N.    | O.    | S.   | Ash. |
|-----|-------|------|-------|-------|------|------|
| I.  | 51.60 | 7.09 | 13.00 | 25.46 | 1.02 | 1.83 |
| II. | 52.50 | 7.2  | 13.20 | 26.07 | 1.03 | —    |

The ash contained lime, magnesia, and phosphoric acid. This substance has the following properties: it is completely soluble in alkalis and is precipitable from such solutions by acetic acid; neutralisation with hydrochloric acid produces a precipitate soluble in excess of acid or alkali; it is precipitated from its solution in dilute hydrochloric acid by saturation with sodium chloride; when heated with sulphuric or hydrochloric acid, it yields no substance which reduces copper sulphate; the solution in dilute sodium hydroxide is coloured red by a drop of copper sulphate solution; but on boiling no reduction occurs. A mucin with similar properties is also obtained from the fresh organ after its extraction with alcohol and ether. Gelatin was obtained also from the organ, best from the residue left after extraction with sodium hydroxide. The fresh organ yields a very small quantity of a globulin which can be extracted by a solution of sodium chloride or ammonium chloride. This is coagulated by heat at 55—60° C.

Abundant proteïd can however be obtained after the exposure of the organ to the air for some time; an acid reaction is also developed simultaneously. Probably the mucin yields a proteïd as a decomposition product.

W. D. H.

**Nitrogenous Contents of the Digestive Juices.** By ELLENBERGER and HOFMEISTER (*Zeit. physiol. Chem.*, **11**, 497—500).—This investigation was carried out in the same way as Goldschmidt's (this vol., p. 743), except that the food given was in all cases free from nitrogen.

Three animals—one pig and two horses—were fed for some days on a diet poor in nitrogen, then for 24 to 36 hours on water only, and finally for three days in the case of the horses, and 36 hours in the case of the pig, on a diet consisting of starch and cellulose, free from nitrogen.

The animals were killed, and the stomach and small intestines were found to be free from food containing nitrogen; the colon and rectum, and in one horse the cæcum, also contained remains of the first diet. The following table gives the results of the analysis of the digestive juices in various parts of the alimentary canal:—

|               | Amount of Proteïd in |                  |           |         |
|---------------|----------------------|------------------|-----------|---------|
|               | Stomach.             | Small intestine. | Cæcum.    | Colon.  |

The large quantity of nitrogen in the small intestine of horse 2 was due to an excessive amount of mucous and epithelial *débris*; and the high percentage of nitrogen in the stomach of the horse compared with that of the pig, was due to the fact that the horses were killed a long time after a meal, so that the saliva had been absorbed, and only the gastric juice, which is rich in nitrogen, was present.

W. D. H.

**Relation of Proteïds to Digestive Ferments.** By A. STUTZER (*Zeit. physiol. Chem.*, **11**, 529—536).—Previous researches having shown that the results of the natural and artificial digestion of proteïds agree closely (this vol., p. 167), the present further investigations were undertaken as a preliminary to extending the process to the investigation of the digestion of carbohydrates and of mixtures of proteïd and carbohydrate material. These investigations were necessary, as the percentage of acid used (1 per cent. HCl) in the previous experiments is too high for experiments in which the digestion of carbohydrates is expected to take place. Meat freed from fat,

two kinds of hay, and cake made from the seeds of *Arachis hypogaea* were the forms of food employed. A given weight (1 or 2 grams) was subjected to the action of different amounts of pepsin solution containing 0.2 per cent. HCl for 12 hours at the temperature of 37—40°.

It was found by estimating the undigested nitrogen that the optimum of pepsin digestion under these circumstances was obtained when the nitrogen in the food was—

| 5 per cent., by 100 c.c. of pepsin solution, |   |   |     |   |
|--|---|---|-----|---|
| 5—10   | “ | “ | 200 | “ |
| over 10                                      | “ | “ | 400 | “ |

to every gram of the food.

On comparing the amount of nitrogen in the undigested residue with that left when 1 per cent. HCl was employed, it was found to be somewhat less in the latter case, as is shown by the following table :—

Nitrogen left in the undigested residue—

| When 1 p. c. HCl was used. |             | When 0.2 p. c. HCl was used. |             |
|----------------------------|-------------|------------------------------|-------------|
| Flesh . . . .              | 0.375 p. c. |                              | 0.375 p. c. |
| Hay 1 . . . .              | 0.339 “     |                              | 0.390 “     |
| Hay 2 . . . .              | 0.282 “     |                              | 0.340 “     |

The next point investigated was how much nitrogen remains undigested on treating the fodder successively with an acid pepsin solution and an alkaline pancreatic liquid, first when the pepsin solution has an acidity of 0.2 per cent. HCl, and secondly when it has an acidity of 1 per cent. HCl. It was found that the difference was so small as to be inappreciable.

The last question related to the comparative activity of the pancreatic ferment when the solution is neutral and feebly alkaline (containing 0.25 per cent. of sodium carbonate), and in all cases it was found that the alkaline fluid was the more active.

W. D. H.

**Comparative Absorption of Fish and Meat in the Alimentary Canal.** By W. O. ATWATER (*Zeit. Biol.*, **24**, 16—28).—During an inquiry into the chemical composition of fish-flesh undertaken on behalf of the United States Fishery Commission, the author investigated the comparative nutritive value of fish and meat as nitrogenous food, by a series of feeding experiments in which a careful determination of the nitrogen intake and output was made.

Weight for weight in dry matter, fish is equivalent to lean or fat-free meat as a source of nitrogenous food.

In the opinion of the author the importance of fish as a food for the mass cannot be too strongly emphasised.

J. P. L.

**Digestion of Fibrin by Trypsin.** A. HERRMANN (*Zeit. physiol. Chem.*, **11**, 508—524).—Hasebroek (this vol., p. 609) has shown that the first products of the tryptic, like those of the peptic digestion of fresh fibrin, are two proteids which coagulate at 52—54° and 72—75°

respectively. Otto (Abstr., 1884, 1056) has also shown that the latter is identical with paraglobulin. The present research is a further investigation of the same subject, as it seems remarkable that whilst fibrin is undoubtedly formed from fibrinogen, it should yield paraglobulin on digestion. Fibrin was well washed with water, and subjected to artificial pancreatic digestion at the body temperature for 24 hours, or in some cases for a longer time at the atmospheric temperature. After this time, a small portion only was left undissolved. Putrefaction was prevented in these experiments by the addition of thymol, or of ether sufficient to give the whole mixture a strong ethereal odour. The fluid product of digestion was saturated with magnesium sulphate; this produced an abundant precipitate, which was collected and dissolved by adding water; the solution so formed was a clear, slightly yellow liquid, and from it, by fractional heat coagulation, two proteids, one coagulating at 54–55°, and another at 75°, were obtained. There was also a slight opalescence at 61°, probably produced by a small amount of heteroalbumose; the presence of albumoses was also detected by the biuret reaction after the separation of the proteids coagulable by heat. Both proteids were also shown to belong to this class of globulins by the fact that they were precipitated by dialysing the salts out from their solutions. By extracting fibrin with a 5 per cent. salt solution, a proteid coagulating at 75° and having the other properties of paraglobulin is obtained. The other globulin, that which coagulates at 55°, is, however, undoubtedly a product of ferment action; it is always the more abundant of the two, and the more thoroughly that fibrin is washed free from paraglobulin by salt solution previous to digestion, the less is the amount of paraglobulin in the product of digestion. The question whether this globulin coagulating at 55° is identical with either of the two proteids, fibrinogen or myosin, which coagulate at the same temperature, was not fully investigated. Its specific rotation was estimated as  $[\alpha]_D = 36.39^\circ$ ; whilst that of fibrinogen prepared by Hammarsten's method was  $[\alpha]_D = 43^\circ$ . Too much weight must not be attached to these numbers, as the opalescent character of fibrinogen solutions renders polarimetric observations difficult.

Attempts to cause coagulation of the proteid by the action of fibrin ferment led to negative results.

Boiled fibrin does not yield this product on digestion; neither does serum-albumin, casein, nor phytovitellin.

W. D. H.

**Fermentation of Cellulose.** By H. TAPPEINER (*Zeit. Biol.*, **24**, 105–119).—From exact quantitative experiments on the digestion of cellulose by the organised ferment contained in paunch contents, it is found that a small quantity of the carbon of the cellulose decomposed is not accounted for by the products hitherto mentioned. At present, the author has not detected the product or products formed by this residual carbon.

Asparagine when added to Naegali's cultivating fluid, which was used in some of the fermentation experiments, acts somewhat curiously. When present in small quantity (0.6 per cent.), it does not undergo any decomposition itself or influence the decomposition of the cellu-

lose. When present in somewhat larger proportion (1·8 per cent.), part of the asparagine undergoes decomposition with the cellulose. If the percentage of asparagine is as much as 3·5 per cent., it readily undergoes decomposition with formation of carbonic anhydride, nitrogen, volatile fatty acids, and succinic acid, but, in this instance, the cellulose undergoes no decomposition.

A similar peculiarity is observed in the case of ammonium acetate. 1 per cent. of ammonium acetate in Naegali's solution undergoes no decomposition when the solution is infected with a small quantity of paunch contents in the absence of cellulose, but, in the presence of cellulose, rapid decomposition of the acetate takes place without any action whatever on the cellulose.

J. P. L.

**Aromatic Products of Putrefaction in Human Sweat.** By A KAST (*Zeit. physiol. Chem.*, **11**, 501—507).—The analysis of the sweat is important because of the correlative functions of the skin and kidneys. The occurrence of indigo compounds in cases of *chromidrosis* has already been noted (Bizio, H. B. Hofmann), and Buisine (*Compt. rend.*, **103**, 66), has shown that phenolsulphonic acid exists in the sweat of the sheep. In the present research, by the use of hot air-baths, large quantities of sweat were collected; about 18 to 20 litres in all. Excess of absolute alcohol was added, and sodium carbonate until it was faintly alkaline; it was then evaporated to a small volume on the water-bath. The relation of sulphuric acid (A) combined as sulphate to that combined as ethereal hydrogen sulphates (B) was then estimated with the following results:—

In 200 c.c. of the concentrated sweat (= 10—12 litres of sweat),  $A = 0.2422$ ,  $B = 0.022$ ;  $\frac{B}{A} = \frac{1}{12.009}$ . In the urine of the same individuals collected at the same time, in 200 c.c. of unconcentrated urine  $A = 0.718$ ,  $B = 0.448$ ;  $\frac{B}{A} = \frac{1}{16.02}$ . By administering 10 grains of salol in three days to the same individuals, the quantity of the ethereal hydrogen sulphates in the urine was much increased;  $\frac{B}{A} = \frac{1.339}{1}$ , whilst in the sweat,  $\frac{A}{B} = \frac{1}{9.504}$ ; in other words the sweat,

unlike the urine, remains fairly constant in composition. With regard to the other salts, the following relation was found to exist:—

|             | Chlorides. | Phosphates. | Sulphates. |
|-------------|------------|-------------|------------|
| Sweat ..... | 1 :        | 0.0015 :    | 0.009      |
| Urine ..... | 1 :        | 0.132 :     | 0.397      |

Favre (*Compt. rend.*, **35**, 721) gives the following relations:—

|             | Chlorides. | Phosphates. | Sulphates. |
|-------------|------------|-------------|------------|
| Sweat ..... | 1 :        | traces :    | 0.043      |
| Urine ..... | 1 :        | 0.0959 :    | 0.38       |

By the distillation of sweat, phenol was easily obtained, and

recognised by Millon's reagent. Another portion of sweat was acidified with hydrochloric acid, shaken with ether, the ethereal extract evaporated to dryness, and the residue taken up with water; this solution showed the presence of aromatic oxy-acids by the red colour produced by Millon's reagent. Indoxylsulphuric acid was sought for by Jaffe's test, with negative results; the same test gave, however, a red colour, showing the presence of scatoxyl. It is suggested that the blue colour of the sweat in chromidrosis is due to bacteria.

W. D. H.

**Relation of Tyrosine to Hippuric Acid.** By K. BAAS (*Zeit. physiol. Chem.*, **11**, 485—491).—Many aromatic compounds which occur in the urine have been shown to be decomposition products of tyrosine formed in the alimentary canal. The question as to whether hippuric acid is derived from tyrosine also, has been investigated by Salkowski, Schotten, and Baumann, but the results obtained have been somewhat contradictory. The present research was carried out in human beings, and consisted in comparing the normal urine with that secreted during the administration of tyrosine. The hippuric acid was estimated by Schmiedeberg and Bunge's method; and the amount of sulphates and ethereal hydrogen sulphates by Baumann's method. The experiments show that giving tyrosine did not alter the amount of hippuric acid in the urine, and therefore that the normal formation of that acid does not result from the tyrosine in the intestine. The conclusion is also drawn that tyrosine does not always undergo putrefactive decomposition in the alimentary canal, but that in spite of the presence of bacteria, it may be wholly absorbed as such.

W. D. H.

**Urinary Pigments.** By L. v. UDRÁNSZKY (*Zeit. physiol. Chem.*, **11**, 537—560).—On looking over the literature of the subject of urinary pigments, which extends from the beginning of the present century, it is found that the following conclusions can be drawn from the work at present done on the subject:—(1.) By the action of oxidising agents, indigo-blue and other indigo compounds, for example, indirubin, can be obtained from normal urine. (2.) In most cases urobilin, which is identical with hydrobilirubin, is also present. (3.) In addition to the foregoing, pigments are obtained by boiling the urine with mineral acids, and are probably derived from the splitting up of certain chromogens in the urine by these strong reagents: to one of these, the name uromelamin is given. It is to the investigation of this third class of pigments that the present research is mainly directed. A litre of normal urine was heated for a quarter of an hour with 5 per cent. hydrochloric acid, and extracted with amyl alcohol; on evaporating the alcoholic extract, a brownish-black, amorphous residue was obtained weighing 0·68 gram. This is the ordinarily received method of obtaining this pigment. The experiment was repeated, using distilled water instead of urine, and a residue weighing 0·51 gram was obtained, having the same characters, including spectroscopic appearances. The prolonged action of hydrochloric acid in the cold has the same action on amyl alcohol. What this resinous substance is was not further investigated;

it was found, however, that the alcohol after distillation still possessed the same action on polarised light as previous to the separation of the pigment from it. This admixture of the resinous substance from the reagents used with the urinary pigment could not be prevented by attempting to wash the acid away from the alcohol by the use of water; it was not found possible to remove the acid in this way. By neutralising the mixture with chalk, however, the author considers he has been able to obviate this source of error. On account, however, of the unsatisfactory nature of amyl alcohol as a reagent, a method was sought for in which it was not necessary to employ it. The method ultimately adopted was as follows:—Normal urine was evaporated to about one-sixth of its original bulk at 60°; 10 per cent. hydrochloric acid was then added, and after 48 hours the crystals of uric acid thus formed were filtered off. The filtrate was boiled for 18 hours, at the end of which time the remains of the uric acid with an abundance of pigment were precipitated; the filtrate had an orange-red colour; to this, chalk and sodium phosphate were added; the bulky precipitate which was formed carried down with it the remains of pigment. The precipitate obtained from the urine by boiling was washed with cold water, hot water, alcohol, and ether, dissolved in dilute sodium hydroxide solution, and precipitated by sulphuric acid. This was repeated three times, and the final product was a bright, brownish-black substance, occurring in plates, but easily powdered. It was insoluble in cold water, dilute alcohol, ether, and chloroform, sparingly soluble in warm water, absolute alcohol, light petroleum, and concentrated sulphuric and hydrochloric acids. It was easily soluble in amyl alcohol, concentrated ammonia, but especially in solutions of potassium or sodium hydroxide. It can be heated to 115° without decomposition; with soda-lime it yields ammonia; on dry distillation, it gives a smell of formic acid, and after complete combustion leaves a minimal amount of ash which contains no iron. The average quantity in which it occurs in urine is 0.03 per cent. By the action of potash, it yields ammonia, formic acid, acetic acid, butyric acid, palmitic acid (?), catechol, protocatechuic acid, and the residue is free from nitrogen, and has the following percentage composition:—Carbon, 62.26; hydrogen, 3.9; and oxygen, 33.84.

---

## Chemistry of Vegetable Physiology and Agriculture.

---

**Nitrifying Microbes.** By M. MILES (*Bied. Centr.*, 1887, 514—515).—Miles confirms Warington's observation as to the length of time which elapses between the infection of the liquid and the commencement of the nitrifying process, and he finds that this period of quiescence may be cut short by introducing a minute quantity of another and earlier culture. When calcium carbonate was absent, the microbes increased rapidly, but nitrification seldom occurred, and microbes which had been cultivated for some generations in liquid not containing calcium

carbonate, caused nitrification in dilute urine to which calcium carbonate had been added. It appears that those microbes which increase rapidly without nitrification are of peculiar aërobic forms, but if they cause rapid nitrification, then they belong to the anaërobic class. Solutions were tested for nitrous acid, but it was seldom found; when found it was in those solutions which gave no reaction for nitric acid, and in which micrococci appeared together with the true nitrifying microbe.

E. W. P.

**Culture of Anaërobic Bacteria. Morphology of Butyric Fermentation.** By M. GRUBER (*Chem. Centr.*, 1887, 535).—Gelatin, contained in a glass tube about 2 cm. wide, fused together at one end and drawn out to a neck 5 to 6 cm. long, and 3 to 4 cm. wide, is inoculated, the tube placed in water at 30—35°, exhausted and sealed. The fused gelatin is spread over the surface of the tube by rotation. In using this method, the author found that the three bacteria known by the joint name of *Clostridium butyricum* (*Bac. amylobacter*), are capable of producing butyric acid and butyl alcohol from carbohydrates.

N. H. M.

**Distribution of the Nitric Ferment and its Function in the Disintegration of Rocks.** By A. MÜNTZ (*Ann. Chim. Phys.* [6], 11, 136—144).—The bare surfaces of calcareous, felspathic, micaceous, schistose, and other rocks at the summits of mountains in the Pyrenees, Alps, and Vosges, yielded large numbers of the nitric ferment, which penetrates to a considerable depth in the cracks in the rocks, and is especially abundant on surfaces which show the greatest disintegration. This organism is not killed by the lowest temperatures of the Alps.

The rocks concerned, especially those above the limits of vegetation, contain small quantities of carbon, which make the rock blacken when heated. This carbon is derived from air and rain. The author has previously proved that alcohol vapour exists in small quantities in the atmosphere. Direct experiments show that the nitrifying organisms will exist and produce nitrates with no other sustenance than the mineral constituents of the rock on which they are placed and small quantities of alcohol vapour and ammonia suspended in a moist atmosphere. Some carbon is also found to have been deposited in or upon the rock on which the organisms are living. There is every reason to believe that these nitrifying organisms play an important part in the superficial disintegration of rocks even at the highest levels.

C. H. B.

**Methane Fermentation of Acetic Acid.** By F. HOPPE-SEYLER (*Zeit. physiol. Chem.*, 11, 561—568).—Calcium acetate was dissolved in water, and river mud added to the solution in a flask. The mixture was allowed to stand at the atmospheric temperature for seven months, during which time the gas which was evolved was collected over mercury and occasionally analysed. For the first few weeks, some atmospheric nitrogen was present in the mixed gases, but after this time carbonic anhydride and methane were alone present, in the

proportion 1 : 2 approximately. The residue in the flask consisted almost entirely of calcium carbonate. The decomposition which had occurred may be represented thus:  $(C_2H_3O_2)_2Ca + H_2O = CO_2Ca + CO_2 + 2CH_4$ . In addition to the calcium carbonate, there was also in the flask a small amount of sodium carbonate: this was derived from a slight impurity in the original salt used, together with some derived from the glass wall of the flask. There was also organic matter from the mud, and a large number of bacteria. The change is believed to be due to the agency of the bacteria, although to which special variety has not yet been ascertained. By an experiment similarly carried out with calcium lactate, carbonic anhydride and methane in the proportion of 1 : 2 were evolved, the residue being composed of calcium acetate. It is possible, therefore, that methane in the alimentary canal is not always derived from cellulose.

W. D. H.

**Formation of Starch in the Chlorophyll Granules.** By G. BELLUCI (*Chem. Centr.*, 1887, 572).—In order to determine whether the production of starch under the influence of sunlight, and the subsequent reconversion during night time, is to be regarded as a physiological or as a chemical change, the effect of the presence of various substances was tried. Chloroform, and to a slighter extent, ether vapour, destroy chlorophyll, and also prevent the transformation of starch formed during sunlight; carbonic anhydride also diminishes the function of the chlorophyll, but does not destroy it, if the action is not allowed to continue unintermittently for 24 hours. The saccharification of starch proceeds in the dark, even in cut-off leaves, but more rapidly with free access of air. From these experiments, the author concludes that the phenomenon is a physiological and not a chemical change.

V. H. V.

**Crystalline Deposits in Dahlia Tubers.** By H. LEITGEB (*Ann. Agronom.*, 13, 378—379).—In order to exhibit the sphero-crystals of inulin, the common plan is to soak sections of dahlia tubers in alcohol. The author having allowed a tuber to soak for several years in this liquid, finds the spheres of inulin with radial striæ grouped in the peripheral region of the tuber. But besides these he has noticed spheres composed of an amorphous nucleus surrounded by an envelope formed of radiating needles. These crystals abounded in the pith and inner portions of the parenchyma. They leave after combustion a mineral residue of the same shape as the crystals, consisting of calcium phosphate. The amorphous nucleus consists of an organic substance which is neither inulin nor fatty matter.

J. M. H. M.

**Absorption of Ammonia by Clay.** By W. WIPPRECHT (*Bied. Centr.*, 1887, 517—518).—The experiments were made on a clay from Texas. All ammonia was removed from the clay previous to the experiments by heating at 400°. The following conclusions are drawn. Moist clay contains more ammonia than drier clay. If the moisture remains constant, the more ammonia is absorbed the longer the clay remains exposed to the air. Dried clay when moistened and exposed for one day to the air, absorbs a considerable quantity

of ammonia. When moist clay is exposed to air, the loss of water is accompanied with a proportionately greater loss of ammonia; on the other hand, when clay is absorbing water from the air, it at first gains more ammonia than it would lose during the evaporation of the same amount of water.

A. J. G.

**Analysis of Onions.** By C. A. GOESSMANN (*Pharm. J. Trans.* [3], 18, 77—78).—1000 parts of air-dried onions, without the leaves, consisted of 892 parts of water, and 108 of dry matter, containing 2.12 parts of nitrogen, 0.48 part of sulphur, and yielding 4.36 parts of ash. The percentage composition of the ash was—

| K <sub>2</sub> O. | Na <sub>2</sub> O. | CaO. | MgO. | Fe <sub>2</sub> O <sub>3</sub> . | SiO <sub>2</sub> . | P <sub>2</sub> O <sub>5</sub> . |
|-------------------|--------------------|------|------|----------------------------------|--------------------|---------------------------------|
| 38.51             | 1.90               | 8.20 | 3.65 | 0.58                             | 3.33               | 15.80                           |

The sulphuric acid in the ash was not determined, because the 0.48 part of sulphur in 1000 parts of the onion includes the total amount of sulphur present in any form. Whilst sulphur is an essential constituent of all plants, it is only in a comparatively few families that it exists in volatile combinations capable of imparting strong and offensive odours. As many plants of this kind when eaten by cows impart their odour to the milk, their absence is one condition of good dairy farm pastures.

R. R.

**Manurial Experiments with Various Phosphates.** By KREMP (*Bied. Centr.*, 1887, 525—527).—The crop was oats, and various phosphates:—super, precipitated and basic cinder, were used in combination with Chili saltpetre. Very little or no gain was obtained by the addition of the phosphates. Analyses of the soil are not given.

E. W. P.

**Manuring with Various Phosphates.** By W. ROBERTS (*Bied. Centr.*, 1887, 528—530).—Superphosphate was compared with precipitated and Ardennes phosphates as to its action on the growth of wheat. The Ardennes produced an intermediate crop, whilst that from the use of the precipitated phosphate was only an eighth of the net gain by the use of superphosphate. Further experiments on potatoes, roots, and buckwheat showed a similar result, the reduced phosphate lagging far behind.

E. W. P.

---

## Analytical Chemistry.

---

**Improved Form of Elliott's Gas Apparatus.** By J. B. MACKINTOSH (*Amer. Chem. J.*, 9, 294—296; compare *Abstr.*, 1884, 215).—The measuring tube is provided at the top with a three-way stopcock, and is thus permanently connected on the one side with the absorption burette, on the other with the explosion burette, the small funnel for the top of which is no longer required.

A convenient method of preparing oxygen for gas analysis is by the

action of hydrogen peroxide on an acidified permanganate solution in the absorption burette. H. B.

**New Mode of Testing for Nitrates.** By E. BRÉAL (*Ann. Agronom.*, 13, 322—327).—The author utilises the tendency of dissolved nitrates to accumulate in capillary spaces, or where evaporation is most active. One end of a strip of white filter-paper is immersed in the solution to be tested, the other end being freely exposed to the air. After the lapse of 12 to 15 hours, if the solution contained only traces of nitrates, these will be found entirely concentrated within a millimetre of the free end of the strip of paper. This is cut off, dried on a white surface, and moistened with a drop of phenolsulphonic acid, made by adding one part of crystallised phenol to one part of recently boiled pure sulphuric acid and diluting with two parts pure distilled water. A more or less intense red coloration indicates nitrates; when a drop or two of ammonia is added the colour changes to an intense blue or green. The filter-paper employed must be purified by repeated washing with pure distilled water. The delicacy of the test is considerable. One drop of a solution containing 1 mgrm. of potassium nitrate in 1 c.c. of water gives with phenolsulphonic acid an intense red coloration; this drop will contain about 0.025 mgrm. of nitric acid. If one drop of this solution is added to 100 c.c. of water, and the strip of filter-paper immersed in it, nitric acid may be distinctly recognised after 12 hours in the millimetre of paper nearest the free end. This method, therefore, affords the means of detecting a quarter of a mgrm. of nitric acid in a litre of water, or 1 in 4,000,000. If the strip of paper be partly immersed in moist soil, any nitrates in the soil can be very easily detected, and the method promises to become of much use in experiments on the relation of nitrates to plant growth. J. M. H. M.

**Detection of Potassium by means of Sodium Bismuth Thiosulphate.** By C. PAULY (*Chem. Centr.*, 1887, 553).—The author has reinvestigated this reaction, first proposed by Carnot, and finds that it is really characteristic for potassium, and can be applied without previous separation from most other metals. It consists in adding an alcoholic solution of sodium bismuth thiosulphate, when a yellow, crystalline precipitate of potassium bismuth thiosulphate,  $K_3Bi(S_2O_3)_3$ , is obtained. A. J. G.

**Determination of Alkaline Chlorides in Potashes.** By H. FOCKE (*Chem. Centr.*, 1887, 699).—In order to determine the proportion of sodium and potassium chlorides in potashes, the dissolved sample is neutralised with dilute sulphuric acid, a few drops of normal soda added, and the whole evaporated. The residue is taken up with 85 per cent. alcohol, the water required for the dilution of the alcohol being poured on the mass, and then the absolute alcohol added gradually. After a time, the liquid is filtered, and the insoluble portion washed with alcohol; the mixed solutions are then evaporated, the residue dissolved in water, and the proportion of alkali-metal, and chlorine determined in aliquot proportions respectively. V. H. V.

**Testing Copper Sulphate.** By BAUDOIN (*Ann. Agronom.*, 13, 319—321).—Copper sulphate being now largely employed for application to vines, it becomes of importance to test commercial samples, especially for the sulphates of iron, zinc, and magnesium. Iron is of course easily detected by boiling the solution with nitric acid and adding excess of ammonia. Zinc is best detected by Chancel's process; sodium hyposulphite is added to the solution of the copper sulphate until the latter is decolorised, sodium carbonate is then added, which precipitates both zinc and magnesium if present. They can be separated in the usual way. The author is engaged in ascertaining whether the density of commercial samples of copper sulphate may be utilised as indications of purity. J. M. H. M.

**Analysis of Clay.** By C. MEINEKE (*Chem. Centr.*, 1887, 553).—The clay is fused with hydrogen sodium carbonate, the product treated with hydrochloric acid, evaporated to dryness, and heated for some time at 150—300°. It is then dissolved in cold water, decanted five times, and the silica washed on a filter. After ignition, the silica is again evaporated with hydrochloric acid and washed. The weighed silica is treated with hydrofluoric acid, the alumina and ferric oxide determined, and the weight deducted.

The filtrate is evaporated in a platinum dish, when a residue is obtained insoluble in hydrochloric acid, and consisting of silica and alumina.

Sand is determined in the residue obtained by decomposing the clay with sulphuric acid. The residue is dried at not too high a temperature, and exposed to air until no further increase in weight takes place during weighing. The greater part of the residue is weighed, and divided into two nearly equal portions, the one (*a*) is ignited, the other (*b*) is extracted with boiling alkali. From the weight of (*a*) the weight of (*b*) when anhydrous is calculated. The filtrate (*c*) with the rest of the residue is now ignited, and thus the whole weight of anhydrous residue and the proportion  $a : b : c$  ( $a + b + c$ ) in the dry and anhydrous state is obtained. N. H. M.

**Determination of Manganese by means of Mercuric Oxide and Bromine.** By C. MEINEKE (*Chem. Centr.*, 1887, 554).—Volhard's method is modified as follows:—The solution in nitric or sulphuric acid containing iron as well as manganese to be determined, is precipitated with zinc oxide and made up to a definite bulk. An aliquot part of the solution is treated in the following manner:—Mercuric oxide rubbed with water and bromine-water are alternately added until the former is in considerable excess, when a sudden separation of manganese occurs. The manganese peroxide adhering to the sides of the vessel is dissolved in hydrochloric acid and treated separately. The precipitate is mixed with the oxides of iron and zinc, but is free from manganous oxide. The pure manganic oxide is determined volumetrically by reducing with oxalic acid mixed with hydrochloric acid (eq. mols.), and determining the excess of oxalic acid with permanganate. N. H. M.

**Estimation of Metallic Iron in Slags.** By G. NEUMANN (*Zeit. anal. Chem.*, **26**, 530—534).—The usual process, which consists in digesting the slag with copper sulphate and ascertaining the quantity of copper deposited, is accurate in the absence of other reducing agents but is tedious. The measurement of the hydrogen evolved by the substance when treated with a dilute acid gives equally accurate results, and is much more rapid. The ferric oxide present seems to remain inert. A special apparatus for the purpose (for which the unfortunate name “hydrometer” is proposed) consists of a graduated tube with a stopcock-funnel at the top, and a wide-bore (5 mm.) stopcock at the bottom. A narrow tube inserted at the side in an upward direction just above the lower stopcock communicates with a pressure tube like that of the nitrometer. The flask containing the substance is connected directly with the lower end of the graduated tube which is widened to the size of the neck, and is filled to the lower stopcock with water. The graduated tube is then filled through the pressure tube with acid which, on opening the stopcock, finds its way down to the slag. The gas rises through the stopcock into the burette. Any carbonic anhydride or hydrogen sulphide can be absorbed by running in potash through the stopcock-funnel until the contents of the burette are alkaline.  
M. J. S.

**Rapid Methods for the Estimation of Silicon, Sulphur, and Manganese in Iron and Steel.** By J. J. MORGAN (*Chem. News*, **56**, 82—83).—Silicon is estimated by the so-called “roasting” method, heating in a muffle at a bright-red heat for 20 minutes, treating with hydrochloric acid, and igniting the insoluble silica, &c.

For the estimation of sulphur, the sample is treated with sulphuric acid, and the gases evolved are passed into a measured quantity of a dilute solution of lead acetate. The colour of this solution is then compared with that obtained by treating a steel having a known amount of sulphur in a similar manner, and so on.

To estimate the manganese, the sample is dissolved in nitric acid, cooled, treated first with a small quantity of water, then with lead peroxide and a few drops of strong nitric acid, boiled for four minutes, and finally cooled. The manganese is calculated from the permanganate formed, which is estimated by comparing the colour with a standard as in the case of the sulphur. For phosphoric acid, the author prefers the molybdate method.  
D. A. L.

**Estimation of Silicon in Iron and Steel.** By T. TURNER (*Chem. News*, **56**, 49—50).—It is shown by experiments that silicon can be correctly estimated in cast irons of very good quality by evaporation with dilute sulphuric acid; but with phosphoric irons the residues obtained are white but impure, and when in addition an iron contains titanium, the residue, although very nearly white, may have 20 per cent. of impurity, and contains iron, phosphoric acid, and titanium. Evaporation with sulphuric acid gives fairly good results with steels containing only a small quantity of silicon. In the aqua-regia method, the colour of the residue is usually an indication of its purity.  
D. A. L.

**Determination of Sulphur in Iron.** By P. PLATZ (*Chem. Centr.*, 1887, 579).—The barium chloride method for the determination of sulphur in iron is modified as follows:—The iron and sulphur are oxidised by nitric acid; on prolonged boiling, the nitric acid is displaced by hydrochloric acid by gradually adding the latter. The whole is then evaporated until vapours of hydrogen chloride are no longer evolved, the residue diluted with water, and the insoluble silica filtered off. To the filtrate, barium chloride is added, and the precipitate collected and heated to oxidise any barium sulphide which may have been formed.

The precipitate is finally digested with hydrochloric acid to dissolve out the iron oxide, and weighed. Control experiments gave satisfactory results.  
V. H. V.

**Volumetric Estimation of Cobalt in Presence of Nickel.** By N. McCULLOCH (*Chem. News*, 56, 27—29).—The author finds that cobalt “peroxide” is reduced by free iodine, iodides, hypochlorites, hypobromites, and hydrogen peroxide and ammonia to a lower oxide or oxides, possibly  $\text{Co}_{13}\text{O}_{19}$ , hence the author confirms Bayley’s results (*Abstr.*, 1879, 507), but he gives no hope of founding a method of estimating cobalt in presence of nickel, depending on the higher oxides of cobalt.  
D. A. L.

**Separation of Nickel and Cobalt from Iron.** By J. B. MACINTOSH (*Chem. News*, 56, 64—65).—Proceeding at first by the old method of precipitating all three metals by ammonium sulphide, and treating with dilute hydrochloric acid; a solution with much iron and little nickel and cobalt, and a precipitate rich in nickel and cobalt but poor in iron are obtained. These are then treated separately in the ordinary way, by precipitating the iron as basic acetate, and perfect separation of the nickel and cobalt from iron is effected much more readily than by the “basic acetate” treatment alone.

D. A. L.

**Direct Precipitation of Nickel Oxide in the Presence of Iron.** By T. MOORE (*Chem. News*, 56, 3).—The solution containing the two metals, freed from acids, is treated first with glacial phosphoric acid or sodium pyrophosphate until the precipitate begins to dissolve, then with potassium cyanide which dissolves the remainder of the precipitate. This solution is now boiled for a couple of minutes, and the addition of potassium cyanide continued until potassium hydroxide does not give a precipitate. When cool, the solution is made alkaline with potassium hydroxide, excess of bromine solution in potassium hydroxide added, and the whole warmed; nickel and manganese (if present) are precipitated, iron and cobalt remain dissolved. The precipitate is dissolved in sulphuric acid and the nickel deposited electrolytically. Good results have been obtained with this method.

D. A. L.

**Water Analysis.** (*Chem. News*, 56, 113.)—The Chemical Section of the American Association for the Advancement of Science recommends the following plan for a uniform method of stating results of

water analysis. They are of opinion that two distinct schemes should be in use, one for mineral and one for potable waters. Mineral water results should state in parts per 1000, by weight, each basic element, each acid element in combination or supposed combination with the bases, the remaining acid elements being given in connection with all the oxygen of their salts ( $\text{CO}_3$ ,  $\text{SO}_4$ , &c.). Volumes of gases expelled on boiling to be in cubic centimetres per litre. Constituents should be arranged in electropositive order, positive ones first. Potable water results to be stated in parts per million, to include—Total solids, chlorine, nitrogen expelled on boiling with sodium carbonate, and nitrogen as free ammonia, nitrogen expelled by boiling with alkaline permanganate and albuminoid nitrogen, nitrogen as nitrite and as nitrate; organic matter; hardness. D. A. L.

**Estimation of Methyl Alcohol in Presence of Ethyl Alcohol.** By O. HEHNER (*Analyst*, 12, 25—29).—Since 1 part of ethyl alcohol (oxidised to acetic acid) reduces 4.278 parts of potassium dichromate, whilst 1 part of methyl alcohol requires 9.224 parts (oxidising to carbonic anhydride and water), the proportions of the two in a mixture can be calculated from a determination of the amount of dichromate reduced by 1 part of the mixture. This was confirmed by several experiments on mixtures of known composition. The oxidising solution contained 80 grams of dichromate, and 150 c.c. of concentrated sulphuric acid in the litre. Of the diluted alcohol, a quantity containing about 0.2 gram is mixed with 25 or 30 c.c. of the chromate solution in a bottle, which is corked and heated in boiling water for at least two hours. The unreduced chromate is then estimated by iron solution and standard dichromate. M. J. S.

**Dimethyl Ethyl Carbinol.** By B. FISCHER (*Arch. Pharm.* [3], 25, 777—779).—This compound (amylene hydrate) has recently been strongly recommended as an opiate. As it may be contaminated with fermentation amyl alcohol, which is poisonous, it should be subjected to the following tests. 1 gram is dissolved in 15 c.c. of water and tinted a faint red with permanganate solution; the colour ought not to change within 15 minutes (ethyl and amyl alcohol). 1 gram is dissolved in 15 c.c. of water, and slightly warmed with potassium dichromate and dilute sulphuric acid, no green colour should appear within half an hour (as above). 1 gram dissolved in 15 c.c. water is warmed with some drops of silver nitrate and a trace of ammonia. The silver should not be precipitated (aldehyde, with which most of the primary alcohols are contaminated). As an opiate this compound is more powerful than paraldehyde, but less so than chloral hydrate. Its therapeutic value depends on the fact that it affects neither the breathing nor the action of the heart. J. T.

**Estimation of Glycerol in Fermented Liquids.** By L. LEGLER (*Analyst*, 12, 14—16).—The ordinary process, in which the crude glycerol is purified by extraction with ether-alcohol, is unsatisfactory, owing to the retention of some of the glycerol by the impurities. The author dilutes the crude glycerol with water, adds an excess of

potassium dichromate, and treats the mixture with sulphuric acid in a Will's carbonic acid apparatus in the ordinary way for a carbonic acid determination. Gentle boiling is required to complete the oxidation of the glycerol to carbonic anhydride and water. In analysing sweet wines, the glucose they contain may be destroyed by evaporation to dryness with baryta-water before extracting the glycerol with alcohol. Cane-sugar must first be inverted by boiling with hydrochloric acid. The crude glycerol contains impurities which yield carbonic anhydride on oxidation. The amount of these precipitated by ammoniacal solution of lead acetate is said to be constant and to be equivalent to 0.035 gram of glycerol per 100 c.c. of wine. Further experiments are promised.

M. J. S.

**Estimation of Glycerol and its Non-volatility with Aqueous Vapour.** By O. HEHNER (*Analyst*, 12, 44—46, and 65—67).—The glycerol is oxidised as in Legler's process (preceding Abstract) by an excess of potassium dichromate and sulphuric acid, but the author measures the amount of dichromate reduced. One part of glycerol requires 7.486 parts of dichromate. The oxidising solution contains 80 grams of potassium dichromate, and 150 c.c. of strong sulphuric acid per litre. The unreduced excess is determined by titration with iron and standard dichromate. In moderately strong solutions (12 grams per litre), two hours' heating is sufficient to ensure the complete oxidation of the glycerol, but in highly dilute solutions a further addition of sulphuric acid is requisite. Such dilute solutions can, however, be concentrated by vigorous boiling without the loss of a trace of glycerol. Even a 50 per cent. solution boiled for two hours in a covered beaker, with continual replacement of the evaporated water (257 c.c.), did not suffer an appreciable loss of glycerol, whilst the loss from a 74 per cent. solution was very insignificant.

M. J. S.

**Determination of Moisture in Starch.** By F. W. DAFERT (*Chem. Centr.*, 1887, 567).—Experiments are described to ascertain the temperature at which starch suffers the maximum loss in weight without appreciable decomposition. At 120° the loss was 11.31 per cent.; at 105—107°, 10.89 per cent.; and at 100° in a vacuum 11.9 per cent.; in the first case, the starch was slightly changed, but in the last it was unaltered. It is recommended that determinations of moisture should be conducted by this method.

V. H. V.

**Logwood Test for Alum in Bread.** By W. C. YOUNG (*Analyst*, 12, 29—32, and 145—147).—Sour bread gives the same blue coloration with logwood as bread to which alum has been added. Specimens of bread which gave no indication with the logwood test, all showed the blue colour intensely after being moistened with very dilute acetic acid. Since aluminium phosphate is perceptibly soluble in cold, though not in hot, acetic acid, it is possible that this may account for the reaction after acidifying.

M. J. S.

**Estimation of Hydrocyanic Acid.** By O. LINDE (*Arch. Pharm.* [3], 25, 690).—In the determination of hydrocyanic acid in bitter

almond water according to the Paris Pharmacopœia, the author proceeds as follows:—The bitter almond water is diluted with two volumes of water as the reactions then proceed most rapidly; basic magnesium acetate is added at once in considerable excess of the potassium chromate solution, not "some" drops, but only two drops per 27 grams of water to be added; of the silver solution almost sufficient to precipitate the whole of the acid should be added *at once*; the titration is best made by daylight, as the persistent red colour is not so well seen by gas- or lamp-light. J. T.

**Estimation of Thiocyanic Acid.** By P. KLASON (*J. pr. Chem.* [2], 36, 74—77).—If hydrochloric acid is not present, thiocyanic acid may be accurately determined by titration with silver nitrate. If hydrochloric acid is present the determination must be made by oxidation with permanganate. Here, however, the degree of concentration influences the result—which is always too low. If the concentration is not less than decinormal, the result is  $1\frac{1}{2}$  per cent. too low, and this should be added to the amount found. L. T. T.

**Estimation of Carbonic Acid in Beer.** By C. A. CRAMPTON and T. C. TRESCOT (*Amer. Chem. J.*, 9, 290—293).—The cork of the bottle is pierced by a champagne tap and the gas passed through an Erlenmeyer's flask (to retain any foam), then dried by sulphuric acid and calcium chloride, and absorbed by soda-lime; the sample is afterwards heated to 80°, and the gas swept into the soda-lime tube by a current of pure air. The authors find an average of almost 0.4 per cent., most authorities giving an average of 0.1 to 0.2 per cent.; a higher amount of carbonic acid indicates either the addition of sodium bicarbonate or a state of after-fermentation. H. B.

**Estimation of the Free Acid in Tannin Liquor by Titration.** By R. KOCH (*Dingl. polyt. J.*, 265, 33—41).—In a previous communication (this vol., p. 871), the author recommended the use of albumin for the separation of tannin and the decolorisation of tannin liquor. He now finds that a solution of gelatin is preferable, as the precipitation of albumin by the aid of heat and the subsequent cooling is found to be inconvenient. It is necessary, however, to adjust the concentration of the gelatin solution to the amount of tannin in the liquor, otherwise difficulties in connection with the filtration and washing of the precipitate will arise. A solution containing 2 grams of gelatin in a litre of water is applicable to most liquors. The process is described in detail in the paper, and several test analyses are given. The author also states that powdered skin cannot be used for decolorising tannin liquor for the purpose of determining the free acid contained therein, owing to the fact that it absorbs acid from such liquors. D. B.

**The Lactocrite; a New Apparatus for Determining Fat in Milk.** By H. FABER (*Analyst*, 12, 6—11).—The principle of this apparatus and method introduced by De Laval, consists in the separation of the fat by centrifugal force, after the casein has been

brought into such a condition that it does not prevent the union of the fat globules. This is effected by heating the milk with an equal volume of glacial acetic acid containing 5 per cent. by volume of concentrated sulphuric acid. The mixture is then introduced into a graduated tube, and several of these tubes at once are rotated for a few minutes in a specially constructed disc. The column of butter-fat obtained gives the percentage by a simple reading on the graduated tube. The results can be trusted to within 0.1 per cent. in whole milk, but in skimmed milk are about 0.2 per cent. too low.

M. J. S.

**Reichert's Distillation Process.** By A. H. ALLEN (*Analyst*, 12, 11—13).—Porpoise oil and some samples of whale oil give nearly as large a percentage of volatile fatty acids as butter does. The appearance of solid fatty acids in the distillate is an indication of the presence of cocoanut oil. They should be filtered off before titrating. It is desirable to saponify the fat in a flask or closed bottle, since saponification in an open basin is found to give low results. The form of the distillation apparatus is of little importance.

M. J. S.

**Volumetric Estimation of Urea.** By G. CAMPANI (*Gazzetta*, 17, 137—141).—The method described is based on the reaction of nitrous acid on urea, and estimation by alkalimetry of the carbonic anhydride evolved. In a tube of 150 to 200 c.c. capacity 20 c.c. of a 10 per cent. solution of potassium nitrite is introduced, then 2 c.c. of urine, and lastly 2 c.c. of 5 per cent. sulphuric acid. The tube is then fitted with a delivery tube, the contents gently warmed and the carbonic acid evolved is collected in lime-water of known strength. When the reaction is complete, the amount of lime neutralised by the carbonic anhydride is determined in the usual manner by a standard solution of oxalic acid; 1 mol. of carbonic anhydride corresponds with 1 mol. of urea, thus:  $\text{CO}(\text{NH}_2)_2 + 2\text{HNO}_2 = 3\text{H}_2\text{O} + 2\text{N}_2 + \text{CO}_2$ . The results obtained in test analyses are fairly concordant with one another and with those obtained by Liebig's method. It is necessary that the reaction should be allowed to proceed slowly; otherwise nitrous acid is evolved.

V. H. V.

**Estimation of Quinine Sulphate.** By O. HESSE (*J. Pharm.* [5], 16, 213—215).—1 gram of the sulphate dried at 100° is agitated with 20 c.c. of water at 60° and filtered after cooling; 5 grams of the filtrate is placed in a somewhat narrow test-tube; 2 c.c. of ether and five drops of ammonia are added; the tube is now stoppered and carefully agitated. The ethereal solution ought to be limpid, and should not deposit crystals. The author thinks that Paul's method gives good results when modified as follows: 5 grams of sulphate is dissolved in boiling water and allowed to crystallise; the mother-liquor is set aside and the crystals are dissolved in 120 c.c. of boiling water, recrystallised, and the process is repeated a third time, &c., the mother-liquor always being set apart. Three crystallisations suffice

with a salt containing 5 per cent. of cinchonidine sulphate; five crystallisations are indispensable when 9 per cent. is present. The mother-liquors of the three first crystallisations are evaporated to dryness, the residue is dissolved in dilute sulphuric acid, water is added to 20 c.c., and this is agitated with 16 c.c. ether and excess of ammonia. After 24 hours, the crystals of cinchonidine are collected. Similarly the remaining mother-liquors are made into a volume of 8 c.c., and treated with ammonia and 2 or 3 c.c. of ether; the crystals obtained are weighed with the preceding crop. The results thus obtained agree sensibly with those afforded by de Vrij's bisulphate method.

J. T.

**Testing Quinine Sulphate.** By G. KERNER and A. WELLER (*Arch. Pharm.* [3], 25, 712—738, and 749—765).—The ammonia test for commercial quinine sulphate was proposed by one of the authors at a time when South America was the chief source of the salt, and the compound was almost free from cinchonidine; more recently Asiatic products have appeared in the market, in which cinchonidine often occurs in very considerable proportions. To meet the new conditions, the following method is proposed:—The sample of quinine sulphate is maintained at 40—50° until completely disintegrated, 2 grams in 20 grams of water is kept at 60—65° for half an hour with frequent stirring. The temperature is now brought to 15° and maintained at that for two hours with stirring, care being taken to have the temperature 15° exactly before the subsequent filtering. 5 c.c. of the filtrate is treated with ammonia of 0.96 sp. gr. until the precipitated quinine is again exactly dissolved. The amount of ammonia required should not exceed 10 c.c. The authors conclude that none of the methods hitherto proposed for the exact separation of cinchonidine and quinine are really exact. The same remark holds for the estimation of hydroquinine.

J. T.

**Detection of Hop-substitutes in Beer.** By A. H. ALLEN (*Analyst*, 12, 107—114).—A litre of the beer is evaporated to about 300 c.c. and precipitated hot with normal lead acetate, which is preferable to the basic or ammoniacal acetate of older processes. This throws down lupulin and hop-resin completely, leaving all or nearly all hop-substitutes in solution. After filtration, first hot and then cold, the lead is removed by hydrogen sulphide and the filtrate further concentrated. It is then acidified with sulphuric acid and shaken repeatedly with chloroform, which extracts absinthin, anthe-min (chamomiles), quassiin, calumbin (colchicine, colocynthis, berberine, gentipicrin, picric acid, and picrotoxin imperfectly); ether is next employed to extract chiratin (chiretta), colocynthin, gentipicrin, picric acid, and picrotoxin. A further treatment with ether-chloroform after addition of ammonia completes the extraction of berberine and colchicine. If the residue from one of these solvents has a bitter taste, the presence of some hop-substitute is certain.

Quassiin, prepared by the above process, does not reduce Fehling's

solution or ammoniacal silver nitrate, and gives no coloration with strong sulphuric acid, or with nitric acid of 1.25 sp. gr., even on warming. It gives a mahogany-brown colour with ferric chloride. Its chloroform solution treated with an excess of bromine and then with ammonia gives a bright yellow colour (Christensen). A solution of 1 part of quassin in 500,000 of water has a strong and persistent bitter taste. Gentipicrin and menyanthin reduce ammoniacal silver nitrate. With sulphuric acid, the former gives a red colour, the latter a yellowish-brown becoming violet-red on warming.

The chloroform extracts from chamomiles, calumba, colocynth, cocculus, and chiretta give no reaction with bromine and ammonia. The ether residue from chiretta, gives a straw-yellow colour changing to dull purplish-brown. Chiratin does not reduce Fehling's solution; it gives a copious precipitate with tannin. M. J. S.

**Estimation of Ipecacuanha.** By F. RANSOM (*Pharm. J. Trans.* [3], 18, 241—242).—The powdered ipecacuanha is thoroughly exhausted with chloroform that has been rendered alkaline by previous agitation with a strong solution of ammonia. An extraction apparatus is employed by means of which the exhaustion can be completed with hot chloroform. The solution is then agitated with dilute sulphuric acid, and the emetine in the acid solution estimated volumetrically by Mayer's reagent. R. R.

**Detection of Aniline Colours in Wine, &c.** By C. O. CURTMAN (*Zeit. anal. Chem.*, 26, 555—556).—The formation of isonitriles when aniline-derivatives are warmed with potash and chloroform serves for the direct detection in wine of even minute traces of many of the aniline colours. The evolution of the isonitrile is accelerated by adding excess of strong sulphuric acid. M. J. S.

**Estimation of Indigo.** By G. MANNLEY (*Chem. Centr.*, 1887, 605).—In order to determine the proportion of indigo in a sample, the moisture is first estimated, and the dried mass introduced into a test-tube moistened with alcohol and a fine emulsion of grape-sugar in alcohol, and a few c.c. of soda solution added to it. The tube is then filled with alcohol, agitated for some time, left for 24 hours, and then poured into dilute sulphuric acid and oxidised by agitation. Hydrogen peroxide can also be used, and is to be preferred, because the precipitate in this case does not adhere so much to the walls of the vessel. The whole is allowed to remain for two days, filtered through a tared filter, dried and weighed. A gram of substance is a convenient quantity for the determination. V. H. V.

**Testing Indigo Dyes on Fabrics.** By W. LENZ (*Zeit. anal. Chem.*, 26, 535—555).—In the course of an enquiry into the genuineness of the indigo dye on a certain fabric, an extensive examination of the methods of testing blue dyes was made, and those at present in use were found not to be altogether trustworthy. Stuffs were

dyed with 12 varieties of indigo, using dilute soda and zinc powder for the reduction in order to avoid the removal of impurities which takes place in the lime-copperas vat. In the case of one of the samples (fine Java indigo), the dyed fabric behaved with acidified alcohol as though it had received a second dyeing with logwood. This anomalous result appears to have been due to the formation of an unstable yellow product of the reduction of indigo. It could not be obtained again with the same sample.

For the detection of the more usual blue dyes the following methods may be trusted:—The stuff is warmed with an acidified 10 per cent. solution of stannous chloride. Prussian-blue remains unchanged. Indigo (vat-blue), indigo-carmin, cotton-blue (triphenyl-rosoaniline trisulphonate) are completely removed from the fibres and yield pale-yellow solutions. Logwood is also removed but gives a rose-red solution. On adding a large excess of hydrogen peroxide to these solutions, the rose-red of logwood is destroyed, cotton-blue gives a blue solution, whilst indigo is not regenerated.

Glacial acetic acid, or concentrated formic acid, dissolves indigo from a fabric. In presence of logwood, either acid in the cold acquires a rose-red colour, which on heating passes into yellowish-red, and is soon obscured by the dissolving indigo. Prussian-blue is unaffected, and indigo-carmin is not dissolved if more than 48 hours have elapsed since the dyeing. On mixing the acetic acid solution with ether and then adding water until the ether separates, the indigo is removed from the aqueous layer, which then in the presence of logwood shows a feeble reddish-yellow tint. If now a few drops of concentrated hydrochloric acid is added, the smallest trace of logwood is revealed by the production of a rich red colour in the aqueous layer. Cotton-blue obscures this reaction. In this case, the aqueous layer must be separated and shaken with chloroform, or better amyl alcohol, which abstracts the aniline-blue. Another method of examining the acetic acid solution is to mix 1 c.c. of it with 5 c.c. of chloroform, then add 2 c.c. of water and crystallised sodium carbonate until alkaline. The chloroform layer is then separated and shaken with strong borax solution, which frees it from logwood. It is then mixed with ether and dilute acetic acid, when the aniline blue passes into the acid and the indigo remains in the mixture of ether and chloroform. The alkaline solution contains the indigo-carmin and logwood; this is acidified with acetic acid and shaken with amyl alcohol, which removes the logwood with reddish colour, further intensified by hydrochloric acid.

If a fabric dyed with the above colours is boiled with borax solution the logwood-blue and indigo-carmin are dissolved, whilst Prussian-blue is decomposed. Aniline-blue and vat-blue remain on the fibre, and may be distinguished by warming with ferric chloride. The filtered borax solution, which in presence of indigo-carmin is blue, is tested for logwood by stannous chloride.

As a special test for logwood, the stuff may be treated directly with hydrochloric acid, or boiled with a 10 per cent. solution of alum, or of glucinum chloride to which an excess of ammonium carbonate is subsequently added. Ammonium molybdate gives at once an intense

blue-violet. The absorption spectra of many of these solutions are figured.

A fabric dyed with indigo alone should stand the following tests :—Alcohol should dissolve no colour even on gentle warming; cold saturated oxalic acid and borax solutions, 10 per cent. alum solution, and 33 per cent. ammonium molybdate must remove no colour even on boiling. Stannous or ferric chloride destroys the colour on warming. Glacial acetic acid dissolves all the colour on repeated boiling, and after mixing the solution with ether and water the aqueous layer is colourless and is not coloured by strong hydrochloric acid. The fabric boiled with hydrochloric acid evolves no hydrogen sulphide, and the acid extract warmed with a large excess of alkali and some chloroform evolves no odour of isonitriles.

M. J. S.

**Detection of Artificial Colouring Matters in Butter, &c.** By E. W. MARTIN (*Analyst*, 12, 70).—The following method serves for the detection of annatto, turmeric, carotin, and the aniline- and naphthol-yellows. Two parts of carbon bisulphide are gradually added to 15 parts of methyl alcohol, with gentle shaking; to 25 c.c. of the mixture, in a convenient tube, 5 grams of the butter-fat or oil is added, and the tube is shaken. In a few minutes the bisulphide falls to the bottom, carrying with it the fat, whilst the foreign colouring matter remains in the alcohol. The natural colouring matters of fats, &c., do not colour the methyl alcohol.

M. J. S.

**Pettenkofer's Reaction.** By F. MYLIUS (*Zeit. physiol. Chem.*, 11, 492—496).—The cause of the blood-red colour produced on adding cane-sugar and sulphuric acid to cholic acid (Pettenkofer's reaction) is unknown. The same colour is produced by the bile acids, by choleic acid, and by the distillation products of cholic acid. On the other hand, dehydrocholic acid and bilianic acid do not give it; in these latter acids hydroxyl is absent, and it is not improbable that the reaction depends on the presence of the hydroxyl-group. The reaction may be obtained by using furfuraldehyde instead of sugar. That it is not the sugar itself on which the reaction depends, but some volatile substance, was considered probable, because the reaction was obtained from the distillate of sugar with dilute sulphuric acid; acetone, mesityl oxide, and phorone, which are formed in this process, do not give the reaction, but furfuraldehyde, which is also formed, does. As a test for furfuraldehyde, it is exceedingly delicate, a drop of a mixture of water and furfuraldehyde in the proportion 20,000 to 1 gives the colour on the addition of cholic acid and sulphuric acid; in other words, the fortieth part of a milligram can be thus detected. The colour can be extracted by ether, which is coloured blue by it.

Other substances, however, besides cholic acid give the same reaction with furfuraldehyde, namely, isopropyl alcohol (to a slight extent), isobutyl alcohol (very intensely), allyl alcohol, trimethyl carbinol, dimethyl ethyl carbinol, amyl alcohol, oleic acid, and petro-

leum. Among the substances which do not give the colour are the following:—Ethyl alcohol, propyl alcohol, capryl alcohol, acetic acid, isobutyric acid, acetaldehyde, and benzene. The substances which give the test are seen in general to be unsaturated compounds, or those which by the loss of water become unsaturated; it is considered not improbable that the reaction depends on some hydrocarbon produced from the foregoing compounds when they lose water owing to the action of sulphuric acid.

W. D. H.

**Detection of Albumin in Urine.** By A. LIEBERMANN (*Chem. Centr.*, 1887, 600).—If albumin is extracted a few times with alcohol, and then washed with cold ether, it gives a deep violet coloration if heated with concentrated hydrochloric acid (sp. gr. 1.196). Positive results were obtained with various pathological products, but experiments with hæmoglobin, chondrin, and keratin, were unsuccessful. In the case of urine, the liquid is at first boiled with a small quantity of acetic acid, and the precipitated albumin treated as above; the reaction succeeded with 5 c.c. of urine to which 0.1 per cent. of egg-albumin was added.

# INDEX OF SUBJECTS.

## ABSTRACTS. 1887.

And also to Transactions, 1887 (marked TRANS.); and to such papers as appeared in Abstract of Proceedings but not in Transactions (marked PROC.).

### A.

Abrin, 990.

Absorption in the stomach of the horse, 743.

Acenaphthene, 592.

— amido-, 592.

— constitution of, 495.

— nitro-, 592, 964.

Acetaldehyde, action of, on polyvalent phenols, 809.

Acetaldoxime hypochlorite, 795.

Acetalresorcinol, 40.

Acetals, chloro-derivatives of, 28.

Acetamide, action of hydroxylamine on, 911.

Acetamido-benzene-*m*-diazopiperidide, 131.

Acetanilide, action of phosphoric chloride on, 481.

— orthazo-*p*-brom-, 251.

Acetates, decomposition of, by water, 767.

— estimation of acetic acid in, by direct titration, 869.

— ethereal, action of alcoholic and metallic alkyl oxides on, TRANS., 632.

Acetic acid and its derivatives, behaviour of, with phosphoric chloride, 359.

— — methane fermentation of, 1135.

— — separation of, from formic acid, 751.

— — specific heat of the vapour of, 429.

— — synthetical, 796.

— chloride, action of aluminium chloride on, 127.

— — chlorination by means of, 932.

$\beta$ -Acetonaphthalide, dimi-*tro*-, 839.

Acetoacetic anilide and its bromo- and isonitroso-derivatives, 159.

Acetoacrylic acid, 465.

Acetobutyl alcohol, TRANS., 718.

— — anhydride of, 32.

— bromide, TRANS., 726.

Acetochloro- $\beta$ -naphthylamine, 961.

Acetodimethylphenylhydrazine, 932.

Acetofluoranilide, 131.

Acetomethylphenylhydrazine, 932.

Acetonaloxybutyric acid, 1030.

Aceto- $\alpha$ -naphthalide, action of chlorine on, 494.

Acetone, action of ethyl oxalate on, 917.

— action of nitrous acid on, 568.

— action of, on *p*-amidoazobenzene, 479.

— and chloroform, action of potash on a mixture of, 569.

— chlorotribrom-, 1097.

— condensation products of, with aniline and ammonia, 599.

— dibromodichlor-, 1098.

— dichlor-, isomeric forms of, 1092.

— diisonitroso-, 28.

— hexachlor-, 1096.

— monochlor-, 1091.

— nitroso-, 1104.

— pentachlor-, 1095.

— tetrachlor-, isomeric forms of, 1094.

— trichlor-, isomeric forms of, 1093.

— trichlorobrom-, 1098.

Acetonebenzoyl phenylhydrazide, 820.

Acetonechloroform, acids from, 1030.

Acetonehydrazinebenzenesulphonic acid, 933.

Acetones, chlor-, 1091.

— — action of ammonia and amines on, 1098.

— chlorobrom-, 1097.

- Acetonitrile, synthetic, 712.  
 Acetonoxisobutyric acid, 1030.  
 Acetophenone, action of potassium ferri-  
 cyanide on, 483.  
 — condensation products with aniline  
 and ammonia, 599.  
 — dichloro-, 141, 922.

Barley, American, 616.

— composition of, 73.

Barytocalcite, chemical constitution of, 18.

Bases, coefficients of affinity of, 324.

— from animal oil, 157.

Basic slag as manure, 995.

— — crystals in, TRANS., 601.

— — phosphoric acid of, 445.

Batteries, voltaic, ferric chloride as an exciting liquid for, 413.

Battery, water, simple form of, 412.

Beans, iron sulphate as a manure for, TRANS., 219.

Beer, detection of hop substitutes in, 1146.

— estimation of carbonic anhydride in, 1144.

— estimation of glycerol in, 306.

Bees-wax, non-acid constituents of, 124.

Beet-juice, analysis of, 751.

Beetroot, destruction of the nematoids of, 617.

Beetroots, ammonia in, 71.

Beet, sugar, superphosphate manuring for, 295.

Beets, sugar, manurial experiments with, 748.

Benzaldehyde, action of sodium alkyl-oxides on, 574.

— nitro-, condensation of, with hydrocarbons, 44.

— *p*-nitro-, action of, on quinaldine, 976.

Benzaldehyde-greens, manufacture of, 579.

Benzaldehydes, nitro-, behaviour of the three isomeric, in the animal body, 684.

— — behaviour of, with ethyl acetoacetate and ammonia, 845.

Benzaldi- $\alpha$ -naphthol, 270.

Benzaldinaphthyl oxide, 270.

Benzaldoxim-*o*-carboxylic acid, 951.

Benzalglycoldinaphthylacetal, 270.

Benzalhomom-*o*-phthalethylimide, 1111.

Benzalhomom-*o*-phthalimide, 726.

Benzal- $\beta$ -naphthylamine, 494.

Benzamide, *o*-amido-, action of nitrous acid on, 667.

Benzene, action of acetylene on, in presence of aluminium chloride, 806.

— action of methylene chloride on, in presence of aluminium chloride, 1102.

— action of sulphurous anhydride on, 371.

— and ethylene, action of heat on the mixed vapours of, 572.

— bromo-, action of sodium methoxide on, 242.

— compounds, constitution of, 1005.

— constitution of, 362, 370, 719; TRANS., 208.

— crystallised, molecule of, 922.

— diamidodiimido-, nitrate, 930.

— *o*-dichloro-, 1101.

— — action of methyl chloride on, in presence of aluminium chloride, 1101.

— *p*-dinitroso-, 575.

— fluoro-, 130.

— *p*-fluoronitro-, 131.

— halogen-, haloids, 806.

— heat equivalents of homologues of, 427.

— hexachloride,  $\alpha$ -trichloro-, 806.

— hexa-derivatives of, 929.

— iodo-, preparation of, from phenylhydrazine, 1042.

— isomeride of, 1033.

— monobromo-, a second, 131.

— nitro-, action of light on alcoholic solutions of, 240.

— nucleus, substitution in the, TRANS., 579.

— tetramido-, and its derivatives, 476.

Benzene-*m*-azodimethylaniline, acetamido-, 41.

- Benzeneazodimethylaniline, amido-, 41.  
 Benzeneazonaphthols, 54.  
 Benzeneazo- $\beta$ -naphtholsulphonic acid, description and measurement of the spectrum of, TRANS., 196.  
 Benzeneazo- $\beta$ -naphthylphenylamine, 730.  
 Benzeneazophenol, chloro-, 664.  
 Benzene-derivatives, oxidation of, with potassium ferrieyanide, 727.  
 Benzenediazoconine, 137.  
 Benzenediazopiperidide, 137.  
 Benzene-*p*-diazopiperidide, nitro-, 131.  
 Benzenesulphinic acid, *m*-nitro-, 723.  
 Benzenesulphonic acids, action of cyanamide on, 833.  
 Benzenoid compounds, an explanation of the laws which govern substitution in, TRANS., 258, 583.  
 Benzenylamido- $\alpha$ -naphthyl mercaptan, 839.  
 Benzenylamido- $\beta$ -naphthyl mercaptan, 840.  
 Benzidine, bromo-, 479.  
 Benzidine-derivatives, 672.  
 Benzil, condensation products of, with ketones, TRANS., 431.  
 — dihydrocyanide, TRANS., 29.  
 — phenylhydrazine, 138.  
 Benzilidenehydrazinebenzoic acid, 150.  
 Benzodimethyldifurfuran (para)-, 803.  
 Benzodimethylfurfurandicarboxylic acid, 804.  
 Benzoic acid, *p*-bromo-, 1107.  
 — — heat of combustion of, 762.  
 — — nitrochloro-, 946.  
 — — tetrachloro-, and its derivatives, 1046.  
 — acids, chloro-, 828.  
 — peroxide as a dehydrogenising agent, 151.  
 — sulphimide, 144.  
 — — *p*-bromo-, 145.  
 Benzomethylamide, *o*-amido-, 1043.  
 Benzophenone-*p*-dicarboxylic acid, 484.  
 Benzoquinonecarboxylic acids, 255.  
 Benzotrimethylfurfuran, 263.  
 Benzotrimethyltrifurfurocarboxylic acid, 263.  
 Benzotritolazine, 474.  
 Benzoyl compounds, heat equivalents of, 878.  
 — thioarsenite, 950.  
 Benzoylacetoneanilide, 849.  
 $\alpha$ -Benzoyl- $\beta$ -acetylphenylhydrazine, 820.  
 Benzoylaldehyde and its derivatives, 940.  
 Benzoyl-*o*-amidobenzamide, 1044.  
 Benzoyl-*o*-amidobenzmethylamide, 1045.  
 Benzoylbenzoic acid, tetrachlorortho-, 831.  
 Benzoylbutyl alcohol, TRANS., 733.  
 — bromide, TRANS., 732.  
 Benzoyldichlorobenzoic acid (ortho-), 832.  
 Benzoylethyltoluenesulphonamide, 145.  
 Benzoylmethylketole, 588.  
 Benzoylmethyltoluenesulphonamide, 145.  
 Benzoylphenylamidoacetic acid, 1108.  
 Benzoylphenylhydrazine, unsymmetrical, and its derivatives, 820.  
 Benzoylphenylhydrazines, isomeric, 365.  
 Benzoylphenylsemicarbazide, 820.  
 Benzoylphenyltoluenesulphonamide, 146.  
 $\beta$ -Benzoylpicolinic acid, 737.  
 Benzoyl- $\beta$ -propionic acids, alkylated, 827.  
 Benzoylpyruvic acid, 944.  
 Benzoyltoluenesulphonamide and its derivatives, 145.  
 Benzoyltrimellitic acid, 942.  
 Benzoyltrimethylenecarboxylic acid, action of water on, TRANS., 837.  
 Benzyl and benzoyl compounds, 951.  
 — chloride, *o*-cyano-, 1035.  
 — cyanide, *o*-cyano-, 1035.  
 — — *o*-nitro-, 131.  
 — ethylether, *p*-bromo- and *p*-chloro-, and their decomposition by heat and nitric acid, 1103.  
 — isoaethyl ether, decomposition of, by heat and nitric acid, 1103.  
 — isobutyl ether, decomposition of, by heat and nitric acid, 1103.  
 Benzylacetone-*o*-carboxylic acid, 144.  
 Benzylamine, 40.  
 — *o*-amido-, 1037.  
 — *o*-nitro-, 1037.  
 — preparation of, 245, 249.  
 Benzylbenzenylamine, 246.  
 Benzyl-derivatives of hydroxylamine, 246, 813.  
 Benzylethylacetic acid, *p*-nitro-, 490.  
 Benzylidene ethylene bisulphide, 462.  
 Benzylidene-acetoxime, action of dehydrating agents on, 666.  
 Benzylidenebenzoyl phenylhydrazide, 820.  
 Benzylidene-bis-diphenylpyrazolone, 1121.  
 Benzylidenecarboxylic acid (ortho-), 951.  
 Benzylidenediphenylpyrazolone, 1121.  
 Benzylidenehydrazinebenzenesulphonic acid, 933.  
 Benzylidenemethylketole, 265.  
 Benzylidenephénylhydrazine, 1105.  
 Benzylidenequinaldine, *p*-nitro-, 976.  
 Benzylidenerhodanic acid, 1109.  
 — — *o*-amido-, 1109.  
 Benzylideneskatole, 957.  
 Benzylidenetolylene, 151.

Benzylidenethiobiuret, 580.  
 Benzylimidobenzylcarbaminoethyl, 43.  
 Benzylimidobenzylcarbaminoethyl, 43.  
 Benzylmalonidamide, 952.  
 Benzylmethylketonesulphonic acid, 141.  
 Benzylnitraniline, *m*- and *p*-, TRANS., 113.  
 Benzyl-*p*-nitraniline, action of diazotised *m*-nitraniline on, TRANS., 114.  
 $\alpha$ -Benzylphenylhydrazine, 1104.  
 Benzylphthalimide and its *o*-nitro-derivative, 1037.  
 — *o*-cyano-, 1038.  
 Benzylpyrroline, 843.  
 — action of acetic anhydride on, 843.  
 Benzylrosanilinedisulphonic acids, preparation of, 579.  
 Berberamine, 284.  
 Berberideæ, alkaloids of, 283.  
 Berberine, oxidation of, with potassium permanganate, 604.  
 — salts, 604.  
 Berberonic acid, 1118.  
 Betorcinol, 39.  
 Biebrich scarlet, description and measurement of the spectrum of, TRANS., 194.  
 Bile acids, 606, 682.  
 — colouring matters, origin of, 290.  
 — Hüfner's reaction in, 390.  
 — pig's, the acids of, 742.  
 Bilianic acid, 982.  
 Biotite, 646.  
 Bis-phenylpyrazolone, 1121.  
 Bismarck brown, description and measurement of the spectrum of, TRANS., 180.  
 Bismuthates, TRANS., 77.  
 Bismuth alkyl compounds, 802.  
 — compounds, fluorescence of, 4.  
 — — organo-, 368.  
 — conductivity of, for heat in a magnetic field, 1009  
 — ethyl, 802.  
 — fluorescence of, 189, 873, 1006.  
 — metallurgy of, 900.  
 — methyl, 802.  
 — microchemical test for, 301.  
 — oxide, colour reactions of, 305.  
 — pentoxide, 340.  
 — phosphorescence of, 1067.  
 — salts, action of hydrogen peroxide on, 340.  
 — separation of, from mercury and palladium, 302.  
 — sulphate, TRANS., 679.  
 — thiocyanate, 566.  
 — valency of, 368.  
 Bismuthic gold, 707.  
 Bismuthite from North Carolina, 783.

Bisulphides and bisulphoxides, organic, reaction of, with potassium sulphide, 226.  
 Bleaching powder, action of ammonia on, 700.  
 — — constitution of, 700.  
 Bloedite, 1085.  
 Blood analysis, new method of (hæmatoscopy), 312.  
 — causes of the alteration of, in contact with air, oxygen, and carbonic anhydride, 609.  
 — colouring matter of, behaviour of sodium nitrite with, 683.  
 — formation of methæmoglobin in, by the action of alloxantin, 508.  
 — human, sp. gr. of, 608.  
 — liver and flesh, composition of, under varying conditions, 855.  
 — peptones in, 188.  
 — stains, detection of, in presence of iron rust, 408.  
 — sugar in the, with reference to nutrition, 66.  
 Blood-serum, new constituent of, 983.  
 Bohemian minerals, analyses of, 644.  
 Boiling point, influence of change of atmospheric pressure on, 206.  
 — points of the fatty acids,  $C_2H_4O_2$  to  $C_5H_{10}O_2$ , 207.  
 — — of the monatomic alcohols and their constitution, relation between, 879.  
 Bone-black, decolorising power of, 619.  
 Borates, microchemical test for, 300.  
 Boric acid, conductivity of, 758.  
 — — determination of, 299.  
 — — separation of, 299.  
 Borneols, inactive, yielding active camphors, 1050.  
 Bornyl phenylamidoformate, 376.  
 Bornylamine and its derivatives, 376.  
 Bornylcarbamide, 377.  
 Bornylphenylcarbamide and thiocarbamide, 377.  
 Boron, detection of, in milk, &c., 864.  
 Botryogene, 21.  
 Brain, distribution of lead in, in cases of lead poisoning, PROC., 71.  
 Brandy from raspberries and strawberries, 292.  
 — normal butyl alcohol and higher alcohols in, 714.  
 Brassamide, 233.  
 Brassic acid-derivatives, 233.  
 — anhydride, 233.  
 Braunitz from Jakobsberg in Werm-land, 643.  
 Bread, logwood test for alum in, 1143.  
 Breithauptite, artificial, 17.  
 "Brilliant-green," preparation of, 580.  
 Brochantite from Chili, 783.

Bromanil, TRANS., 148.  
 Bromanilic acid, action of bromine on, 1106.  
 ——— constitution of, 1036.  
 Bromides, decomposition of, by the stomach, 508.  
 Bromine, chlorine, and iodine, improved form of apparatus for the separation of, TRANS., 690.  
 ——— indirect determination by electrolysis of their silver salts, 525.  
 ——— liberation of, from hydrogen bromide by the action of light in presence of oxygen, TRANS., 804.  
 ——— refractive equivalent of, 193.  
 ——— "solid," use of, in analysis, 688.  
 ——— vapour, dissociation of, by the electric discharge, 1013.  
 Bromoform, 787.  
 Bromostannic acid, 554.  
 Brookite from Magnet Cove, Arkansas, 116.  
 Brucine and strychnine, estimation of, 853.  
 ——— constitution of, 505.  
 ——— distillation of, with zinc, 282.  
 ——— ferro- and ferri-cyanides, 852.  
 Brucite from the Ural, 345.  
 Buratite from Laurium, 644.  
 Burette jet, 688.  
 Butaldehyde, normal, condensation of, 794.  
 Butter analysis, 309.  
 ——— Reichert's method of, 309, 1145.  
 ——— carrot colour in, 310.  
 ——— colours, examination of, 621.  
 ——— detection of artificial colouring matters in, 1149.  
 ——— determination of, in milk, 752.  
 ——— from various districts, 996.  
 ——— testing, 308, 309.  
 Butyl alcohol, normal, in Cognac brandy, 714.  
 ——— chloride and ether, tertiary trichloro-, 570.  
 ——— perchloro-, perchlorosebate, 801.  
 ——— sebate, 801.  
 ——— vanadate, TRANS., 753.  
 Butylchloral hydrate as an antidote for strychnine and picrotoxin, 391.  
 Butyrates, acid, 231.  
 Butyrellite, chemical composition of, 17.  
 Butyric acid, dichloro-, constitution of, 30.  
 ———  $\alpha$ - $\beta$ -dichloro-, 655, 1029.  
 ——— pure, 29.  
 ——— fermentation, morphology of, 1135.  
 Butyrochloralbiuret, 1032.  
 Butyrylacetophenone, 943.

## C.

Cadaverine, 742.  
 ——— identity of, with pentamethylene-diamine, 125, 1057.  
 Cadmium borotungstate, crystallography of, 334.  
 ——— chloride, ammoniacal compounds of, 637.  
 ——— heat of hydration of, TRANS., 75.  
 ——— determination of, and separation from copper, 398.  
 ——— nitrate and sulphate, ammoniacal compounds of, 638.  
 ——— basic, 1080.  
 ——— sulphide, titration of, with iodine, 301.  
 Cæsium cobalt nitrite, 12.  
 Caffeine, action of, on voluntary muscle, 985.  
 Calamus root, bitter principle of, 972.  
 Calimetry, 865.  
 Calcium ammonium arsenate, 108.  
 ——— arsenate, 108.  
 ——— borate, 108.  
 ——— carbonate, effect of manganese on the phosphorescence of, 190.  
 ——— chloride, solubility in water at 0°, 771.  
 ——— determination of, in presence of manganese, 865.  
 ——— diisobutyloxamate, 357.  
 ——— hypochlorite, conversion of, into calcium chlorate, 11.  
 ——— isobutyloxamate, 357.  
 ——— isobutyrate, solubility of, 547, 548.  
 ——— orthobutyrate, solubility of, 547, 548.  
 ——— silicostannate, 333.  
 ——— sulphate, phosphorescence of, 1067.  
 ——— sulphide, phosphorescence of, 539, 540.  
 ——— preparation of, with a violet phosphorescence, 2.  
 ——— tartrate, preparation of, 571.  
 ——— tetramethylenecarboxylate, distillation of, with lime, TRANS., 229.  
 ——— urate, 469.  
 ——— vanadates, 339.  
 Calorimeter, Bunsen's ice, 1073.  
 Calorimetric bomb, 627.  
 Camphene, active, 596.  
 ——— levogyrate, action of glacial acetic acid on, 969.  
 Camphol, racemic, 1050.  
 Camphols, isomeric, 375.  
 Camphor, bromo- and chloro-, oxidation of, 1115.  
 ———  $\beta$ -chloronitro-, 970.  
 ——— derivatives of, 842, 1049, 1115.  
 ———  $\alpha$ -nitro-, 842.  
 ———  $\beta$ -nitro-, 842.

Camphor, racemic, 1050.  
 Camphoric acid, heat of neutralisation, 205.  
 — — racemic, 1050.  
 Camphoroxime, derivatives of, 496.  
 Camphors, active, from inactive borneols, 1050.  
 — isomeric, 375.  
 — — mononitro-, 842.  
 Camphyldiphenylhydrazine, 1050.  
 Cane-sugar, absorption spectrum of, TRANS., 59.  
 — — influence of temperature on the rate of inversion by hydrochloric acid, 768.  
 Capillarity and evaporation, relation between the theories of, 323.  
 — — relation of weight of drops to, 210.  
 Capillary constants and meniscus angle, 101.  
 — — meniscus angle, relation of weight of drops to, 210.  
 Capraldehyde, constitution of, 788.  
 Capraldoxime, 795.  
 Caprocyamidine,  $\alpha$ -amido-, 850.  
 Caprocyamine,  $\alpha$ -amido-, 850.  
 Caprylidene, 788.  
 Caracolite from Chili, 902.  
 Carbamide, action of bromine on, 656.  
 — action of, on cyanhydrins, 1054.  
 — action of, on phenylhydrazine, 1042.  
 — decomposition of, by water and dilute acids, 235.  
 — sulphinic compounds of, TRANS., 666.  
 — trichloromethylsulphinate, TRANS., 668.  
 Carbazole-blue, 959.  
 — synthesis of, 372.  
 $\beta$ -Carbocinchomeronic acid, 1118.  
 Carbodinicotinic acid, 1118.  
 Carbohydrates, 26.  
 — action of sulphuric acid on, 125.  
 — formation of fat from, in the dog, 288.  
 Carbon, absorption of gases by, TRANS., 249.  
 — amorphous, in the Saxon Erzgebirge, 341.  
 — bisulphide, action of chlorine on, 1015.  
 — — molecular refractive energy of derivatives of, 753.  
 — chains, closed, synthetical formation of, TRANS., 1, 228, 240, 702, 820, 849.  
 — combined, determination of, in iron, 866.  
 — compounds, determination of the constitution of, from thermochemical data, 421, 423.

Carbon compounds, homologous, heat of evaporation of, 9.  
 — — of high refractive power, molecular dispersion of, 626.  
 — — relation between their molecular structure and their absorption spectra. Part VIII, TRANS., 152.  
 — — determination of the relative values of the four units of chemical activity of the atom of, 711.  
 — — electrodes, alteration of, 1009.  
 — — estimation of, in the organic constituents of water, 184.  
 — — in cast iron, influence of silicon on the condition of, 220.  
 — — in the sun, 1065.  
 — — oxysulphide, preparation and properties of, 1015.  
 — — reaction of absorbed oxygen on, at various temperatures, TRANS., 252.  
 — — refractive index of, 193.  
 — — soft, electrical resistance of, under pressure, 315.  
 — — tetrachloride, action of, on chromyl dichloride and ferric phosphate, 330.  
 — — action of, on metallic oxides, 329.  
 — — action of, on oxides, 552.  
 — — action of sulphur on, 1015.  
 — — thiodichloride, reactions with, 937.  
 Carbonates, ethereal, 37.  
 — — insoluble, preparation of, 221.  
 — — normal, detection of, in hydrogen carbonates of the alkali metals, 528.  
 — — testing of, 80.  
 Carbonic anhydride, absorption of, by leaves, 172.  
 — — and ethyl alcohol, specific gravities of mixtures of, 435.  
 — — apparatus for determining, in carbonates, 999.  
 — — &c., apparatus for estimating, 398.  
 — — cooling of, on expansion, 880.  
 — — decomposition of, by chlorophyll, 685.  
 — — estimation of, in air, 300.  
 — — estimation of, in beer, 1144.  
 — — estimation of, in coal-gas, 86, 297.  
 — — expired, in respiration, estimation of, 507.  
 — — in soil, 521.  
 — — in the air of schoolrooms, 888.  
 — — in the atmosphere, 214, 549.  
 — — portable apparatus for the estimation of, in the atmosphere, 999.  
 — — quick volumetric determination of, 528.  
 — — oxide, poisoning by, 392.

- Carbonyl-*o*-amidophenol, 477.  
 Carbonylcarbazole, 959.  
 Carbonylferrocyanogen, 649.  
 Carbonylphenylphosphoric dichloride,  
   *p*- and *m*-chloro-, 947.  
 Carbostyryl, reduction of, 279.  
 Carbo-*o*-toluylenediphenyltetramine,  
   247.  
 Carbo-*o*-toluylenedi-*p*-tolyltetramine,  
   247.  
 Carboxyl, introduction of, into aromatic  
   compounds, 935.  
   — method for the introduction of,  
   into aromatic hydrocarbons, 254.  
 Carboxylphenylthylorthophosphoric di-  
   chloride,  $\alpha$ -chloro-, 963.  
 Carboxylphenylorthophosphoric acids  
   (para- and meta-), 947.  
 Carrageen moss, galactose from, 791.  
 Carrot colour in butter, 310.  
 Carrotene, 265.  
   — in leaves, 859.  
 Carvacryl dipotassium phosphate, 241.  
   — oxidation of, 241.  
   — potassium sulphate, 241.  
 Carvacrylamine, 721.  
 Carveol, 376.  
 Carvole-derivatives, 475, 923.

 Cerussite, crystallised, 342.  
 Chelerythrine, 854.  
 Chelidonine, 854.  
 Chemical affinity, dependence of, on  
   temperature, 628.  
   — changes produced by sunlight, 93.  
   — combination, 99.  
   — constitution and physiological ac-  
   tion, 985.  
   — reactions, velocity of, 697.  
 Chemistry and thermodynamics, 431.  
   — integral weights in, 1077.  
 Chili saltpetre and ammonium sulphate,  
   comparative manurial value of, 77.  
   — — as manure, 77, 78.  
   — — phosphoric acid in, 558.  
*China bicolor*, 76.  
 Chinine dibromide, 1123.  
 Chloral, density and magnetic rotation  
   of, TRANS., 808.  
   — fate of, in the organism, 613.  
   — hydrate as an antidote for strych-  
   nine and picrotoxin, 391.  
   — — density and magnetic rota-  
   tion of, TRANS., 809.  
   — — detection of, 866.  
   — — red dye from, 793.  
 Chloralcyanhydrins, action of carbamide  
   on, 1032.  
 Chloralide, action of phosphoric chlo-  
   ride on, 915.  
 Chloranilic acid, action of bromine on,  
   1106.  
   — — constitution of, 1036.  
 Chlorides, compressibility of aqueous  
   solutions of, 696.  
   — dissolved, effect of pressure on the  
   decomposition of, 697.  
   — effect of hydrochloric acid on the  
   solubility of, 445.  
   — metallic, anhydrous, preparation  
   of, 702.  
 Chlorination by means of acetic chlo-  
   ride, 932.  
   — influence of light and temperature  
   on, 922.  
 Chlorine, bromine, and iodine, improved  
   form of apparatus for the separation  
   of, TRANS., 690.  
   — — — indirect determination  
   by electrolysis of their silver salts,  
   525.  
   — liberation of, from hydrogen chlo-  
   ride, by the action of light in presence  
   of oxygen, TRANS., 802.  
   — preparation of, using Kipp's appa-  
   ratus, 442.  
   — refractive index of, 193.  
 Chloroform and acetone, action of pot-  
   ash on a mixture of, 569.  
   — fate of, in the organism, 612.  
   — new reaction for, 866.  
   — post-mortem detection of, 305.  
 Chloroformamide, 569.  
 Chlorophyll, 972, 1116.

- Chlorophyll, absorption bands of, 693.  
 — decomposition of carbonic anhydride by, 685.  
 — functions of, 516.  
 — granules, formation of starch in, 1136.  
 — presence of, in sponges, &c., 613.  
 Chlorosis in plants, 76.  
 Chlorostannic acid, 554.  
 Choleic acid, anhydrous, 682.  
 — — crystalline form of, 683.  
 Cholesterin, 926.  
 — acetate, 926.  
 Cholesteryl chloride and its dibromide, 926.  
 Cholic acid, 982.  
 — — anhydrous, 682.  
 — — iodo-, 606.  
 Choline, presence of, in germinating plants, 747.  
*Chondrus crispus*, galactose from, 791.  
 Chromate, estimation of, in presence of dichromate, 304.  
 Chromatology, invertebrate, 613.  
 Chrome iron ore, analysis of, 532.  
 — — decomposition of, 619.  
 — — paints, analysis of, 304.  
 Chromiodic acid, 776.  
 Chromium, detection and determination of traces of, 531.  
 — extraction of, from iron ores, 449.  
 — heptasulphide, non-existence of, 553.  
 — oxalates, double, constitution of, *PROC.*, 4.  
 — phosphorescence of, 1067.  
 — potassium fluoride, 448.  
 — volumetric determination of, 303.  
 Chromorganic acids, *TRANS.*, 383.  
 Chromoxalates, *TRANS.*, 383.  
 Chromoxalic acid, *PROC.*, 5.  
 Chromyl dichloride, action of carbon tetrachloride on, 330.  
 Chrysoïdine, description and measurement of the spectrum of, *TRANS.*, 178.  
 Chrysoinaphthazine, 1049.  
 Chrysophanic acid, reactions for discriminating, from santonin colouring matters in urine, 406.  
 Chrysoquinone, azines of, 1049.  
 Chrysotoluazine, 1049.  
 Cider ash, 520.  
 Cincholine, action of bromine on, 1122.  
 — dibromide, 282.  
 — —  $\alpha$ - and  $\beta$ -, 1122.  
 Cincholine, 58.  
 Cinchona alkaloids, 281, 1122.  
 — bark, ash of, 394.  
 Cinchonine acid, 598, 846.  
 Cinchonidine, estimation of, in quinine sulphate, 623.  
 Cinchonine, bromination of, 1123.  
 — constitution of, 164.  
 — dibromide, 281.  
 Cinnabar, natural solutions of, 555.  
 Cinnamene of the pyridine series, 737.  
 Cinnamylpropionic acid, *o*-amido-, 485.  
 Cinnamic acid, bromo-, a fourth, 582.  
 — —  $\beta$ -dichloro-, 363.  
 — — presence of, in the Ericaceæ, 517.  
 — — series, isomerism in, 582, 830.  
 — acids, bromo-, reduction of the isomeric, 668.  
 — — Glaser's monobromo-, 829.  
 Cinnamide,  $\alpha$ -bromo-, 829.  
 Cinnamyl hydrazine, 665.  
 — thiényl ketone, 237.  
 Cinnamylidiphenylamine, 814.  
 Citraconic acid, constitution of, 917.  
 — — heat of neutralisation of, 205.  
 Citrazinic acid, *TRANS.*, 407.  
 Citrazinimide, *TRANS.*, 406.  
 Citric acid, action of monamines on, 154.  
 — — fermentation of, 235.  
 — — heat of neutralisation of, 205.  
 — — use of turmeric as an indicator for, 307.  
 Citrodinaphthylamic acid,  $\alpha$ - and  $\beta$ -, 154.  
 Citrodinaphthylamide,  $\alpha$ - and  $\beta$ -, 154.  
 Citrodi-*p*-toluide, 40.  
 Citro-*p*-ditoluidic acid, 40.  
 Citro-*p*-toluidic acid, 40.  
 Citro-*p*-toluidide, 40.  
 Citrotrimethylamide, 154.  
 Citrotrinalphthylamide,  $\alpha$ - and  $\beta$ -, 154.  
 Claret, detection of artificially coloured, 91, 187.  
 Clay, absorption of ammonia by, 1136.  
 — analysis of, 1139.  
 — pink, analysis of, 647.  
 Clays, action of heat on, 785.  
 — constitution of, 785.  
 Coal, estimation of sulphur in, 296.  
 — analysis of, 84.  
 — tar colours, acid, detection of, in wine, 405.  
 — — constituents of, 471.  
 — — relation between petroleum and the hydrocarbons of, 648.  
 Coal-gas. See Gas, coal-.  
 Cobalt and nickel, separation of, from iron, 1141.  
 — salts, new class of, 220.  
 — separation of zinc from, 182.  
 — variations in the electric resistance of, in a magnetic field, 760.  
 — volumetric estimation of, in presence of nickel, 1141.

- Cobaltammonium compounds, 775.  
 Cobra-poison, 170.  
 Coca leaves, alkaloïds of, 1125.  
 Cocaïne, amorphous, 980.  
 — higher homologues of, 1126.  
 — hydrochloride, rotatory power of, 506.  
 — rotatory power of, 506.  
 — separation of hygrine from, 1126.  
 Cocamine, 1126.  
 Cocceryl alcohol and its derivatives, 650.  
 Coccerylic acid, 650.  
 Codeïne, 280.  
 Coffee, 1002.  
 — amount of caffëine in various kinds of, 394.  
 Coffees, analyses of, 1002.  
 Cohesion figures, 209.  
 Coke, estimation of sulphur in, 296.  
 Colchiceïne, 284.  
 Colchicine, 284.  
 — therapeutic action of, 614.  
 — toxic action of, 515.  
 Collidine, symmetrical dibromo-, 844.  
 Columbite, 20.  
 — from Colorado, 347.  
 — from Graveggia in Val Vigizzo, 645.  
 — from Standish, Maine, 343.  
 — of the Val Vigizzo, mineral associated with, 1085.  
 Concentration, influence of, on the vapour-tension of ethereal solutions, 631.  
 — of solutions by gravitation, 1013.  
 Conductivity, electrical, of hot gases, 1071.  
 — of mixtures, 877.  
 — of mixtures of aqueous solutions of acids, 415.  
 Conichalcite, 20.  
 Coniferin, new test for, 692.  
 Conine, active, synthesis of, 160.  
 Convolvulin, physiological action of, 291.  
 Conyryne platinochloride, 161, 383.  
 Copper, action of ammonia on, at a red heat, 702.  
 — ammonium iodides, 772.  
 — analysis of, 529.  
 — atomic weight of, 444.  
 — cobalt potassium sulphate, *PROC.*, 53.  
 — commercial determination and valuation of, 80.  
 — Cornish, dry assay of, 81.  
 — crystals, artificial, 342.  
 — electrolysis of, 315.  
 — electrolytic estimation of, 1000.  
 — higher oxides of, 334.  
 — influence of, on the estimation of sulphur, 296.  
 Copper iron potassium sulphate, *PROC.*, 53.  
 — magnesium group, isomorphous mixtures of sulphates of, *PROC.*, 53.  
 — potassium sulphate, *PROC.*, 53.  
 — microchemical test for, 300.  
 — mineral from Sunnerskog, Sweden, 343.  
 — minerals, rare, from Utah, 19.  
 — native, crystallisation of, 341.  
 — nitride, 702.  
 — oxide, compound of manganese-sesquioxide with, 1081.  
 — platinum, and iron, alloys of, 778.  
 — polarisation of, by the extension of the surface in contact with a liquid conductor, 757.  
 — salts, electromotive dilution constants of, 1072.  
 — separation of, from lead, cadmium, manganese, &c., 530.  
 — separation of, from mercury and palladium, 302.  
 — slag of bright red colour, 447.  
 — sulphate, dissociation of, 208.  
 — reduction of, during alcoholic fermentation, 171.  
 — solubility of, 772.  
 — testing, 1139.  
 — wet assay of, 80.  
 — See also Cuprous.  
 Cordierite, altered, from Tuscany, 1086.  
 Corrosive sublimate solutions, stability of, 774.  
 Cosmical powder which fell on the Cordilleras, near San Fernando, Chili, 22.  
 Cotton oil, properties of, 536.  
 Coumaraldehydes, nitro-, 939.  
 Coumaric acid, para-. See Paracoumaric acid.  
 Coumarin, amido-, 939.  
 — nitro-, 939.  
 Cows, amounts of nitrogen ingested and recovered in manure, 175.  
 Creatines, 850.

 — red, of alumina, 191, 538, 625.  
 Fluorescences of manganese and bismuth, 1006.  
 — with well-defined spectra, 1008.  
 Fluorine, atomic weight of, 892.  
 — estimation of, 295.  
 — volumetric method of estimating, 179.  
 Fluorspar from Vesuvius, 18.  
 Food stuffs, action of micro-organisms from the mouth and from fæces on, 1059.  
 Formamides, substituted, action of phosphoric chloride on, 384.  
 Formanilide, *p*-nitro-, 250.  
 Formates in the organism, 513.  
 Formic acid, estimation of, in water, 1000.  
 — — separation of acetic acid from, 751.  
 Formopiperidine, 385.  
 Formose, 459.  
 Formotoluide (meta-) and its derivatives, 935.  
 Franklinitite, artificial formation of, 557.  
 Freezing point, alteration of, 879.  
*Fuchsia ovata*, chlorophyll in, 1117.  
 Fuchsinite from Canada, 782.  
 Fumaramic acid, 34.

- Fumaranilic acid, 934.  
 Fumaric acid, constitution of, 916.  
 ——— conversion of, into asparagine, 1100.  
 ——— conversion of, into aspartic acid, 917, 1110.  
 ——— heat of neutralisation of, 205.  
 ——— dianilide, 934.  
 Fungi, fluorescence of pigments of, 314.  
 Furfuracryl-glycocine, 1033.  
 Furfuracrylic acid, 1033.  
 Furfuraldehyde, 571.  
 ——— action of quinaldine on, 976.  
 ——— behaviour of, in the animal organism, 1032.  
 Furfuran,  $\beta$ -bromo-, 658.  
 ——— constitution of, 470.  
 ——— derivatives, 803.  
 ——— from phloroglucinol, 262.  
 ——— from resorcinol, 262.  
 ——— transformation of, into pyrroline, 470.  
 Furfurylamine, 568.  
 ——— and its salts, 470.  
 Furnace, Cowle's electrical, products from, 551.

## G.

- Ga, G $\beta$ , evidence as to nature of, 1069.  
 Gadenium, 107.  
 Gadolinite and samarskite, new elements in, 334.  
 Gadolinium oxide, equivalent of, 109.  
 $\gamma$ -Galactan, 652.  
 Galactose, formation of, from raffinose, 791.  
 ——— from Carrageen moss, 791.  
 ——— phenylhydrazine, 567.  
 ——— properties of, 652.  
 Galenobismuthite, containing selenium, from Falun, 343.  
 Gallein, tetrachloro-, 833.  
 Gallium, 1081.  
 ——— as a halogen carrier, 326.  
 ——— chromiferous, red fluorescence of, 755.  
 ——— oxide, fluorescence of, 409.  
 Galloflavin and its derivatives, 1107.  
 Galvanic cell, standard, 541.  
 ——— element, 541.  
 ——— elements, 757.  
 ——— polarisation of aluminium, 415.  
 ——— produced by feeble electromotive forces, 317, 541.  
 Gamsigradite, 351.  
 Garnet, pseudomorphs of, 117.  
 Gas analysis, apparatus for, 179.  
 ——— source of error in, 1062.  
 ——— apparatus, 1137.

- Gas burette, 687, 1062.  
 ——— coal-, estimation of hydrogen sulphide, carbonic anhydride, and cyanogen in, 86.  
 ——— estimation of sulphur and impurities in, 297.  
 ——— compressed, products from the residues of, 787.  
 ——— demonstration of the coefficient of expansion of, as a lecture experiment, 1013.  
 ——— generator-, and water-, composition of, 1078.  
 ——— generator, constant, 634.  
 Gas-coal, analysis of, 84.  
 Gaseous and liquid states of matter, representation of the connection between, by isopycnics, 432.  
 Gases, absorption of, by carbon, TRANS., 249.

 — Chaldean, 443.  
 — compounds of, with nitrogen, 112.  
 — estimation of minute quantities of, 184.  
 — from Burmah, 221.  
 — fulminating, 112.  
 — native, from Thibet, 780.  
 — natural solutions of, 555.  
 — oxides, 15.  
 — preparation of pure, 554.  
 — purple oxide of, non-existence of, 16.  
 — separation of, from other metals, 555.  
 — separation of, from the platinum metals, 1084.  
 — spark spectrum of, 555.  
 — sulphides, 1019.  
 — superoxide, non-existence of, 16.  
 — See also Aurous and Auric.  
 Goslarite from Montana, 346.  
 Grain, spectroscopic notes on the carbohydrates and albuminoids from, *TRANS.*, 58.  
 Grangesite, 351.  
 Grape-sugar, action of sulphuric acid on, 125.  
 Grapes, detection and estimation of aluminium in, 690.  
 — formation of sugar in, 517.  
 — organic and inorganic constituents of, 860.  
 Graphite, celestial, 351.  
 — from Ceylon, 901.  
 — New Zealand, 555.  
 Graphitoid, 341.  
 Griqualandite, 709.  
 Growth, loss of nitrogen by plants, during, 292.  
 Guaiacum resin, distinguishing purified from natural, 752.  
 Guanidine cyanurate, 358.  
 Guanine, colour reaction of, 280.  
 Guano, Australian bat, and minerals therein, 708.  
 Guanylcarnamide salts, 358.  
 — synthesis of, 357.  
 Gum, animal, 26.  
 Gums, colour reactions of, 534.  
 Gun-cotton, regeneration of acid residues in the manufacture of, 770.  
 — — sodium nitrate in, 715.  
 Gypsum, solubility of, in solutions of ammonium salts, 333.

## H.

- Hæmatin, action of reducing agents on, 1127.  
 — compound of, with nitric oxide, 854.  
 — occurrence of reduction products of, in pathological urine, 1127.  
 Hæmatoporphyrin, 1127.  
 — in molluscs, 613.  
 Hæmatoporphyröidin, 1127.  
 Hæmatoscope, 312.  
 Hæmatoscopy, a new method of blood analysis, 312.  
 Hæmatostilbite from Örebo, 645.  
 Hæmidin crystals, 408.  
 Hæmin crystals, 165.  
 Hæmoglobin, amount of oxygen taken up in the decomposition of, into albumin and hæmatin, 854.  
 Halogen carriers, 130, 326.  
 — — in the natural groups of the elements, 806.  
 Halogens, hydrides of, action of light on, in the presence of oxygen, TRANS., 801.  
 Hannayite, 709.  
 Harpenden, well waters of, TRANS., 520.  
 Hay, meadow, iron sulphate as a manure for, TRANS., 215.  
 Heat and solar radiation, comparative action of, 411.  
 — animal, relation of the production of, to the destruction of glucose, 289.  
 — development of, when powders are moistened, 9.  
 — equivalents of benzoyl-compounds, 878.  
 — influence of, on the decomposition of oxalic acid by ferric chloride, 324.  
 — latent, of vaporisation of certain volatile substances, 627.  
 — of combustion of ethyl ether, 425.  
 — of conversion of the benzene to the acetic series, 1011.  
 — of dissolution of anhydrous sodium carbonate, TRANS., 73.  
 — — of salts, influence of temperature on, TRANS., 290.  
 — — of salts in water, influence of temperature on, PROC., 66.  
 — of evaporation of homologous carbon-compounds, 9.  
 — of formation of crystallised tellurides, 1010.  
 — — of organic compounds, criticism of Thomsen's theory of, 423.  
 — — of potassium alkyl oxides, 318.  
 — — of potassium glyceroxide, 320.  
 Heat of formation of sodium alkyl oxides, 319.  
 — — of tartar emetic, 544.  
 — of hydration of salts, TRANS., 75.  
 — of neutralisation of meconic and mellitic acids, 206.  
 — of oscillation, 419.  
 — of solution, variation of solubility with variations in, 548, 632.  
 Heats of combustion and formation of homologous phenols, 98.  
 — — — of quercite, inosite, and quinic acid, 1011.  
 — — of organic compounds, 95, 878.  
 — — of organic compounds determined by different methods, values of, 1011.  
 — of formation of potassium methoxide and ethoxide, 204.  
 — of neutralisation of glyceric, camphoric, malic, and citric acids, 205.  
 — — of homologous and isomeric acids, 95.  
 — — of malonic, tartronic, and malic acids, 96.  
 — specific, and changes of states at high temperatures, 201.  
 Helianthin, description and measurement of the spectrum of, TRANS., 192.  
 Hemellithene and its bromo- and nitro-derivatives, 36.  
 — synthesis of, 659.  
 Hemellithenol, 36.  
 Hemellithylic acid, 36.  
 Hemialbumose, 1127.  
 Hemipinethylimide, 46.  
 Hemipinic acid, nitro-, 46.  
 — anhydride, nitro-, 49.  
 Hemipinimide, 46.  
 — isomeride of, 258.  
 Hemipinimidine, 585.  
 Hemipinphenylhydrazide, amido-, 45.  
 Hemp-seed oil, acid from, 799.  
 Hentriacontane from beeswax, 124.  
 Heptacosane from beeswax, 124.  
 Heptamethylene-derivatives, attempted synthesis of, PROC., 96.  
 Heptine, action of heat on, 565.  
 Heptylbenzene, 253.  
 — amido-, 816.  
 — nitro-, 815.  
 Herderite, 19,  
 — remarkable crystal of, 117.  
 Hesperidin, sugar from, 715.  
 Hesperidium, 107.  
 Heteroalbumose, 285.  
 Heterovitellose, 286.  
 Heteroxanthine in urine, 740.  
 Heulandite, 903.  
 — occurrence of strontia in, 453.

- Hexadecylbenzene and its derivatives, 252.  
 Hexadecylphenol, 252.  
 Hexahydroterephthalic acid and its dibromo-derivative, 370.  
 Hexahydro-xylene from Caucasian petroleum, 922.  
 Hexamethylantracene, 1102.  
 Hexamethylbenzene, 1101.  
 Hexamethylene-derivatives, synthesis of, *Proc.*, 96.  
 Hexamethyltriimidotriphenylmethane, 1039.  
 Hexazoxybenzene, 479, 664.  
 Hexine, 565.  
 Hexyl alcohol, dextrorotatory, from essence of chamomile, 228.  
 — dimethamidophenyl ketone, 253.  
 — phenyl ketone, 253, 816.  
 Hexyldiphenylmethane and its derivatives, 253.  
 Hexylene glycol, *Trans.*, 722.  
 Hexyltetramethyldiamidodiphenylmethane, 253.  
 Hippuric acid, compound of, with pyruvic acid, 44.  
 — — — determination of, in urine, 535, 1001.  
 — — — relation of tyrosine to, 1133.  
 Hofmann's violet, description and measurement of the spectrum of, *Trans.*, 171.  
*Holcus sorgho*, grain of, 519.  
 Homo-*o*-phthalaminic acid, 726.  
 Homo-*o*-phthalbenzylimide, 1111.  
 Homo-*o*-phthalethylimido - azobenzene, 1111.  
 Homo-*o*-phthalide, 50.  
 Homo-*o*-phthalimido-azobenzene, 726.  
 Homo-*o*-phthalimide, 725, 1111, 1112.  
 Homo-*o*-phthalomethylimide, 51.  
 Homopterocarpin from sandal wood, 971.  
 Hoofs, analysis of, 408.  
 Hop substitutes, detection of, in beer, 1146.  
 Hornblende from Porthalla Cove, Cornwall, 1022.  
 Horns, analysis of, 408.  
 Horse, absorption in the stomach of, 743.  
 — digestion and digestive secretions in, 744.  
 — intestinal digestion in the, 610.  
 Humous substances, formation and composition of, 229.  
 Hydrargyrene, 676.  
 Hydrastine, 174, 383, 505.  
 — and its derivatives, 1057.  
 Hydrastinic acid, 384.  
 Hydrastinine and its derivatives, 383.  
*Hydrastis Canadensis*, substances contained in the root of, 174.  
 Hydrazimido-compounds, 731.  
 Hydrazine, 715.  
 — (diamidogen) sulphate, 715.  
 Hydrazinebenzenesulphonic acids, 933.  
 Hydrazinebenzopyruvic acid, 150.  
 Hydrazines, 932.  
 — secondary, unsymmetrical, 1104.  
 Hydrazinetoluenesulphonic acids, action of concentrated sulphuric acid on, 146.  
 Hydrazobenzene, bromo-, 479.  
 — dibromo-, 479.  
 — halogen-derivatives of, 478.  
 Hydrazocamphenes, action of hydrogen on, 675.  
 Hydrazodimethylquinol, 364.  
 Hydrazotoluene, *p*-bromo-, 479.  
 Hydrindonaphthene-derivatives, *Proc.*, 92.  
 Hydrindonaphthenecarboxylic acid, *Proc.*, 93.  
 Hydrindonaphthenedicarboxylic acid, *Proc.*, 93.  
 Hydriodic acid, action of, on zinc containing lead, 1076.  
 Hydroacridylacrylic acid, 850.  
 Hydroazemonin, 843.  
 Hydrobenzamidetricarboxylic acid, 951.  
 Hydrobromic acid, action of, on zinc containing lead, 1076.  
 — — — new hydrate of  $\text{HBr}, \text{H}_2\text{O}$ , 631.  
 — — — the hydrate,  $\text{HBr}, 2\text{H}_2\text{O}$ , 630.  
 — — — thermal study of solutions of the solid hydrate,  $\text{HBr}, 2\text{H}_2\text{O}$ , 628.  
 Hydrobromocinchine, 1124.  
 Hydrobromocinchonine, 1124.  
 Hydrobromodehydrocinchonine, 1125.  
 Hydrobromoquinine, 1123.  
 Hydrobromostannic acid, 554.  
 Hydrocarbons, detection of certain, in alcohols, 1088.  
 — from tar-oils boiling between  $170^\circ$  and  $200^\circ$ , 35.  
 Hydrocarrotene, 265.  
 Hydrochloric acid, action of, on zinc containing lead, 1075.  
 — — — electrolysis of: a lecture experiment, 633.  
 — — — free, in the gastric juice, 287.  
 Hydrochlorocinchonine, 1124.  
 Hydrochloroquinine, 1123.  
 Hydrochlorostannic acid, 554.  
 Hydrocoumaric acid, *Trans.*, 70.  
 Hydrocoumarin, *Trans.*, 71.  
 Hydrocyanic acid, estimation of, 1143.  
 — — — poisoning by, 392.  
 Hydrodicoumaric acid and its salts, *Trans.*, 65.  
 Hydrodicoumarin, *Trans.*, 66.  
 — bromo-, *Trans.*, 67.

- Hydrogen, apparatus for estimating, in presence of methane, 618.
- bromide, action of light on, in presence of oxygen, TRANS., 804.
- chemical structure of, and dissociation in the sun's atmosphere, 1070.
- chloride, action of light on, in presence of oxygen, TRANS., 801.
- influence of liquid water in promoting the interaction between oxygen, &c., in presence of light, TRANS., 806.
- origin of, in the gases of volcanoes, 643.
- combustion of weighed amounts of, 1078.
- comparison of the equivalent of zinc with that of, TRANS., 854.
- iodide, action of light on, in presence of oxygen, TRANS., 805.
- peroxide, estimation of, 862.
- presence of, in saliva, 298.
- test for, 296.
- phosphide, hydroxylated solid, 635.
- reduction of inorganic thio-salts by, 111.
- refractive index of, 193.
- sulphide, estimation of, in coal-gas, 86.
- poisoning by, 392.
- preparation of, free from arsenic, 885.
- purification of, from hydrogen arsenide, 885.
- Hydrogiobertite, 17.
- Hydrohydrastinine, 384.
- derivatives of, 1057.
- Hydromethylamidophenol, 135.
- Hydro-*m*-methyleinnamic acid, 724.
- Hydromethylindole, 957.
- Hydromethylketole, 957.
- Hydromethyl- $\beta$ -naphthindole, 154.
- $\alpha$ -Hydronaphthindole, 964.
- Hydroskatole and its derivatives, 957.
- Hydrothiocinnamic acid, amido-, 1109.
- derivatives of, 1108.
- nitro-, 1109.
- Hydroxyamidopyridine, trichloro-, 156.
- Hydroxyanthraquinone dyes, 593.
- spectra of methyl derivatives of, 1.
- Hydroxyazo-compounds, 819.
- Hydroxyazophenine, 1105.
- Hydroxybenzoic acids, *m*- and *p*-, action of phosphoric chloride on, 947.
- Hydroxybenzyl alcohol (para-), 38.
- Hydroxybromophenylpyrazoline, 933.
- Hydroxybutyric acid, chloro-, constitution of, 30.
- $\beta$ -, in diabetic urine, 290, 464, 857.
- $\beta$ -, laevorotatory, in the blood of a diabetic patient, 986.
- Hydroxycoumarilic acid (meta-), 262.
- Hydroxydehydracetic acid and its acetyl compound, TRANS., 491, 492.
- Hydroxydimethylpyrrolinecarboxylic acid, 275.
- Hydroxydiquinolyl, 848.
- Hydroxyethylolucarbostyryl, 738.
- Hydroxyhemellithylic acid, 36.
- Hydroxyhydrastinine and its derivatives, 1057.
- Hydroxyindonaphthenecarboxylic acid, 728.
- Hydroxyisopropylsalicylic acid (para-), 241.
- Hydroxyl group, reagent for, 124.
- quantitative estimation of, 749.
- Hydroxylamine, benzyl-derivatives of, 246.
- formation of, from silver, mercury and sodium nitrites, TRANS., 661.
- reaction of, with ferrous hydroxide and water, TRANS., 655.
- titration of, by iodine, effects of dilution and the presence of sodium salts and carbonic anhydride on, TRANS., 794.
- Hydroxylamines, aromatic, 663.
- Hydroxylepidine, 159.
- reduction of, 278.
- Hydroxymethenylamidophenol, 245.
- Hydroxymethenyltoluylenediamine, 135.
- Hydroxy-*o*-methoxycinnamic acid (meta-), 140.
- Hydroxymethyleoumarone, 262.
- Hydroxynaphthaquinone, 674.
- $\alpha$ -Hydroxynaphthoic acid, action of phosphoric chloride on, 963.
- Hydroxynaphthyl sulphide, 808.
- $\zeta$ -Hydroxynitrobenzoic acid, 485.
- Hydroxynitrobenzoic acids, meta- and para-, 485.
- Hydroxyphenyl sulphide, 807.
- Hydroxyphenyllutidine (meta-), 1053.
- Hydroxyphenyl-*p*-methoxyhydroquinoline ( $\alpha$ -meta-), 979.
- Hydroxyphenyl-*p*-methoxyquinoline ( $\alpha$ -meta-), 978.
- Hydroxyphenylpyrazoline, 933.
- Hydroxy- $\alpha$ -phenylquinoline (para-), 847.
- Hydroxypicolinic acid, chloro-, 158.
- $\alpha$ - and  $\beta$ -Hydroxypiperic acids, oxidation of, 488.
- Hydroxypiperohydrolactone, 488.
- $\alpha$ -Hydroxypropylpyrrolone,  $\omega$ -trichloro-, 845.
- Hydroxypyridine, di-iodo-, 845.
- $\gamma$ -Hydroxyquinaldine, 847.
- and its derivatives, 679.
- Hydroxyquinolinecarboxylic acid (ortho-), 1119.
- and its derivatives, 738.

Hydroxyquinolinecarboxylic acid, para-, 1120.  
 ——— and its derivatives, 63.  
 ——— synthesis of, 1119.  
 $\alpha$ -Hydroxyquinolinesulphonic acid, 379.  
 Hydroxystearic acids of different origin, 30.  
 ——— anhydride, 31.  
 Hydroxythiotoluene, 473.  
 Hydroxytoluic acid, 669.  
 Hydroxyuracil, nitrobromo-, 920.  
 Hydroxyvaleric acid, 717.  
 Hydroxyxanthine, 919.  
 Hydrozincite, 1021.  
 Hygrine, separation of, from cocaine, 1126.  
 $\beta$ -Hyoglycocholic acid, 742.  
 Hypomelanin, 168.  
 Hyponitrites, formation of, TRANS., 646, PROC., 119, 121.  
 Hypoxanthine in urine, 739.

## I.

Ice, calorimeter, Bunsen's, 1073.  
 ——— refractive index of, 753.  
 Idrialine from Idria, 1021.  
 Ignatieffite, a new variety of alumnite, 1085.  
*Illicium religiosum*, subsances from, 497.  
 Indian-yellow, 498.  
 Indigo-blue, formation of, from *o*-nitrophenylpropionic acid by means of potassium cyanide, 672.  
 ——— dyes on fabrics, testing, 1147.  
 ——— estimation of, 1147.  
 ——— estimation of, in textile fabrics, 871.  
 ——— fermentation, microbe of, 1061.  
 Indium as a halogen carrier, 326.  
 Indole-derivatives, constitution of, 148.  
 ——— ——— methylation of, 588.  
 ——— ——— synthesis of, 148.  
 ——— from dichlorether and aniline, 836.  
 ——— intermediate products in the formation of, from dichlorether and aromatic amines, 813.  
 ——— methylation of, 976.  
 ——— transformation of homologues of, into quinoline homologues, 1113.  
 Indoles, 956.  
 ——— from *m*-hydrazinebenzoic acid, 149.  
 ——— from methylphenylhydrazine, 149.  
 ——— from  $\alpha$ -naphthylhydrazine, 963.  
 ——— from  $\beta$ -naphthylhydrazine, 153.  
 ——— from phenylhydrazine, 149.  
 ——— from tolylhydrazine, 956.  
 Indonaphthalene-derivatives, conversion of  $\beta$ -naphthaquinone into, 728.  
 ——— ——— synthesis of, 729, 836.  
 ——— ketone, 728.  
 Induline, 821.  
 Indulines, 1105.

Inosite, 355.  
 ——— acetyl compound of, 1090.  
 ——— and dambose, identity of, 909.  
 ——— derivatives, 908.  
 ——— formation of, 1089.  
 ——— heats of combustion and formation of, 1011.  
 ——— hexacetic, 908.  
 ——— hexabenzoin, 908.  
 ——— hexanitrin, 908.  
 ——— reduction and oxidation of, 459.  
 Integral weights in chemistry, 1077.  
 Invertase, absorption spectrum of, TRANS., 60.  
 Invertin, action of, 166.  
 Iodates and sulphates, precipitation of mixtures of, by barium salts, 884.  
 Iodic anhydride, combination of, with sulphuric anhydride, 328.  
 Iodides, decomposition of, by the stomach, 508.  
 Iodine, bromine, and chlorine, improved form of apparatus for the separation of, TRANS., 690.  
 ——— ——— ——— indirect determination by electrolysis of their silver salts, 525.  
 ——— carrier, sulphuric acid as, 573.  
 ——— detection in *Laminaria*, 996.  
 ——— free, occurrence of, in a mineral water, 221.  
 ——— liberation of, from hydrogen iodide by the action of light in presence of oxygen, TRANS., 805.  
 ——— occurrence of, in phosphorites, 222.  
 ——— origin of, in the gases of volcanoes, 643.  
 ——— oxyacids of, 327.  
 ——— refractive equivalent of, 193.  
 ——— solutions, new method of standardising, 618.  
 ——— trichloride, action of hypochlorous anhydride on, 106.  
 ——— vapour, dissociation of, by the electric discharge, 1013.  
 ——— volumetric estimation of, 862.  
 Iodine-green, description and measurement of the spectrum of, TRANS., 174.  
 Iodoform, 787.  
 Iodometric studies, 688, 997.  
 Ipecacuanha, estimation of, 1147.  
 Iridium and tin, alloy of, 779.  
 Irisin, 26.  
 Iron, action of ammonia on, at a red heat, 702.  
 ——— action of ferric sulphate on, 703.  
 ——— cast, influence of silicon on the condition of carbon in, 220.  
 ——— copper, and platinum, alloys of, 778.  
 ——— determination of combined carbon in, 866.  
 ——— determination of phosphorus in, 299, 396, 527.

- Iron, direct separation of manganese from, 183.  
 — Eggertz's method of estimating sulphur in, 296.  
 — estimation of sulphur in, 1141.  
 — estimation of silicon in, 527, 1140.  
 — influence of silicon on the properties of, TRANS., 129.  
 — influence of silicon on the mechanical properties of, TRANS., 141.  
 — manganese in, 619.  
 — metallic, determination of, in slags, 1140.  
 — nitride, 702.  
 — oxide, estimation of, in mineral phosphates and manures, 302.  
 — pig-, effect of silica on the estimation of manganese in, 183.  
 — — estimation of phosphorus in, 183.  
 — — titanium carbide in, 703.  
 — potassium fluoride, 448.  
 — precipitation of nickel in presence of, 1141.  
 — pyrites, assay of, for sulphur available for sulphuric acid manufacture, 180.  
 — rapid estimation of phosphorus in, 865.  
 — rapid estimation of silicon, sulphur, and manganese in, 1140.  
 — separation of nickel and cobalt from, 1141.  
 — separation of zinc from, 182.  
 — specially pure, silicon in, TRANS., 134.  
 — sulphate, agricultural experiments with, TRANS., 215.  
 — telluride (emmonsite), 344.  
 Isethionic acid in the body, and thio-sulphuric acid in the urine, 68.  
 Isoamylamine, preparation of, 652.  
 Isoamylphenylamine, 721.  
 $\alpha$ -Isoamylphenylhydrazine, 1104.  
 $\alpha$ -Isoaspartic acid, 801.  
 Isobenzal, chloro-, phthalimidine, 62.  
 Isobutaldehyde, action of quinaldine on, 975.  
 — and acetaldehyde, action of aniline on a mixture of, 974.  
 — and its polymeric modification, 461.  
 — and methylal, condensation of, with aniline, 957.  
 Isobutane, tribromo-, 712.  
 Isobutyryldiamidotoluene, 817.  
 Isobutylamines, mono-, and di-, separation of, by means of ethyl oxalate, 357.  
 — preparation of, 356.  
 Isobutylbenzoylcongonine, 1126.  
 $\alpha$ -Isobutylcinchonic acid, 504.  
 Isobutylene, action of bromine on, 712.  
 Isobutylisobutyryldiamidotoluene, 817.  
 Isobutylphenylamine, 721.  
 $\alpha$ -Isobutylphenylhydrazine, 1104.  
 Isobutyl-*m*-pyrazole, 1055.  
 $\alpha$ -Isobutylquinoline, 504.  
 Isobutyronitrilecarbamide, 1055.  
 Isobutyrothiënonesulphonic acid, 141.  
 Isobutyrylacetophenone, 943.  
 Isocarvoxime, 923.  
 Isochoric lines, TRANS., 773.  
 Isocinchonine, 1124.  
 Isocrotic acid,  $\alpha$ -chloro-, 655.  
 Isocymenesulphonic acid, ( $\alpha$ -meta-), action of bromine and water on, 147.  
 — —  $\alpha$ -bromo-, 147.  
 Isodulcitol, 906.  
 — oxidation of, 652.  
 — tetracetate, 907.  
 — trinitrate, 907.  
 Isohæmatoporphyrin, 1127.  
 Isomerism of position, 420.  
 Isonitroso-compounds, 466, 1103.  
 — — intramolecular changes of, when treated with sulphuric acid, 826.  
 Isonitrosodiacetone nitrate, 563.  
 Isophotosantonin acid, 57.  
 Isopropyl chlorocarbonate, 1028.  
 — formamide, 1028.  
 — formonaphthylamide, 1028.  
 — phenylformamide, 1028.  
 Isopropylacetylpyrroline and its derivatives, 598.  
 Isopropylamide of isobutyric acid, TRANS., 688.  
 $\alpha$ -Isopropylcinchonic acid, 504.  
 Isopropylene,  $\alpha$ -chloro-, 656.  
 $\alpha$ -Isopropyl- $\beta$ -isobutylhydracrylic acid, 1100.  
 $\alpha$ -Isopropylphenylhydrazine, 1104.  
 $\alpha$ -Isopropylpiperidine, 740.  
 Isopropylpiperidines,  $\alpha$ - and  $\gamma$ -, 65.  
 Isopropylpyridines,  $\alpha$ - and  $\gamma$ -, 60.  
 Isopropylpyrroline, 598.  
 $\alpha$ -Isopropylquinoline, 504.  
 Isophthalaldehyde, 940.  
 Isophthalaldoxime, 482.  
 Isopyknics, 432.  
 Isoquinoline and its derivatives, 61, 505.  
 — chloro-, 62.  
 — dichloro-, 61.  
 — homologues of, 739, 1112.  
 — methiodide, 63.  
 — red, 380.  
 Isosuccinic acid,  $\alpha$ -amido-, 801.  
 Itacolumite, flexibility of, 21.  
 Itaconic acid, heat of neutralisation of, 205.

## J.

- Jalapin, physiological action of, 291.  
 Jequirity, the proteids of the seeds of, 990.  
 Juglone, synthesis of, 674.

## K.

- Kamala, 272.  
 — crystalline substance from, 498.  
 Kersantite from Wüstewaltersdorf, Silesia, 562.  
 Ketinedicarboxylic acid, 29.  
 Ketines, 29.  
 Ketipic acid, 362.  
 Ketoindonaphthene, dibromo-, 729.  
 Ketones, action of nitrous acid on, 463.  
 — action of yellow ammonium sulphide on, 1045.  
 — aromatic, 940.  
 — — action of concentrated sulphuric acid on, 251.  
 — — action of hydroxylamine and phenylhydrazine on, 482.  
 — compounds of, with mercaptans, 126, 462.  
 — condensation compounds of, with benzil, TRANS., 431.  
 — introduction of acid radicles into, 575, 943.  
 — nitroso-, 463, 944.  
 — of the acetic series, formation of, 653.  
 — oxidation of, with potassium ferricyanide, 825.  
 — synthesis of diatomic monobasic acids from, 717.  
 Ketonic acids,  $\gamma$ -, constitution of, 126.  
 — — synthesis of ethyl salts of, 587.  
 Kombic acid, 1115.

## L.

- Lac-dye, composition of, 734.  
 Laccic acid, 734.  
 Lactic acid, detection and estimation of, 307.  
 — — formation of, during muscular activity, and its fate in the organism, 508.  
 — — in animals, 167.  
 "Lactocrite," the, 1144.  
 Lactones, action of phenylhydrazine on, 489.  
 — combinations of, with ethereal salts, 952.

- Lactotoxine, 389.  
 Lactucerin, 605.  
 Lactucol, 606.  
 Land, cropped, drainage water from, TRANS., 513.  
 — — uncultivated, amount of assimilable nitrogen in, 82.  
 Långbanite, 782.  
 Lanthana, phosphorescent, sharp line spectrum of, 1070.  
 Lanthanum sulphate, phosphorescence of, 1067.  
 Laubanite, a new zeolite, 903.  
 Laumontite from Striegau, 903.  
 Law, periodic, 211.  
 Laws of chemical combination, 99.  
 Lead calcium oxychloride, 446.  
 — carbonate, preparation of, 446.  
 — chloride, solubility of, in solutions of mercuric chloride, 772.  
 — diphenyl diiodide, 573.  
 — — dinitrate, 573.  
 — distribution of, in the brain in cases of lead poisoning, PROC., 71.  
 — estimation of, in alloys, 304.  
 — microchemical test for, 301.  
 — nitrates, basic, 1080.  
 — oxide, action of, on barium, strontium, calcium, and magnesium chlorides, 446.  
 — oxychloride, 446.  
 — separation of, from mercury and palladium, 302.  
 — silicate, artificial, from Bonne Terre, Missouri, 109.  
 — strontium oxychloride, 446.  
 — sulphate, phosphorescence of, 1068.  
 — tetraphenyl, 572.  
 — tetra-*p*-tolyl, 573.  
 Leaves, absorption of carbonic anhydride by, 172.  
 — action of mercurial vapour on, 395.  
 — carotene in, 859.  
 — decomposition of silicic acid by, 70.  
 Lecture experiment: continuous flame of nitric oxide and carbon bisulphide, 442.  
 — — demonstration of Avogadro's law, 698.  
 — — — of Dulong and Petit's law, 634.  
 — — — of the coefficient of expansion of a gas, 1013.  
 — — electrolysis of hydrochloric acid, 633.  
 — — preparation of potassium ferrate, 769.  
 — — — of silicon hydride, 769.  
 — — — synthesis of ammonia, 442.

Leguminous seeds, composition of, 991.  
 Lepidine, bromo- and chloro-, 1113.  
 $\gamma$ -Lepidine, and its chloro-derivative, 159.  
 Lepidolites of Maine, 347.  
 Leucophenosafranine, constitution of, 140.  
 Leucosafranine, 250.  
 Levulinic acid,  $\beta$ -bromo-, 464.  
 ——— preparation of, 799.  
 ——— reactions for, 459.  
 ——— salts of, 800.  
 Levulose, formation of, from raffinose, 791.  
 Light, absorption of, by oxyhæmoglobin, 1126.  
 ——— action of, on the hydrides of the halogens in presence of oxygen, TRANS., 801.  
 ——— white, production of, by mixing the colours of the spectrum, 1.  
 Lime, determination of, in presence of manganese, 865.  
 ——— phosphorescent spectrum of, 1067.  
 Lime-water, sp. gr. of, 700.  
 Limestones, granular, of Stainz in Styria, 780.  
 Limonite-pseudomorphs after iron pyrites, 116.  
 Linoleic acid, 126.  
 ——— oxidation of, 716.  
 Linolenic acid, 913.  
 Linolic acid, 913.  
 Linusic acid, 798.  
 ——— and its derivatives, 359.  
 Liquid and gaseous states of matter, representation of the connection between, by isopycnics, 432.  
 ——— to the gaseous state of matter, continuous transition from, at all temperatures, 763.  
 Liquids, nature of, 100.  
 ——— as shown by a study of the thermal properties of stable and dissociable substances, 430.  
 ——— solidification of, by pressure, 1013.  
 ——— specific inductive power of, 413.  
 ——— thermic expansion of, at various pressures, 626.  
 Lithia micas, 347.  
 Lithium and sodium, estimation of, in mixtures of their carbonates, 864.  
 ——— carbonate, 1000.  
 ——— solubility of, 699.  
 ——— chromiodate, 777.  
 ——— occurrence of, in psilomelane, 222.  
 ——— salts, poisoning of plants by, 991.  
 ——— vanadates, 705.  
 Liver, flesh, and blood, composition of, under varying conditions, 855.  
 ——— importance of ammonia in the formation of glycogen in the,

Liver of new-born dogs, glycogen in, 167.  
 ——— power of the, to form sugar from fat, 67.  
 Lobelia, alkaloids of, 854.  
 Lucasite, a new variety of vermiculite, 349.  
 Lupetidine,  $\alpha$ - $\alpha$ -, 64.  
 Lupines, composition of, 518.  
 ——— feeding value of, 991.  
 Luteocobalt salts, 775.  
 Lutidine, chloro-, and its derivatives, 501.  
 ——— dibromo-, 845.  
 Lutidinecarboxylic acid, 378.  
 Lutidinedicarboxylic acid, chloro-, 501.  
 Lutidines of coal-tar, 499.  
 Lutidone, 500.  
 Lutidonecarboxylic acid, 500.  
 Lutidylquinolyl, 1053.

## M.

Madder root, Caucasian, examination of, 1061.  
 Magnesia, determination of, in presence of manganese, 865.  
 ——— fluorescence of, 409.  
 ——— phosphorescence of, 1068.  
 ——— salts and ammonia, thermochemistry of reactions between, 96.  
 ——— saturation of arsenic acid by, 204.  
 Magnesium ammonium sulphite, 887.  
 ——— chloride, solubility in water at 0°, 771.  
 ——— melting point of, 445.  
 ——— sodium chromate, 111.  
 ——— sulphate, TRANS., 682.  
 ——— sulphite, 886.  
 ——— vanadates, 339.  
 Magnetic field, variations in the electric resistance of antimony and cobalt in, 760.  
 ——— rotation of chloral, chloral hydrate, and hydrated aldehydes, TRANS., 808.  
 ——— rotatory power of ethyl salts of maleic and citraconic acids and their isomerides, PROC., 98.  
 Magnetite, artificial production of, 708.  
 Maize, silage of, 521.  
 ——— starch, absorption spectrum of, TRANS., 59.  
 Malachite-green, preparation of, 580.  
 Malamic acid, 34.  
 Maleic acid, constitution of, 916.  
 ——— conversion of, into aspartic acid, 917, 1100.  
 ——— heat of neutralisation of, 205.  
 ——— transformation of, into aspartic acid and asparagine, 1100.  
 ——— dianilide, 934.

Maleinamil, 934.  
 Malëylphenylhydrazine, 671.  
 Malic acid, heat of neutralisation of, 96, 205.  
 ——— diphenylhydrazide, 138.  
 Mallotoxin, 272.  
 Malonic acid, heat of neutralisation of, 96.  
 Malt, estimation of acidity of, 87.  
 Malto- $\gamma$ -diamidobenzoic acid, 931.  
 Mandelic acid and its derivatives, preparation of, 948.  
 ——— *o*-nitro-, 948.  
 Manganates, formation of, from permanganates, 552.  
 Manganese ammonium fluoride, 448, 892.  
 ——— apatite, 781.  
 ——— benzoate, 582.  
 ——— chlorides, 335.  
 ——— compounds, fluorescence of, in a vacuum under the influence of the silent discharge, 3.  
 ——— determination of, 399, 1139.  
 ——— dioxide, action of selenious acid in, 775.  
 ——— direct separation of, from iron, 183.  
 ——— effect of, on the phosphorescence of calcium carbonate, 190.  
 ——— effect of, on the properties of steel, 639.  
 ——— effect of silica on the estimation of, in pig-iron, 183.  
 ——— fluorescence of, 189, 873, 1006.  
 ——— fluoride, 335.  
 ——— in steel and iron, 619.  
 ——— metallic, magnetic properties of, 1081.  
 ——— microchemical test for, 300.  
 ——— oxysulphate, 893.  
 ——— paratungstate, 895.  
 ——— potassium fluorides, 336.  
 ——— rapid estimation of, in iron and steel, 1140.  
 ——— sesquioxide, compound of, with cupric oxide, 1081.  
 ——— sodium fluoride, 448.  
 ——— sulphate, 774.  
 ——— sulphide, solubility of, in fused sodium sulphide, 449.  
 ——— tetroxide, 1016.  
 ——— trioxide, 893.  
 ——— volumetric determination of, 399, 531.  
 Manganic acid, 894.  
 ——— manganous oxide, 1016.  
 Mangel-wurzel, iron sulphate as a manure for, TRANS., 217.  
 Manure, Chili saltpetre as, 77, 78.  
 ——— farmyard-, production of, 175.  
 ——— potash-, ground felspar as, 996.

Manures, basic cinder and other finely-ground insoluble phosphates as, 995.  
 ——— chemical, organic nitrogen in, 863.  
 ——— estimation of iron oxide and alumina in, 302.  
 ——— incompatibility of nitrates and superphosphates as, 617.  
 ——— valuation of, 174.  
 Manurial experiments with various phosphates, 1137.  
 ——— value of basic steel slag, 176, 525.  
 ——— of Chili saltpetre and of ammonium sulphate, 77.  
 Manuring with basic slag and other phosphates, 524.  
 Marble, influence of temperature on the rapidity of the action of acids on, 882.  
 Marcasite, recent formation of, 901.  
 Matter, continuous transition from the liquid to the gaseous state of, at all temperatures, 763.  
 Meat and fish, comparative absorption of, in the alimentary canal, 1130.  
 Meconic acid, heat of neutralisation of, 206.  
 Meconine, action of potassium cyanide on, 586.  
 $\psi$ -Meconine and its derivatives, 585.  
 Meconine-acetic acid, 47.  
 ——— *o*-nitro-, 48.  
 Melamines, constitution of, 650.  
 Melanin, 168, 855.  
 Melitose, 25.  
 ——— estimation of, 306.  
 ——— estimation of, in cane-sugar, 306.  
 Mellitic acid, heat of neutralisation of, 206.  
 Meniscus angle and capillary constants, 101.  
 Menthyl phenylamidofornate, 376.  
 Mercaptan, compounds of aldehydes and ketones with, 126.  
 Mercaptans, aromatic, *o*-amidated, 961.  
 ——— compounds of, with aldehydes and ketones, 462.  
 Mercuric ammonio-chromates, 218.  
 ——— chloride, behaviour of, with hydrogen ammonium carbonate, 774.  
 ——— solutions, stability of, 774.  
 ——— oxide, action of, on soluble chlorides, 447.  
 Mercurous hydroxide, 447.  
 Mercury barium oxychloride, 447.  
 ——— calcium oxychloride, 447.  
 ——— detection of, in organic liquids, 302.  
 ——— dixylyl, 824.  
 ——— expansion of, between 0° and 39°, 317.  
 ——— microchemical test for, 300.

- Mercury, oxychloride, 447.  
 — relations of, to other metals, 1080.  
 — separation of, from palladium, lead, copper, and bismuth, 302.  
 — strontium oxychloride, 447.  
 —  $\alpha$ -thiobenzoate, 950.  
 Mesaconic acid, constitution of, 917.  
 — — heat of neutralisation of, 205.  
 Mesityl oxide, compound of phenylhydrazine with, 932.  
 — phenyl ketone and its derivatives, 942.  
 Mesitylene, nitro-, oxidation of, 132.  
 — trichloro-, 1101.  
 Metallic oxides, action of sulphur on, in presence of water, 328.  
 Metals, action of nitrogen on, 702.  
 — bivalent, affinity of certain, for sulphuric acid, 885.  
 — of ancient Chaldea, 443.  
 — separation of, by oxalic acid, 529.  
 Metasaccharic acid, double lactone of, 466.  
 Meteoric iron at Fort Duncan, Texas, 647.  
 — — from Augusta Co., Virginia, 454.  
 — — from Glorieta Mountain, New Mexico, 120.  
 — — from Texas, 119.  
 — — the Mazapil, 564.  
 — stones from Utah and Cape Girardeau, Missouri, 120.  
 Meteorite from Angra dos Reis, 1087.  
 — from Djati Pengilon, Java, 1024.  
 — in a tertiary lignite, 22.  
 — of Karang-Modjo or Magetan in Java, 710.  
 — supposed metallic, from Highland Co., Virginia, 455.  
 Meteorites, Coahuila, 455.  
 — from Kentucky and Mexico, 564.  
 — gaseous constituents of, 351.  
 — iron, crystalline structure of, 119.  
 Methæmoglobin, formation of, in blood by the action of alloxantin, 508.  
 Methamidoformic chloride, 358.  
 Methane-derivatives, volatility of, 24.  
 — liquid, density of, 694.  
 Methenylamido- $\alpha$ -naphthyl mercaptan, 839.  
 Methenyl-*m*-ditolylamidine and its derivatives, 935.  
 Methethopropionic acid, 228.  
 Methethopropyl carbinol, 228.  
 Methoxychlorisoquinoline, 62.  
 Methoxycinnamic (ortho-) acid diazo-chloride, 140.  
 — — *o*-*m*-nitro- and *m*-amido-, 140.  
 Methoxydiallylacetic acid, 359.  
 Methoxydibromosalicylic acid, 487.  
 Methoxydiquinolyline ( $\alpha$ - and  $\beta$ -para-), 979.  
 Methoxyhydroxyquinoline, 973.  
 Methoxylepidine, 159.  
 $\gamma$ -Methoxymethylpseudocarbostyryl, 977.  
 Methoxy-*p*-nitrobenzaldehyde (meta-), 483.  
 Methoxyphenylchlorisoquinoline, 62.  
 Methoxyquinaldine, 680.  
 Methyl acetate, influence of normal salts on the hydrolysis of, 102.  
 — alcohol, estimation of, in presence of ethyl alcohol, 1142.  
 — amidophenyl thioether, 823.  
 — anacardate, TRANS., 665.  
 — anthracene- $\gamma$ -carboxylate, 594.  
 — benzyl carbinol, 35.  
 — bromisopropylphenyl oxide, oxidation of, 472.  
 — bromosalicylate, 486.  
 — bromoterephthalate, 52.  
 — carbanilate, derivatives of, 143.  
 — chloride, action of, on *o*-dichlorobenzene in presence of aluminium chloride, 1101.  
 — cresolcarboxylate, 45.  
 — dehydracetate, TRANS., 496.  
 — diazosuccinamate, 34.  
 — *m*-*o*-dimethoxycinnamate, 140.  
 — dimethylgentisate, 140.  
 — dinitro-*o*-toluate, 945.  
 — formates, chlorinated derivatives of, 1027, 1099.  
 — fumaramate, 34.  
 — malamate, 34.  
 — methoxybromosalicylate, 487.  
 — methyl dibromo-*p*-coumarate, 488.  
 — methyltetrahydropyridyl- $\beta$ -benzoylhydroxypropionate (cocaine), 742.  
 — phenyllutidonecarboxylate, TRANS., 498.  
 — phosphate, TRANS., 754.

- 1 : 3 Methylphenylthiophen and its derivatives, 1101.  
 $\alpha$ -Methylpiperidine, 740.  
 Methylpiperidines,  $\alpha$ - and  $\beta$ -, 64.  
 Methylpropylaniline and its derivatives, 134.  
 Methylpropylhydroxyphenyl (para-) sulphide, 808.  
 Methylpseudocarbostyryl and its derivatives, 977.  
 Methylpyridines,  $\alpha$ -,  $\beta$ -, and  $\gamma$ -, 59.  
 Methylpyrrolidine, 463.  
 $\beta$ -Methylpyrrolidine, 735.  
 Methylpyrroline, action of acetic anhydride on, 843.  
 Methyl- $\gamma$ -quinaldone, 680.  
 Methylquinolinecarboxylic acid [1 : 4], 502.  
 Methylsalicylaldehyde, *m*-nitro-, 140.  
 Methyltetrahydropyridyl- $\beta$ -hydroxypropionic acid (ecgonine), 742.  
 $\beta$ -Methyltetramethylenediamine, 735.  
 Methylthiénylglyoxylic acids,  $\alpha$ - $\alpha$ -, and  $\alpha$ - $\beta$ -, 804.  
 Methylthioformaldine, 27.  
 Methylthiophenecarboxylic acid, 921.  
 Methyl-*p*-toluidine, trinitro-, 1038.  
 Methyltrihydro-*o*-hydroxyquinolinecarboxylic acid, 738.  
 Methyltriphenylmethanecarboxylic acid, 265.  
 Methyluracil, dichloroxy-, 129.  
 — nitro-, 919.  
 — nitro-derivatives of, 128.  
 Mica from Leon Co., Texas, 119.  
 Micas, iron-lithia, of Cape Ann, Massachusetts, 348.  
 Microbe of the indigo fermentation, 1061.  
 Microbes, nitrifying, 1134.  
 Microchemical tests, 301.  
*Micrococcus cereus*, a nitrifying agent, 858.  
 Micro-organisms, behaviour of, in artificial mineral waters, 393.  
 — — from the mouth and from faeces, action of, on foodstuffs, 1059.  
 Microscopic analysis, 300.  
 Milk analysis, 751.  
 — — Adams' method for, 186.  
 — changes in, produced by freezing, 745.  
 — constituents, determination of, 1003.  
 — detection of boron in, 864.  
 — determination of fat in, 308, 752, 1144.  
 — human and cows', albuminoids of, 388.  
 — poisonous ptomaine in, 389.  
 — presence of nitrites and nitrates in, as evidence of adulteration, 87.  
 Milk-sugar, alcoholic fermentation of, 1090.  
 — variations in the proportion of phosphoric acid in, 856.  
 Mineral springs in Aegina and Andros, 23.  
 Mineralogical notes, 342.  
 Minerals from the Sjö Mine, Sweden, 902.  
 — from Vulture and Melfi, composition of, 1087.  
 Mirror amalgam, composition of, 447.  
 Mirrors, magic, 327.  
 Molecular structure of carbon compounds and their absorption spectra, relation between. Part VIII, TRANS., 152.  
 Molecules, enveloping and secondary, 419.  
 Molybdenite, twin crystals of, 116.  
 Molybdenum, lower oxides of, 553.  
 Molybdic anhydride, colour reactions of, 305.  
 Monazite, twin crystals of, from North Carolina, 118.  
 Moorlands, basic-slag and other phosphates as manure for, 294.  
 Morindin, TRANS., 52.  
 Morindon, TRANS., 52.  
 Morphine, 280.  
 — estimation of, 622, 869.  
 — hydroxyl meconate, 505.  
 — reaction, 870.  
 — separation of, from fatty matters, 187.  
 Mountain ash berries, tannic acid in, 950.  
 Mucic diphenylhydrazide, 138.  
 Mucin in urine, 390.  
 Murexide, description and measurement of the spectrum of, TRANS., 199.  
 Muscle plasma, 984.  
 — voluntary, action of caffeine and theine on, 985.  
 Muscles, heat developed by the activity of, 1059.  
 Muscovite from South Africa, 561.  
 Muscular activity, and the chemical effect of respiration, relation between, 1058.  
 — — formation of lactic acid during, 508.  
 Mydaleme, 386.  
 Myo-albumose, 984.  
 Myoetonine, 858.  
 Myoglobulin, 984.  
 Myohæmatin, 983.  
 Myosinogen, 984.  
*Myristica Surinamensis*, aleurone grains in the seed of, 1061.

## N.

- $\beta$ -Naphthacridine, 682.  
 $\beta$ -Naphthaldehyde, 675.  
 Naphthalene, action of heat on the vapour of, 572.  
 — and ethylene, action of heat on the vapour of, 572.  
 —  $\beta$ -chloro-,  $\beta$ -bromo-, and  $\beta$ -iodo-, action of sulphuric acid on, *Proc.*, 22.  
 — chlorobromo-, 1113.  
 — compounds, constitution of, 1005.  
 — dichloro-, 495, 961.  
 —  $\gamma$ -dichloro-, 837.  
 — heat of combustion of, 762.  
 —  $\beta$ -nitro-, preparation of, 590.  
 — sulphonic acids derived from the  $\beta$ -monohaloid-derivatives of, *Proc.*, 22.  
 — trichloro-, 270.  
 Naphthalenesulphonic acid, 1:4 chloro-, 374.  
 — — 1:4' chloro-, 374.  
 — —  $\beta$ -chloro-, 374.  
 — —  $\alpha$ -cyano-, *Proc.*, 43.  
 — —  $\gamma$ -, formation of, by means of sulphuric anhydride, *Proc.*, 42.  
 Naphthalene- $\beta$ -sulphonic acid, bromination of, *Proc.*, 113.  
 Naphthalenesulphonic acids,  $\beta$ -bromo-, *Proc.*, 23.  
 — —  $\beta$ -chloro-, *Proc.*, 22.  
 — —  $\beta$ -iodo-, *Proc.*, 23.  
 Naphthalenetetracarboxylic dianhydride, 271.  
 — diimide, 272.  
 Naphthalic acid, constitution of, 495.  
 $\alpha$ -Naphthamide, 496.  
 $\alpha$ -Naphthamidoxime, 373.  
 $\beta$ -Naphthamidoxime, 373.  
 Naphthaphenazine, 591.  
 Naphthaquinone, trichloro-, 270.  
 $\alpha$ -Naphthaquinone, bromamido-, 838.  
 — *p*-chlorobromo-, 1114.  
 $\beta$ -Naphthaquinone, and its bromo- and chloro-derivatives, 53.  
 — conversion of, into indonaphthene-derivatives, 728.  
 Naphthaquinone-anilide, dichloro-, 270.  
 $\alpha$ -Naphthaquinoneimide, bromamido-, 838.  
 $\alpha$ -Naphthaquinoneoxime, bromo-hydroxy-, 838.  
 $\beta$ -Naphthaquinone-*o*-tolylhydrazide and its derivatives, 55.  
 $\beta$ -Naphthaquinone-*p*-tolylhydrazide and its derivatives, 55.  
 $\alpha$ - $\beta$ -Naphthaquinoxaline, 153.  
 Naphthase, Laurent's, 153.  
 $\alpha$ - $\beta$ -Naphthazine, *Trans.*, 99, 100.  
 $\alpha$ -Naphthazoximethenyl, 373.  
 $\beta$ -Naphthazoximethenyl, 374.  
 $\beta$ -Naphthazoximenaphthenyl, 374.  
 Naphthenylamidoxime,  $\alpha$ - and  $\beta$ -, and their derivatives, 374.  
 $\alpha$ -Naphthindole, 964.  
 $\beta$ -Naphthindole, 153.  
 $\alpha$ -Naphthindolecarboxylic acid, 963.  
 $\beta$ -Naphthindolecarboxylic acid, 154.  
 $\alpha$ -Naphthoic acid, dinitro-, 373.  
 Naphthoic acids, 373, 840.  
 Naphthol, dichloro-, 270.  
 $\alpha$ -Naphthol, diamido-, action of bromine on, 838.  
 $\beta$ -Naphthol, nitroso-, use of, in quantitative analysis, 530.  
 $\beta$ -Naphtholazonitro- $\psi$ -cumenesulphonic acid, 953.  
 Naphtholcarboxylic acid, amido-, 732.  
 — acids, 732.  
 $\beta$ -Naphthol- $\beta$ -disulphonic acid, 269.  
 Naphthols, chlorination of, 960.  
 $\beta$ -Naphthol- $\delta$ -sulphonic acid, 733.  
 $\beta$ -Naphthonitrile, action of sodium on alcoholic, 840.  
 Naphthophenone oxide,  $\alpha$ - and  $\beta$ -, and their derivatives, 152.  
 Naphthostyryl, amido-, 373.  
 Naphthoxyacetic acids,  $\alpha$ - and  $\beta$ -, 495.  
 $\alpha$ -Naphthoylformic acid, 271.  
 $\alpha$ -Naphthoylhydroxamic acids,  $\alpha$ - and  $\beta$ -, 840.  
 $\alpha$ -Naphthoyl- $\alpha$ -naphthamidoxime, 373.  
 $\beta$ -Naphthyl carbinol, 675.  
 Naphthyl ethyl carbonate, 37.  
 — mercaptans, amido-, 839.  
 — — amido-,  $\alpha$ - and  $\beta$ -, 840.  
 — methyl ketone and its derivatives, 252.  
 $\alpha$ -Naphthyl methyl ketone, 271.  
 — phenyl ketone, 943.  
 $\beta$ -Naphthylamine, chloro-, 961.  
 — derivatives of, 838.  
 Naphthylamine citrates,  $\alpha$ - and  $\beta$ -, 154.  
 — dichloro- and monochloro-, 495.  
 — dinitro-, preparation of, 152.  
 $\alpha$ -Naphthylamine, manufacture of, 1048.  
 $\beta$ -Naphthylaminesulphonic acid, Brønner's, 375.  
 $\beta$ -Naphthylamine- $\delta$ -sulphonic acid and its derivatives, 732.  
 $\beta$ -Naphthylaminesulphonic acids, 962.  
 $\alpha$ -Naphthyldimethylpyrrolidine, 275.  
 $\beta$ -Naphthyldimethylpyrrolidine [1:2:5], 275.  
 $\alpha$ -Naphthyldimethylpyrrolidinedicarboxylic acid, 275.  
 1:3-Naphthylenediamine, 674.  
 Naphthylenediamine (para-), 1048.  
 Naphthylenediamines, substituted, 839.  
 $\alpha$ -Naphthylglyoxylic acid, 271.  
 $\alpha$ -Naphthylhydrazine, indoles from, 963.  
 $\alpha$ -Naphthylhydrazinepyruvic acid, 963.  
 $\beta$ -Naphthylhydrazinepyruvic acid, 153.

- $\beta$ -Naphthylmethylamine, 675.  
 $\beta$ -Naphthylphenylamine, amido-, 730.  
 $\alpha$ -Naphthylphenyl- $\beta$ -pinacoline, 943.  
 $\beta$ -Naphthylthiamide, 675.  
 Narceine, 280.  
   — test for, 870.  
 Narcotine, 280.  
 Naringenic acid, constitution of, 497.  
 Naringin, 497.  
   — sugar from, 715.  
 Nematoids of beetroot, destruction of, 617.  
 Nephrite from Alaska, 222.  
 Neutralisation, thermal phenomena of, TRANS., 593.  
 Newberyite, 709.  
 Nickel and carbon galvanic elements, 757.  
   — and cobalt, separation of, from iron, 1141.  
   — cobalt potassium sulphate, PROC., 53.  
   — detection of adulteration in, by the magnet, 531.  
   — estimation of, in ores, mattes, slags, &c., 303.  
   — microchemical test for, 300.  
   — precipitation of, in presence of iron, 1141.  
   — regulus, peculiar formation in, 1081.  
   — separation of zinc from, 182.  
   — volumetric estimation of cobalt in presence of, 1141.  
 Nicotine, reaction of, with ethyl iodide, 603.  
   — reaction with methyl iodide, 851.  
   — reduction of, 161.  
   — specific rotation of, 756.  
 Nicotinic acid, bromo-, 159.  
   — — dichloro-, 158.  
 Niobic acid from fergusonite, 706.  
   — anhydride, action of carbon tetrachloride on, 329.  
   — — colour reactions of, 304.  
   — — crystallised, 642.  
   — — molecular heat of, 706.  
 Niobium hydride and its molecular heat, 706.  
   — potassium fluoride, reduction of, with sodium, 706.  
 Nitranilic acid, constitution of, 134.  
   — — formation of, 574.  
   — — from chloranil, 926.  
 Nitrates and superphosphates, incompatibility of, as manures, 617.  
   — determination of, in well waters, 691.  
   — estimation of, in water by means of aluminium, 184.  
   — formation of, in the organism of the higher plants, 859.  
 Nitrates in animals and plants, 389.  
   — new method of testing for, 1138.  
   — percentage of, in unmanured soils, 83.  
   — production of, in arable soil, 993.  
 Nitratopurpleorhodium chloride, 114.  
   — dithionate, 114.  
   — nitrate, 114.  
 Nitric acid, detection of, in a mixture of alkaline salts, 297.  
   — — determination of, 181.  
   — — not formed in the organism of higher plants, 686.  
   — ferment, distribution of, and its function in the disintegration of rocks, 1135.  
   — nitrogen obtained from soils and sub-soils, TRANS., 128, 129.  
   — or nitrous acid produced in dilute urine with gypsum seeded with soil from various fields, TRANS., 120, 121, 122, 123.  
   — oxide, absorption of, by sulphuric acid, 526.  
   — — density of, at  $-100^{\circ}$ , 887.  
   — — poisoning by, 392.  
   — — reaction of, with ferrous hydroxide and water, TRANS., 648.  
 Nitrification, 84, 858.  
   — order of priority of commencement of, in solution seeded with soils of different depths, TRANS., 125.  
 Nitrifying microbes, 1134.  
   — organism, distribution of, in the soil, TRANS., 118.  
 Nitriles, aromatic, action of sodium and alcohol on, 719.  
 Nitrites, absence of, in plants, 989.  
   — and sulphites of metals other than potassium, reaction between, TRANS., 659.  
   — colorimetric determination of, in water, 533.  
   — formation of, 106.  
   — reduction of, to hydroxylamine by hydrogen sulphide, TRANS., 48.  
 Nitrogen, action of, on certain metals, 702.  
   — allotropic modification of, 329.  
   — ammoniacal, estimation of, in soils, 82.  
   — assimilable, amount of, in uncultivated land, 82.  
   — atmospheric, acquisition of, by plants, 515.  
   — — direct absorption of, by vegetable soils, 395.  
   — chlorides, substituted, 44.  
   — compounds in vegetable soils, 293.  
   — determinations, apparatus for Kjeldahl's method for, 298.

Nitrogen, estimation of, in organic substances, 862.  
 — estimation of, in urine, 863.  
 — fluoride, 770.  
 — free, absorption of, by vegetable soils, 617.  
 — formation of, during putrefaction, 172, 746.  
 — Kjeldahl's method for estimating, 78, 863.  
 — liquefied, density of, 694.  
 — loss of, by plants during germination and growth, 292.  
 — organic, in chemical manures, 863.  
 — passage of electric discharge through, 328.  
 — peroxide, action of heat on, TRANS., 397.  
 — compound of amylene with, PROC., 108.  
 — refractive equivalent of, 193.  
 — tetroxide, specific heat of, 429.  
 Nitrogenous contents of the digestive juices, 1129.  
 — organic matter of soils, nature of, 523.  
 — substances, separation of, by means of phosphomolybdic acid, 310.  
 Nitro-group, substitution of the amido-group by the, in aromatic compounds, 720.  
 Nitrometer, simple, 998.  
 Nitrosamines, 729, 1114.  
 — action of hydrogen chloride on, 244.  
 Nitrous acid, 698.  
 — action of, on sulphurous acid, 549.  
 — detection of, in a mixture of alkaline salts, 297.  
 — Griess's test for, in presence of hydrogen peroxide, 298.  
 — reaction of, with sulphurous acid, 635.  
 — volumetric estimation of, 396.  
 Nobili's rings and allied electrochemical phenomena, 759.  
 Norhydtropidine, 740.  
 Normeconine-acetic acid, 47.  
 Normethyl-*o*-anhydramidohemipinic acid, 49.  
 Normethylazo-opianic acid, 49.  
 Normethylnitrohemipinic acid, 50.  
 Normethylnitrohemipinimide, 50.  
 Normethylnitropianic acid, 49.  
 — phenylhydrazine, 50.  
 Normethylnitropianoximic acid, 50.  
 Normethylnitropianphenylhydrazide, 46.  
 Normethylnitropiazide, 50.  
 Nutrition, animal, 856.

## O.

Oak-tannin, 584.  
 Oats, American, variations in the chemical composition and physical properties of, 293.  
 Octadecylbenzene and its derivatives, 253.  
 Octadecylphenol, 253.  
 Octyl mono-, di-, and tri-chloracetates, 653.  
 — nitrile, secondary, 458.  
 Octylbenzene, 133.  
 — *o*-amido-, hydrochloride, 134.  
 — bromo-, 133.  
 — chloro-, 133.  
 — dinitro-, 133.  
 — iodo-, 133.  
 — *o*-, *m*-, and *p*-nitro-, 133.  
 Odorous substances, minute quantities detectable of, 983.  
 Oenanthaldehyde and heptyl chloride, action of, on dimethylaniline in presence of zinc chloride, 814.  
 Oil, black pepper, 969.  
 — ethereal, of *Allium ursinum*, 1089.  
 — of cardamoms, 596.  
 — of peppermint, test for, 1001.  
 — Turkey-red, 914.  
 Oils, analysis of, 402.  
 — drying, acids from, 359, 798, 913.  
 — essential, 375.  
 — ethereal, 595, 596, 965.  
 — fixed, bromine and iodine absorptions of, 88.  
 — chemistry of, 88.  
 — coefficients of expansion of, 88.  
 — determination of glycerol in, 89.  
 — methods of examining, 88.  
 — saponification of, 186.  
 — sp. gr. of, 88.  
 — viscosity of, 88.  
 — iodine absorption by, 402.  
 — Maumené's test for, 89, 402.  
 — mineral, separation of, from saponifiable fats, 1001.  
 — the elaidin test for, 402.  
 Oleum bergamottæ, 375.  
 — citri, 375.  
 — cort. aurantium dulcium, 375.  
 Oleic acid, new, 32.  
 Oligoclase, 20.  
 Olive oil, characteristics of, 535.  
 — detection of sesame and cotton oils in, 536.  
 — properties of, 536.  
 Onions, analysis of, 1137.  
 Opianic acid derivatives, 45, 47.  
 — etherification of, 584.

Opianic acid, nitro-, reduction of, 584.  
 — anhydride, 47.  
 Opianoxime anhydride, 46.  
 Opianoximic anhydride, 258.  
 Opianphenylhydrazide, amido-, 45.  
 Opiaurin, 580.  
 Opium alkaloïds, 280.  
 — — separation of the, 851.  
 — — analysis, 403.  
 — — assay of, 622.  
 — — testing, 310.  
 Orcinol, action of chloral hydrate on, 724.  
 — dinitroso-, 808.  
 Ore-veins, investigations on, 224.  
 Organic compounds, liquid, specific heats of homologous series of, 6.  
 — — matter, determination of, in natural water, 533.  
 — — — estimation of, in water, 1000.  
 — — — in air, determination of, 532.  
 — — substances, ferric chloride as a test for, 400.  
 Organism, fate of certain chlorine compounds in the, 612.  
 — — fate of lactic acid in the, 508.  
 — — formates in the, 513.  
 Orthobenzoquinone, derivatives of, 808.  
 Orthoclase, artificial production of, 559.  
 Orthocumic acid, 264.  
 Orthoquinone, tetrabromo-, 808.  
 — — tetrachloro-, 808.  
 Osmotic equilibrium, 1013.  
 Oxalates, ethereal, action of alcohols and metallic alkyl oxides on, TRANS., 629.  
 Oxaethyl- $\alpha$ -naphthyl, 911.  
 Oxalic acid, decomposition by sunlight, 189.  
 — — — estimation of, in urine, 401.  
 — — — from the residue of *Spiritus atheris nitrosi*, 360.  
 — — — hydrated, dissociation of, 915.  
 — — — influence of heat on the decomposition of, by ferric chloride, 324.  
 Oxalimide, 234.  
 Oxalmethyl- $\alpha$ -naphthyl, 911.  
 Oxalpropyl- $\alpha$ -naphthyl, 911.  
 Oxalyldiamido- $\alpha$ -naphthyl mercaptan, 840.  
 Oxalyldiamido- $\beta$ -naphthyl mercaptan, 840.  
 Oxamide, decomposition of, by water and dilute acids, 236.  
 Oxanilic acid, halogen-derivatives of, 251.  
 Oxanilide, halogen-derivatives of, 251.  
 Oxidation in the animal body, 610.  
 — — with potassium permanganate, 146.  
 Oxides, metallic, change in volume during the formation of, 1073.  
 Oxyacanthine and its derivatives, 283.  
 Oxy carbimidophenol, 245.

Oxychlorisoquinoline, 62.  
 Oxydihydrotoluinoxaline, 383.  
 Oxygen absorbed in respiration, estimation of, 507.  
 — — absorption of, by carbon, TRANS., 252.  
 — — action of animals on, 855.  
 — — action of light on the hydrides of the halogens in presence of, TRANS., 801.  
 — — active, formation in the atmosphere, 211.  
 — — — formation of, in paper, 211.  
 — — — reagents for determining minimal quantities of, 295.  
 — — amount of, in the atmosphere, 634.  
 — — and ozone, volumetric relations of, TRANS., 625.  
 — — atomic weight of, 1078.  
 — — chemical structure of, and its dissociation in the sun's atmosphere, 1070.  
 — — "devitalised," 855.  
 — — exhalation of, by fleshy-leaved plants in absence of carbonic anhydride, 988.  
 — — in the sun, 1065.  
 — — liquid, absorption spectrum of, 625.  
 — — — density of, 694.  
 — — percentage of, in air, 885.  
 — — preparation of, with use of a Kipp's apparatus, 769.  
 — — pure, preparation and storage of, TRANS., 611.  
 — — refractive index of, 193.  
 — — relation of bacterial life to, 291.  
 Oxyhemoglobin, absorption of light by, 1126.  
 Oxy methylethylenyldiamidotoluene, 937.  
 Oxymethylpyrrolidine, 463.  
 Oxyquinizinecarboxylic acid, amido-, 468.  
 Ozone and oxygen, volumetric relations of, TRANS., 625.  
 — — boiling point of, 634.  
 — — connection of the formation of, with atmospheric electricity, 211.  
 — — from pure oxygen, TRANS., 610.  
 — — influence of, on germination, 516.  
 — — production of, 327.

## P.

Palladium, separation of mercury, lead, copper, and bismuth from, 302.  
 Pallasite from Campo de Pucará, 904.  
 Papaverine, 280.  
 — — composition of, 852.  
 — — derivatives, 163.  
 — — salts, 164.  
 Paper, formation of active oxygen in, 211.

- Paper, quantitative estimation of wood in, 620.
- Paper-making, use of talc in, 452.
- Paracoumaric acid, 1109.
- — dibromide, bromo-, 110.
- Paracymyl phenyl carbinol, 942.
- — ketone, 942.
- Paraffin oil, alkaloid-like bases in, 979.
- — series, synthesis in the, by means of aluminium chloride, 656.
- Paragalactin, 460.
- Paragonite schist from the Oral, 351.
- Paraldehyde, action of quinaldine on, 975.
- — physiological action of, 391.
- Paramyosinogen, 984.
- Paratungstates, 895.
- Parvoline, oxidation of, 379.
- Pease, composition of, 73.
- Pectolite from Auchensterry Quarry, Kilsyth, 645.
- — from Disco Island, 783.
- Pentadecyl phenyl ketone, 252.
- Pentadecylic acid, 651.
- Pentahydroxycaproic acid, 465.
- Pentamethylbenzene, action of sulphuric acid on, 660.
- Pentamethylbenzenesulphonic acid and its derivatives, 660.
- Pentamethylene-derivatives, TRANS., 240.
- Pentamethylenediamine, identity of cadaverine with, 125, 1057.
- Pentamethylenedicarboxylic acid, TRANS., 244.
- — anhydride, TRANS., 247.
- Pentane- $\omega_2\omega_3$ -tetracarboxylic acid, TRANS., 242.
- Pentathiophen group, 239.
- $\gamma$ -Pentylene glycol, TRANS., 836.
- — and its anhydride, 33.
- Pepper, analysis of, 312.
- — oil, black, 969.
- Pepsin, comparative estimation of preparations of, 66.
- — methods of preparing extracts of, 65.
- — versus animal digestion, 513.
- Peptones in the blood and urine, 188.
- Perbromic acid, 698.
- Percylite, from Chili, 902.
- Peridote of Schelinger Matten, 1086.
- Periodates, TRANS., 356.
- Periodic law, 211.
- Permanganates, formation of manganites from, 552.
- Per-ruthenic acid in histology, 1060.
- Petroleum and the hydrocarbons of coal-tar and shale-tar, relations between, 648.
- — Caucasian, constitution of hydrocarbons,  $C_nH_{2n}$ , from, 922.
- — Galician, bases in, 979.
- — Russian, hydrocarbons of, 225.
- Pettenkofer's reaction, 1149.
- Phellandrene, 967.
- Phenaceturic acid, synthesis of, 368.
- Phenacite from Colorado, 118, 452.
- Phenanthraquinone dihydrocyanide, TRANS., 32.
- Phenazine-derivatives, 139.
- — pyrogenic formation of, 249.
- Phenazoxine, 665.
- Phenethylamine, preparation of, 245.
- Phenetoil, heat equivalent of, 428.
- Phenol, action of phosphorous chloride on, 947.
- — action of sulphur dichloride on, 807.
- — *o*-amido-, action of chloracetic chloride on, 814.
- — cause of the red colour of, 807.
- — chloracetamido-, 814.
- — *m*-chloro-, 946.
- — *o*-chloro-*p*-brom-*o*-nitro-, derivatives of, TRANS., 791.
- — *p*-chloro-*o*-brom-*o*-nitro-, derivatives of, TRANS., 788.
- — *p*-chloro-*p*-brom-*o*-nitro-, derivatives of, TRANS., 790.
- — *p*-chloro-*o*-nitro-, action of bromine on, TRANS., 787.
- — dibromo-, 242.
- — dichloro-*o*-nitro-, TRANS., 782.
- — dichloro-*p*-nitro-, TRANS., 786.
- — higher homologues of, conversion of, into amines, 721.
- — homologues of, oxidation of, 241.
- — isolation and detection of, 867.
- — monobromo-, a fourth, 134.
- — occurrence of, in human sweat, 1132.
- — oxidation of homologues of, 1035.
- — series, isomeric change in, TRANS., 147, 782.
- — tribromo-, derivatives of, 573.
- Phenolphthaleïn, behaviour of alkaline solutions of, in presence of alcohol, 618.
- 4' Phenolquinolines,  $\alpha$ - and  $\beta$ -, 599.
- Phenols, action of aldehydes on, 270.
- — action of benzaldehyde on, 723.
- — action of chlorine on, 960.
- — action of hydrogen chloride on a mixture of, with aldehyde, 231.
- — condensation of, with aldehydes, 825.
- — conversion of, into amines, 576.
- — dibromonitro-, action of bromine on, TRANS., 147.
- — higher, action of cyanuric chloride and chlorocyanuric diamide on, 1033.
- — homologous, heats of combustion and formation of, 98.
- — nitro-, and phenylhydrazine, 722.
- — polyvalent, action of acetaldehyde on, 809.

- Phenols, reaction of diazoamido-compounds with, 664.  
 Phenolsulphonic acid, amido-, action of bleaching powder on, 834.  
 Phenosafranine, constitution of, 140.  
 — hydrochloride, 250.  
 Phenoxyaceticacrylic acid methyl ketone, 259.  
 — acids, 259.  
 Phenoxyacetic-*m*-carboxylic acid, 259.  
 Phenoxyacetic-*p*-carboxylic acid, 258.  
 Phenyl, *o*-amido-, mercaptan and disulphide, 823.  
 — benzoate, *m*-nitro-, 254.  
 — diphenylcarbamate and its nitro- and amido-derivatives, 936.  
 — ethyl ketone and its derivatives, 252.  
 — group, negative nature of the, 572.  
 — mercaptan, *o*-amido-, and its derivatives, 1039.  
 — methyl ether, chlorine-derivatives of, 923.  
 — *m*-nitrobenzoate, nitro-, 254.  
 — paratolyl bisulphide, 242.  
 — propyl ether, heat equivalent of, 428.  
 — pyridyl ketone, 737.  
 — tetrasulphide, 923.  
 — thiobenzenesulphonate, reduction of, 954.  
 — thiotolyl ketone, 238.  
 Phenylacetic acid, 829.  
 — phenylhydrazide, 138.  
 Phenylacetoneitrile carbamide, 1055.  
 Phenylamidine, 1040.  
 Phenylamidoacetic acid, derivatives of, 1108.  
 Phenylamidolutidine, 501.  
 Phenylamidopropionic acid from the decomposition of proteids, 369.  
 Phenylamidoquinaldine, 680.  
 Phenylammeline, 1034.  
 Phenylasparaginanyl, 934.  
 Phenylaspartic acid, 934.  
 Phenylazodimethylamidobenzene, *m*-nitro-, 152.  
 Phenylazoethylresorcinol (ortho-), 662.  
 Phenylbismuthine dibromide, 368.  
 $\alpha$ -Phenylcinchoninic acid, 504.  
 Phenylcrotonitrilecarbamide, 1055.  
 Phenylcumylthiocarbamide, 1039.  
 Phenyleyantetrazole, 139.  
 Phenyldehydrohexone, TRANS., 731.  
 — action of hydrogen bromide on, TRANS., 732.  
 Phenyldehydrohexonecarboxylic acid, TRANS., 728.  
 — — action of hydrogen bromide on, TRANS., 732.  
 — — action of water on, TRANS., 733.  
 Phenyldehydrohexonecarboxylic acid, *p*-nitro-, TRANS., 736.  
 Phenyl- $\gamma$ - $\delta$ -dibromovaleric acid, *o*-amido-dibromo-, 486.  
 Phenyl dimethylethylammonium tri-, penta-, and hepta-iodides, 910.  
 Phenyl dimethylpyrazolecarboxylic acid, 678.  
 Phenyl dimethylpyrazolone, 601.  
 Phenyl dimethylpyrroline [1 : 2 : 5], 275.  
 Phenyl ditolylmethane, *m*-nitro-, 44.  
 Phenylethane, dimethamido-, 1039.  
 — nitrosomethamido-, 1039.  
 Phenylene dibromodichlorethylene ketone, 955.  
 — tetrachlorethylene ketone, 955.  
 — *o*-, *p*-, and *m*-thiocarbamide, 366.  
 Phenylenechlorohydroxyacetylene ketone, 728.  
 Phenylene diamine (meta-), dinitro- and diacetodinitro-, 477.  
 Phenylene dibromacetylene ketone, 729.  
 Phenylene-*m*-diphenylsulphone, action of potash on, 372.  
 Phenylglucosazonecarboxylic acid, 150.  
 Phenylglutaric acid, 672.  
 Phenylglycerosazone, 651.  
 Phenylglycidic acid, 254.  
 — — Plöchl's, 142.  
 Phenylglycinephenylamidoacetic acid, 1108.  
 Phenylglycollic acid, *o*-nitro-, reduction of, 948.  
 Phenylglyoxylic acid, formation of, from benzoic cyanide, 487.  
 — — preparation of, from acetophenone, 483.  
 Phenylhydrazine, 138.  
 — action of carbamide on, 1042.  
 — preparation of, 1042.  
 — titration of, 1042.  
 Phenylhydrazineamidoxalacetic acid, 467.  
 Phenylhydrazinebenzal acetone, 678.  
 Phenylhydrazinedehydracetic acid, TRANS., 494.  
 Phenylhydrazine-ethyl oxalacetate, 235.  
 $\beta$ -Phenylhydroxypropionic acid,  $\alpha$ -iodo-, 45.  
 Phenylhydroxypropionic acids,  $\alpha$ - and  $\alpha$ - $\beta$ -, 1046.  
 Phenylindole, 956.  
 Phenyl iodohydracrylic acid, 45.  
 Phenylisobutyric acid, derivatives of, 583.  
 Phenylisopropylamine, 583.  
 Phenylizindihydroxytartaric acid, 578.  
 Phenyllactosazone, 567.  
 Phenyllepidinamine, 159.  
 Phenyllutidine, *m*-amido-, 1053.  
 Phenyllutidinedicarboxylic acid, *m*-amido-, 1053.  
 Phenyllutidone, 501; TRANS., 499.

 Propylene,  $\alpha$ -chloro-, 656.  
 $\alpha$ -Propylene dinitrite, 458.  
 Propylhydrocarbostyryl, 132.  
 Propylhydrocinnamic acid (*para*-), 133.  
 $\alpha$ -Propylpiperidine, 161.  
 Propylthiénylglyoxylic acid, 804.  
 Propylthiophen, bromo-, 804.  
 — derivatives, 804.  
 — dinitro-, 804.  
 — iodo-, 804.  
 Propylthiophenic acid, 804.  
 Propylxanthic acid, 800.  
 Proteids of cerebrospinal fluid, 614.  
 — of muscle plasma, 984.  
 — of seeds, changes in, during germination, 987.  
 — of the seeds of jequirity, 990.  
 — relation of, to digestive ferments, 1129.  
 Protoalbumose, 285.  
 Protoplasm from recently killed animals, fermentation by, 984.  
 — living, reduction of silver salts by, 987.  
 Protovitellose, 286.  
 Prussian and Turnbull's blues, composition of, TRANS., 644.  
 Pseudobiotite, 646.  
 Pseudocarbostyryl, derivatives of, 977.  
 Pseudocumene, action of methylene chloride on, in presence of aluminium chloride, 1102.  
 Pseudocumenequinol, 255.  
 Pseudocumenequinone, nitro-, 255.  
 Pseudocumenyl- $\gamma$ -ketonic acid, 827.  
 Pseudocumyl phenyl ketone, 942.  
 Pseudolutidinecarbostyryl, 502.  
 Pseudomorphine, 163.  
 Pseudophite from South Africa, 561.  
 Pseudophthalimidine, 1038.  
 Pseudoquinisatin, 978.  
 Psilomelane, occurrence of lithium in, 222.  
 Pterocarpin from sandal wood, 971.  
 Pterolite from Lövö, 350.  
 Ptomaine, a new, producing tetanus, 284.  
 — poisonous, in milk, 389.  
 Ptomaines, 385.  
 — from pure cultivations of *Vibrio proteus*, 742.  
 Ptomaines, origin of, 387.  
 Purpurogallin, 733.  
 Putrefaction, aromatic products of, in human sweat, 1132.  
 — formation of free nitrogen during, 746.  
 — is free nitrogen formed during? 172.  
 Pyrazole-derivatives, 678, 1054.  
 Pyrazoles (*meta*-), 1055.  
 Pyrazolines, 601.  
 Pyrazolone-derivatives from ethyl benzoylacetate, 1121.  
 Pyrazolones (*meta*-), 1055.  
 Pyrene, 271.  
 — constitution of, 496.  
 — ketone, 272.  
 Pyridanthrilic acid, 979.  
 Pyridine, action of chlorine on, 277.  
 — bases, halogen-derivatives of, preparation of, from pyridinecarboxylic acids, 844.  
 — — preparation of, 499.  
 — constitution of, TRANS., 409.  
 — derivatives, conversion of pyrroline into, 678.  
 — — from *m*-nitrobenzaldehyde, 1053.  
 — — preparation from citric acid, TRANS., 403.  
 — — synthesis of, 155.  
 — dichloramido-, 157.  
 — dichlorethoxyhydroxyamido-, 157.  
 — dichlorodiethoxyamido-, 157.  
 — silicon chloride, TRANS., 47.  
 — tetrachloramido-, 157.  
 — trichloramido-, 156.  
 — trichlorethoxyamido-, 157.  
 — trichloro-, 158.  
 Pyridinedicarboxylic acid, 63.  
 — — bromo-, 159.  
 Pyridinepolycarboxylic acids, 1117.  
 Pyridinetricarboxylic acid, dibromo-, 844.  
 Pyridylquinoline, 64.  
 Pyridylquinolinecarboxylic acid, 64.  
 Pyrimidines, 1053.  
 Pyrites, burnt, estimation of small quantities of silver in, 79.  
 "Pyrocresols," isomeric, constitution of, PROC., 114.  
 Pyrogallol, action of chlorine and bromine on, 925.  
 — heat of combustion of, 762.  
 — trichloro-, 925.  
 Pyrogenic reactions, 572.  
 Pyrometer, new, 1073.  
 Pyromucic acid, chloro-, 469.  
 — — dichloro-, 34.  
 — —  $\beta$ - $\gamma$ -dichloro-, and its derivatives, 470.  
 Pyromykuric acid, 1032.  
 — — carbamide, 1033.

Pyrotritaric acid, bromo- and chloro-derivatives of, 658.  
 ——— constitution of, 657.  
 Pyroxene from the Krimlerthal, 902.  
 Pyrrolidine, 499.  
 ——— formation of, 1052.  
 Pyrroline, action of acetone on, 1052.  
 ——— action of propionic anhydride on, 844.  
 ——— bases, synthesis of, 598.  
 ——— constitution of, 273.  
 ——— conversion of, into pyridine-derivatives, 678.  
 ——— derivatives, conversion of, into pyridine-derivatives, 378.  
 ——— ——— synthesis of, 273.  
 ——— extraction of, from animal oil, 59.  
 ——— reaction of acetone with, 598.  
 ——— series, determination of position in the, 597.  
 ——— synthesis of, from succinimide, 273.  
 ——— tetriodo-, 597.  
 ——— transformation of furfuran into, 470.  
 Pyruvic acid, compound of, with hippuric acid, 44.  
 ——— ——— derivatives, 260.  
 Pyuramide, dibromo-, 918.  
 Pyvureid, dibromo-, 918.  
 Pyvurine, tribromo-, 918.

## Q.

Quartz, artificial production of, 559.  
 ——— crystals with basal plane, 119.  
 Quartzite, 451.  
 Quercin, 909.  
 ——— crystalline form of, 1026.  
 Quercite, heats of combustion and formation of, 1011.  
 Quinaldine, bromo- and chloro-, 1113.  
 ———  $\gamma$ -chloro-, 680.  
 ——— condensation of, with aldehydes, 975.  
 ——— combination of, with formamide, 381.  
 Quinalizarin and its derivatives, 593.  
 Quinazolines, 1044.  
 Quinic acid, heats of combustion and formation of, 1011.  
 Quinine chromate in analysis, 404.  
 ——— hydrochloride, normal, 980.  
 ——— sulphate, analysis of, 404, 405.  
 ——— estimation of, 1145.  
 ——— estimation of cinchonidine in, 623.  
 ——— ——— testing, 623, 1146.  
 Quinzines, 601.  
 Quinol and its derivatives, 364.  
 ——— chlorotribromo-, TRANS., 784.  
 ——— diacetylchlorotribromo-, TRANS., 784.

Quinol, dinitro-, constitution of, 574.  
 ——— heat of combustion of, 762.  
 ——— tetrachloro-, 42.  
 Quinoline, bromo-, and its derivatives, 158.  
 ——— *o*-chloro-, action of acetamide on, 848.  
 ——— derivatives, 738.  
 ——— ——— from  $\beta$ -diketones, 849.  
 ——— ——— synthesis of, 847.  
 ——— ——— synthesis of, by means of ethyl acetoacetate, 679.  
 ——— existence of two series of 4-(ana) substituted derivatives of, 973.  
 ——— homologues of, transformation of homologues of indole into, 1113.  
 ——— propiobromide and its dibromide, diiodide, dichloride, and tetriiodide, 60, 61.  
 ——— propiochloride and its dibromide, dichloride, and diiodide, 61.  
 ——— propiodide and its dibromide, dichloride, diiodide, tetrabromide, tetrachloride, and tetriiodide, 61.  
 ——— reactions of, 847.  
 ——— red, 380.  
 ——— silicon chloride, TRANS., 47.  
 ——— tribromo-, 278.  
 $\alpha$ -Quinoline dicyanide, 379.  
 Quinolinecarboxylic acid, 1 : 4 bromo-, 502.  
*m*-Quinolinecarboxylic acid, 160.  
 ——— ——— synthesis of, 503.  
 $\alpha$ -Quinolinedicarboxylic acid, 379.  
 Quinolinedisulphonic acid, 379.  
 $\alpha$ -Quinolinedisulphonic acid, derivatives from, 973.  
 Quinolinesulphonic acid, 737.  
 ——— acids *o*- and *m*-, 601.  
 ——— ——— *o*- and *p*-, 278.  
 Quinoline anhydride, 737.  
 Quinone, a, obtained in the destructive distillation of teak, TRANS., 870.  
 ——— chlorotribromo-, TRANS., 783.  
 ——— derivatives, constitution of, 719.  
 ——— dinitro-diamido-, 930.  
 ——— heat of combustion of, 762.  
 Quinonedioxime, 575.  
 Quinone, ortho-. See Orthoquinone.  
 Quinones, action of yellow ammonium sulphide on, 1045.  
 ——— preparation of, 1036.  
 ——— secondary and tertiary, 473.  
 Quinoneoximes, 41.  
 Quinoxaline series, nomenclature of, 382.

## R.

Racemic acid, TRANS., 362.  
 Radiant matter spectroscopy, 1066.

- Radiation, comparative, of fused platinum and fused silver, 1010.
- Raffinose, formation of galactose and levulose from, 791.
- See also Melitose.
- Rain-water collected at Cirencester, amount of chlorine in, TRANS., 92.
- Rape seed oil, constituents of, 1030.
- Rapic acid, 1030.
- Ralstonite, 345.
- Raspberries, wine and brandy from, 292.
- Reactions, chemical, application of the electrometer to the study of, 882.
- Realgar, chemical nature of, 888.
- Recalescence, 14.
- Red liquors, examination of, 1063.
- Refraction, molecular, of carbon compounds of high dispersive power, 626.
- of liquid organic compounds of high dispersive power, 191.
- of the hydrocarbons, supposed influence of multiple bonds of union on, 198.
- relations, 200.
- Refractive power of compounds, influence of simple and so-called multiple union of atoms on, 1005.
- Reichert's distillation process, 1145.
- Resin from teak, TRANS., 869.
- oil, fatty acids occurring in, 683.
- Resins, separation of, 406.
- Resorcinol, behaviour of ethyl oxalate with, 949.
- derivatives, 660, 661.
- dinitroso-, 808.
- furfuran-derivatives from, 262.
- manufacture of, 574.
- mono- and di-bromo-, 924.
- Respiration, chemical effect of, and muscular activity, relation between, 1058.
- estimation of the carbonic anhydride expired and oxygen absorbed in, 507.
- intermolecular, 686.
- molecular, of plants, 988.
- Rhodium and tin, alloy of, 779.
- Ricinoleic acid, oxidation of, 716.
- Rock salt, dispersion in, 754.
- Rocks, eruptive, from Krzeszowice, Cracow, 563.
- from Vulture and Melfi, composition of, 1087.
- function of the nitric ferment in the disintegration of, 1135.
- Japanese, 564.
- Norwegian, 562.
- Persian eruptive, analyses of, 223.
- volcanic, composition of, 1023.
- Rosaniline base, description and measurement of the spectrum of, TRANS., 164.
- description and measurement of the spectrum of, TRANS., 169.
- salts, and sulphonated rosaniline, detection of, 405.
- Roseocobalt pyrophosphate, 776.
- Roseo-rhodium bromide, 113.
- cobalticyanide, 114.
- iodide sulphate, 114.
- nitrate, 113.
- orthophosphate, 114.
- platinochloride nitrate, 113.
- sulphate, 114.
- sodium pyrophosphate, 114.
- sulphate, 113.
- Roshydrazine, 822.
- Rosindole, 588.
- Rottlerin, 498.
- Rubazonic acid, 602.
- Ruberythric acid, 1051.
- Rubidium cobalt nitrite, 13.
- Rubies, artificial, formation of, 556.
- Ruby, Balas, artificial production of, 707.
- Ruthenium and tin, alloy of, 779.
- Rye, manuring with basic-slag and other phosphates, 294.

## S.

- "Saccharin," 836.
- Saccharose, decomposition of, by boiling with lime, 1026.
- tetrabenzoate, 229.
- Saccharoses, action of dilute acids on, 229.
- Safranine, constitution of, 249, 250.
- dyes, 249.
- Safranines, constitution of, 139, 480.
- Safrole, 990.
- Salicylaldehyde, action of, on sodium succinate in presence of acetic anhydride, TRANS., 61.
- Salicylaldehydes, nitro-, 938, 939.
- Salicylic acid, action of phosphoric chloride on, 725, 947.
- action of phosphorous chloride on, 946.
- detection of, 185.
- dibromo-, constitution of, 487.
- heat of combustion of, 762.
- acids, chloro-, 945.
- substituted bromo-, 486.
- Salicylphosphorous chloride, 946.
- Saliva, action of, on starch, 354.
- parotid, gases of, 287.
- presence of hydrogen peroxide in, 298.

- Salt solutions, boiling points of, 1012.  
 ——— expansion of, 760.  
 ——— supersaturation of, TRANS., 389.  
 ——— vapour-tension of water from, 321.  
 ——— vapour-tensions of, 764.  
 Salts, conductivity of, in dilute solutions, 758.  
 ——— containing water of crystallisation, dissociation of, 207.  
 ——— deliquescence and efflorescence of, in relation to the maximum vapour-tensions of their saturated solutions, 208.  
 ——— density of weak aqueous solutions of certain, 209.  
 ——— heat of dissolution of, in water, influence of temperature on, PROC., 66; TRANS., 290.  
 Samarium, spectra of, 1008.  
 Samarskite, new elements in, 334.  
 Sanguinarine, 854.  
 Santonin, manufacture of, 677.  
 ——— oxidation of, 733.  
 Saponification, velocity of, 767.  
 Sapphirine from Greenland, 784.  
 Saprine, 386.  
 Sarcomata, melanotic, pigments of, 168.  
 Sarkinite, a new manganese arsenate, 346.  
 Sative acid, constitution of, 799.  
 Sausage poisoning, 392.  
 Scale, crystalline, formed in the manufacture of sodium hydrogen carbonate, 108.  
 Scandium, phosphorescence of, 1068.  
 Scapolite series, 560.  
 Scheelite from the Krimlerthal, 902.  
 Schoolrooms, carbonic anhydride in the air of, 888.  
 Schweizer's reagent, 773.  
 Scolezite from Striegau, 903.  
 Scorodite from Utah, 783.  
 Sebacedinitranilide, 935.  
 Secretions, digestive, in the horse, 744.  
 Seeds, changes in the proteids of, during germination, 987.  
 ——— ripening of, 173.  
 Seleniferous sulphuric acid, detection of nitrogen compounds in, 998.  
 Selenious acid, saturation of, by bases, 106.  
 ——— and sulphuric anhydrides, compound of, 212.  
 Selenium, action of, on aqueous silver nitrate, 331.  
 ——— alums, 1014.  
 ——— electromotive force produced by light in, 693.  
 ——— microchemical test for, 301.  
 Sensitisers, photographic, 874.  
 Serin, absorption-spectrum of, TRANS., 59.  
 Serpentine-chlorite group, minerals of, 783.  
 ——— manganese zinc, from Franklin, New Jersey, 646.  
 Serpentes from Porthalla Cove, Cornwall, 1022.  
 Serum, blood, new constituent of, 983.  
 ——— fibrinogen, 983.  
 Sesame oil, properties of, 536.  
 Sesquauramine, 112.  
 Sesquihydraurylamine, 112.  
 Sesqui-magnesia alum, 558.  
 Sesquiterpenes, 596.  
 Shale spirit, composition of, PROC., 97.  
 ——— tar, relation between petroleum and the hydrocarbons of, 648.  
 Sheep, amounts of nitrogen ingested and recovered in manure, 175.  
 ——— grazing, quantity of fertilising matter supplied to the soil by, 175.  
 Shikimic acid, 497.  
 Shot, analysis of, 446.  
 Silage of maize, 521.  
 ——— of vegetable matter, 521.  
 Silica, crystallised, artificial production of, 559.  
 Silicates, analysis of, in the dry way, 181.  
 ——— Lawrance Smith's plan for estimating alkalis in, 181.  
 Silicic acid, decomposition of, by leaves, 70.  
 Silicocarbonate, crystalline, from soda liquors, 12.  
 Silicon, atomic weight of, TRANS., 576.  
 ——— chlorobromide, a new, TRANS., 590.  
 ——— compounds and their derivatives, TRANS., 202.  
 ——— dichloro-, di- $\beta$ -naphthylidiamide, TRANS., 45.  
 ——— ——— diphenyldiamide, TRANS., 40.  
 ——— ——— o-ditolylidiamide, TRANS., 44.  
 ——— ——— dixylyldiamide, TRANS., 44.  
 ——— estimation of, in iron, 527.  
 ——— estimation of, in iron and steel, 1140.  
 ——— fluoride, compounds of, with organic bases, 243.  
 ——— hydride, preparation of, as a lecture experiment, 769.  
 ——— influence of, on the condition of carbon in cast iron, 220.  
 ——— influence of, on the properties of iron and steel. Part I, TRANS., 129.  
 ——— in iron, influence of, on the mechanical properties, TRANS., 141.

Silicon in specially pure iron, *TRANS.*, 134.

— phosphate, hydrated, 329.

— rapid estimation of, in iron and steel, 1140.

— tetrabromide, action of, on thiocarbamide, *TRANS.*, 202.

Silicotungstic acid, 703.

Silkworms, feeding and development of, 68.

Silver, action of acidified potassium permanganate on, 1079.

— ammonio-nitrate, 331.

— arsenates, 215.

— atomic weight of, 444.

— Chaldean, 443.

— chloride, photochromatic properties of, 1071.

— chromate, solubility of, in ammonium nitrate, 216.

— containing bismuth, *TRANS.*, 410.

— electrolysis of, 315.

— estimation of small quantities of, in burnt pyrites, 79.

— fused, and fused platinum, comparative radiation of, 1010.

— hydrogen tartrate, *TRANS.*, 370.

— lowest compounds of, 639.

— microchemical test for, 300.

— nitrate, action of arsenic, phosphorus, selenium, and tellurium, on solutions of, 331.

— — action of metals on solutions of, 550.

— — reaction of, with sodium thioarsenate, 889.

— occurrence of, in volcanic ash from Cotopaxi, 454.

— periodates, *TRANS.*, 358.

— phosphates, 214, 215.

— phosphorised, 1079.

— potassium thiosulphate, *TRANS.*, 39.

— pyrophosphate, 215.

— salts, electromotive dilution constants of, 1072.

— suboxide, 771, 1079; *TRANS.*, 416.

— See also *Argentous*.

Skatole-derivatives, 957.

— from strychnine, 682.

Skatoxyl, occurrence of, in human sweat, 1133.

Slag, basic (basic converter or Thomas slag), 216.

— as manure, 995.

— as manure for moorlands, 294.

— crystals in, *TRANS.*, 601.

— determination of phosphorus in, 527.

— influence of the ferrous oxide in, on the growth of plants, 178.

Slag, basic, manurial value of, 176, 525.

— — manuring rye with, 294.

— — manuring with, 524.

— — value of the phosphoric acid in, 687.

Slags, determination of metallic iron in, 1140.

— soluble, estimation of sulphur in, 526.

Smell, sensitiveness of the sense of, 983.

Soap, carbolic, assay of, 185.

— determination of fatty acids in, 307.

Soaps, estimation of fatty acids in, 401.

Soda liquors, a crystalline silicocarbonate from, 12.

— lyes, crude, examination of, 1063.

— manufacture, occasional products of, 331.

Sodium, action of, on the ethyl salts of the higher fatty acids, 1099.

— alkyl oxides, heat of formation of, 319.

— amidohemipinate, 49.

— and lithium, estimation of, in mixtures of their carbonates, 864.

— and potassium, separation from lithium, magnesium, and calcium, 528.

— arsenate, *TRANS.*, 95, 97.

— — hydrates of, 698.

— benzoic sulphinide, 835.

— calcium carbonates from the soda manufacture, 12.

— carbonate, an alleged reaction for preparing, 330.

— — anhydrous, heat of dissolution of, *TRANS.*, 73.

— — decomposition of, by fusion, *TRANS.*, 72.

— chromiodate, 777.

— copper chromate, basic, 111.

— diazomethylamidobenzenesulphonate, 666.

— dichromate, 110.

— — cell, 412.

— ethylamidoazobenzenesulphonate, 666.

— glyceroxide, alcoholates of, 426.

— — heat of solution of, 8.

— hydrogen carbonate, detection of thiosulphate in, 79.

— — — particular case of the formation of, 699.

— hydroxide, new hydrate of, 550.

— hyponitrite, reaction of, with sodium amalgam and water, *TRANS.*, 654.

— — reaction of, with ferrous hydroxide and water, *TRANS.*, 654.

— methylamidoazobenzenesulphonate, 666.

- Sodium, monosulphide, influence of heat on the combination of water with, 331.
- naphthionate, action of benzaldehyde on, 962.
  - nitrate in gun cotton, 715.
  - — reaction of, with ferrous hydroxide and water, TRANS., 655.
  - nitrite, reaction of with ferrous hydroxide and water, TRANS., 651.
  - periodates, TRANS., 357.
  - phosphate, TRANS., 97.
  - — dissociation of, 436.
  - production of, 107.
  - salts, normal, action of aqueous soda on, 440.
  - sulphide, conductivity of solutions of, 758.
  - thioarsenate, decomposition of, by silver nitrate, 444, 889.
  - thiosulphate, action of potassium permanganate on, 336.
  - trichromate, 111.
  - vanadate, TRANS., 96.
  - vanadates, 640.
- Soil, arable, determination of ammonia in, 297.
- — production of nitrates in, 993.
  - influence of the physical properties of a, on the amount of free carbonic anhydride present, 521.
  - quantity of fertilising matter supplied to, by grazing sheep, 175.
- Soils, absorption by, 76.
- behaviour of urea in, 524.
  - decomposition of organic matter in, 523.
  - distribution of the nitrifying organism in, TRANS., 118.
  - estimation of absorbed bases in, 77.
  - estimation of ammoniacal nitrogen in, 82.
  - nature of nitrogenous organic matter of, 523.
  - percentage of nitrogen in, 83.
  - Tunisian, 860.
  - unmanured percentage of nitrates in, 83.
  - vegetable, absorption of free nitrogen by, 617.
  - — direct absorption of atmospheric nitrogen by, 395.
  - — evolution of ammonia from, 860.
  - — — nitrogen compounds in, 293.
- Soja bean, fat of the, 687.
- — sugars of the, 686.
- Solanine, amount of, in diseased potatoes, 860.
- Solar radiation and heat, comparative action of, 411.
- Solids, electrical conductivity of, at high pressure, 5.
- Solubility of chlorides, effect of hydrochloric acid on, 445.
- of solid substances, 436.
  - of sulphates, effect of sulphuric acid on, 546.
  - — variation of, with variations in the heat of solution, 548, 632.
- Solution, a particular case of, 547.
- Solutions, aqueous, conditions of equilibrium in, 440.
- ethereal, influence of concentration on the vapour-tension of, 631.
  - — vapour-tensions of, 207.
  - nature of, TRANS., 779.
- Sorbus aucuparia*, tannic acid in the berries of, 950.
- Sorghum, fermentation of, 519.
- Sparteine, 162, 1056.
- ethiodide, 163.
  - methiodide, 163.
  - reaction of, with ethyl iodide, 603.
- Specific gravity of soluble substances, determination of, 9.
- heat, determination of atomic weight from, 419.
  - — of liquids, 419.
  - heats of homologous series of liquid organic compounds, 6.
  - inductive power of liquids, 413.
  - rotation of optically active substances in very dilute solution, 755.
- Spectra, absorption, compounds of rare earths yielding, 890.
- — relation between the molecular structure of carbon compounds and their. Part VII, TRANS., 152.
  - — variations in the, of didymium salts, 873.
  - of didymium and samarium, 1008.
  - of methyl-derivatives of hydroxy-anthraquinone, 1.
  - phosphorescent, of the earths present in gadolinite and samarskite, 334.
  - sharp line, of phosphorescent alumina, yttria and lanthana, 1069, 1070.
  - spark, obtained with coils of low tension, 537.
- Spectral lines of solar and terrestrial origin, distinction between, 313.
- Spectroscope, universal, 179.
- Spectroscopy, radiant matter, 1066.
- Spectrum, absorption-, of didymium, variations in, 537.
- analysis, 1066.
  - of germanium, 313.
  - practical methods of photographing the, 93.

- Spectrum, production of white light by mixing the colours of the, 1.
- Sphalerite, action of hydrochloric acid on, 442.
- Spheroidal state, 768.
- Spinel, fluorescence of, 1005.
- rose, artificial production of, 707.
- Spodiosite, place of, in the mineral system, 346.
- Spodumene from North Carolina, 118.
- Sponge, sea water, presence of chlorophyll in, 613.
- Stannic oxide, colour reactions of, 304.
- compounds of, with sulphuric acid and selenic acid, 336.
- sulphide, detection of, in presence of antimonious sulphide, 183.
- Starch, action of saliva on, 354.
- action of sulphuric acid on, 125.
- alcoholic fermentation of, 171.
- cellulose, true nature of, 460, 686.
- colour reactions of, 534.
- conversion into glucose, by means of hydrochloric acid, 125.
- determination of moisture in, 1143.
- dry distillation of, with lime, 460.
- estimation of, 867, 868.
- estimation of, in potatoes, 868.
- formation of, in chlorophyll granules, 1136.
- granules, 355.
- iodide of, 568.
- saccharification of, 354.
- saccharification of, by nitric acid, 792.
- soluble, so-called, 173.
- Stassfurt potash liquors, working up of, 1079.
- salt mines, minerals from, 1085.
- Steel, cast, heating and cooling of, 14.
- determination of phosphorus in, 183, 299, 396, 527.
- effect of manganese, phosphorus, silicon and tungsten on the properties of, 639.
- estimation of silicon in, 1140.
- fused, heating and cooling of, 219.
- influence of silicon on the properties of, *TRANS.*, 129.
- manganese in, 619.
- rapid estimation of silicon, sulphur and iron in, 1140.
- residues obtained from, by the action of acids, 894.
- Stilbene bromide, *p*-dinitro-, 151.
- diamido-, 268.
- reaction of, 53.
- tetrazo-, dyes from, 268.
- Stilbenes, substituted, formation of, 151
- Stilbenesulphonic acid, diamido-, 268.
- Stomach, decomposition of bromides and iodides by, 508.
- of the horse, absorption in, 743.
- Strawberries, wine and brandy from, 292.
- Stromeyerite from Mexico, 643.
- Strontia, phosphorescence of, 1068.
- Strontium and sodium, double arsenates and phosphates of, 637.
- hydroxide, hydrates of, 765.
- microchemical test for, 301.
- oxide, dihydrate of, 108.
- action of carbonic anhydride on, 217.
- hydrated, 217.
- vanadates, 339.
- Strophanthidin, 1116.
- Strophanthin, 970, 1115, 1116.
- reaction of, 1001.
- Strophanthus, 970, 1116.
- seeds, constituents of, 991.
- Struvite, 709.
- Strychnine and brucine, estimation of, 853.
- colour tests for, 752.
- constitution of, 604.
- distillation of, with zinc, 282.
- ferrocyanides and ferrieyanides, 852.
- separation of, from fatty matters, 187.

 Tolunitrile, bromo-*o*-, 663.  
 $\alpha$ -Toluphosphinic acid and its derivatives, 825.  
 Toluquinol and its chloro- and bromo-derivatives, 1036.  
 Toluquinone and its chloro- and bromo-derivatives, 1036.  
 Toluylene-blue, 139.  
 Toluylenediamine, *o*-aceto-*m*-, 41.  
 Toluylenediamine (ortho-), action of ethyl acetoacetate on, 247.  
 Toluylenediamine (meta-para-), action of monatomic aldehydes of the fatty series on, 816.  
 Toluylene-dithiourethane (meta-), 367.  
 Toluylene-red, 139.  
 Toluylene-thiocarbamide (ortho- and meta-), 367.  
 Tolyacetic acid (para-), 949.  
 Tolybenzene,  $\alpha$ -bromo-, TRANS., 87.  
     — derivatives of, TRANS., 87.  
     —  $\alpha$ - and  $\beta$ -dibromo-, TRANS., 89.  
 Tolybenzoic acid,  $\beta$ -dibromo-, TRANS., 90.  
 Toly carbamide, di-*o*-chloro-*m*-, 810.  
 Tolydichlorobenzoic acid, 832.  
 Tolydiphenylpyrroline, 736.  
 Tolyethylamide (para-), 358.  
 Tolyglycine, nitro-, salts of, 383.  
 Tolyglyoxylic acid (para-), 826, 948, 949.  
 Tolyhydrazineacetone (para-), 956.  
 Tolyhydrazinepyruvic acid (ortho- and para-), 956, 957.  
 Tolyhydroxyacetic acid (para-), 949.  
 Tolymethamide (para-), 358.  
 Toly- $\beta$ -naphthylamine (para-), 592.  
 Tolylnitrotoluenesulphazide, nitro-, 723.  
 Tolyphthalamide (ortho-) and its methyl-derivatives, 586.  
 Tolyphthalimide (ortho-), 586.  
 Toly- $\beta$ -propionic acid (para-), 827.  
 Tolypyrrolinedibenzoic acid (para-), 736.  
 Tolythiényl ketone (ortho-), 238.  
 Tolythiocarbamide, di-*o*-chloro-*m*-, 810.  
 Tolythiocarbimide oxide (para-), 581.  
 Tolytoluenesulphazide (ortho-), 723.  
 Topaz from the Thomas range, Utah, 453.  
*Torpedo*, chemical studies on, 1128.  
 Torpedo-mucin, 1128.  
 Tortoise, urine of the, 170.  
 Tourmaline, black, from North Carolina, 118.  
 Trachyte-dolerites of the Vogelsberg, 904.  
 Trachytic rocks from the island of San Pietro, 904.  
 Trialkylpyridines, symmetrical, oxidation of, 378.  
 Trianisylarsine, 367.  
 Triauramine, 112.  
 Triazobenzenesulphonic acid (para-) and its derivatives, 817.  
 Triazonaphthalenesulphonic acid and its derivatives, 818.

 Tribenzylbenzoxammonium iodide, 246.  
 Tribenzylhomo-*o*-phthalimide, 1112.  
 Tribressidin, 233.  
 Trichloromethylsulphonylthiocarbamide, TRANS., 669.  
 Tricresyleyanurate, *o*-, *p*-, and *m*-, 1033.  
 Tridymite, artificial production of, 559.  
 Trierucin, 1030.  
 Triethyl carbinol, 353.  
     — chloraurophosphite, 227.  
     — cyanuride, 1024.  
     — formate, 911.  
 Triethylbenzylphosphonium salts, action of heat on, 1106.  
 Triethylhomo-*o*-phthalimide, 1111.  
 Triethylmethylammonium pent- and hept-iodides, 910.  
 Triegenyl cyanurate, 1033.  
 Trihydroaurylamine, 112.  
 Trihydroxymethylanthraquinone from *Drosera Whitakeri*, TRANS., 373.  
 Trihydroxypyridine [2 : 4 : 6] and its derivatives, 155.  
     — anhydride of, 156.  
 Trihydroxyxanthogallol, 925.  
 Triisobutylamine platinumchloride, 461.  
 Trimesic acid, synthesis of ethereal salts of, 492.  
 Trimethyl chloraurophosphite, 227.  
 Trimethyl- $\alpha$ -amidobutyro-betaïne and its derivatives, 792.

Trimethylamine, source of, in ergot of rye, 394.  
 Trimethylanthracene, 941.  
 Trimethylanthragallol, 593.  
 2, 4, 5 Trimethylbenzoyl- $\beta$ -propionic acid, 827.  
 Trimethylbismuthine, 802.  
 Trimethyldipiperidyl, 162.  
 Trimethylene bromide, action of, on the sodium compounds of ethylic acetate, benzoylacetate, *p*-nitrobenzoylacetate, and acetonedicarboxylate, 32, TRANS., 702.  
 — iodide, TRANS., 12.  
 Trimethylenedicarbanilic chloride and anilide, 578.  
 Trimethylenedicarboxylic acid, TRANS., 849.  
 Trimethylenediphenyldiamine, action of carbonyl chloride on, 577.  
 — and its derivative, 577.  
 Trimethylenediphenylcarbamide, 577.  
 Trimethylene- $\alpha$ -tetramethylenedipyrroline, 273.  
 Trimethylenetricarboxylic acid, constitution of, 468.  
 Trimethylethylammonium enneaiodide, 910.  
 Trimethylethylene, action of nitric peroxide on, PROC., 109.  
 Trimethylhomophthalimide and its derivatives, 726.  
 Trimethylindole [ $1' : 2' : 3'$ ], 149.  
 Trimethylnaphthalene, 841.  
 Trimethylphenylpyrazoline, 933.  
 Trimethylpropylammonium hydroxide and iodide, 461.  
 Trimethylpyrroline, 275.  
 Trimethylthiophen, 921.  
 Trimethyltricoumaric acid, 830.  
 Trimethyltricoumarin, 830.  
 Trinaphthyl cyanurates,  $\alpha$ - and  $\beta$ -, 1034.  
 Tri-*p*-nitrophenyl cyanurate, 1033.  
 Triphenetylarsine, 367.  
 Triphenylammeline, a third, 662.  
 Triphenylbismuthine, 368.  
 — dibromide, 368.  
 — dichloride, 368.  
 Triphenylcarbinoldicarboxylic acid, 267.  
 $\alpha$ -Triphenylguanidine, a physical peculiarity of, 366.  
 Triphenylmelamine, 663.  
 — formula of, 650.  
 Triphenylmethane-derivatives, 836.  
 — description and measurement of the spectrum of, TRANS., 162.  
 — *m*-nitro-, 44.  
 Triphenylmethanecarboxylic acid, 267.  
 Triphenylmethyl bromide, action of, on ethyl sodomalonnate, TRANS., 224.  
 $\beta$ -Triphenylpropionic acid, 671.  
 — and its salts, TRANS., 226.

Triphenylpyridine, 599.  
 Triphenylpyrroline [ $1 : 2 : 5$ ], 736.  
 Triphenylthiammeline, 662.  
 Trithiovaleraldehyde, 462.  
 Trithymyl cyanurate, 1034.  
 Tri-*p*-xylylmethane, 942.  
 Trona, 1021.  
 — artificial production of, 771.  
 Tropæolin O, description and measurement of the spectrum of, TRANS., 182.  
 — OOO, description and measurement of the spectrum of, TRANS., 184.  
 Tropine, constitution of, 740.  
 Trypsin, digestion of fibrin by, 1130.  
 — in urine, 69.  
 Tungsten, 14.  
 — atomic weight of, 111.  
 Tungstic acid, separation of phosphoric acid from, 866.  
 Turkey-red oil, 914.  
 Turnbull's and Prussian blues, composition of, TRANS., 644.  
 Turquoise from New Mexico, 116.  
 — from the Kirghise Steppes, 1021.  
 Tuscany, minerals from, 19.  
 Tyrosine, relation of, to hippuric acid, 1133.

## U.

Ultramarine, action of carbonic anhydride on, 774.  
 — formation of, in the wet way, 110.  
 Uracil, nitro-, 128.  
 — — metallic derivatives of, 920.  
 Uracilcarbamide, nitro-, 920.  
 Uracilcarboxylic acid, nitro- and amido-, 128.  
 — acids, amido- and bromo-, 920.  
 Urea, artificial production of, 771.  
 Urea and uric acid, excretion of, from the human system, 856.  
 — behaviour of, in soils, 524.  
 — behaviour of quinol with, 514.  
 — estimation, 1001.  
 — estimation of, in human urine with sodium hypobromite, 90.  
 — Hufner's method of estimating, 90.  
 — volumetric estimation of, 1145.  
 — See also Carbamide.  
 Ureometer, 310.  
 Uric acid, estimation of, 621.  
 — place of origin of, in the animal organism, 388.  
 — series, synthesis of compounds of, 919.  
 — solubility of, 919.

Uric acid, synthesis and constitution of, 918.  
 Urinary pigments, 1133.  
 Urine, behaviour of, with quinol, 514.  
 — creatinine in, 513.  
 — detection of albumin in, 1003, 1150.  
 — determination of hippuric acid in, 535, 1001.  
 — diabetic, active  $\beta$ -hydroxybutyric acid in, 290.  
 — hydroxybutyric acid in, 464, 857.  
 — reducing substance in, 513.  
 — estimation of nitrogen in, 863.  
 — human, estimation of urea in, with sodium hypobromite, 90.  
 — is free acid contained in? 986.  
 — mucin in, 390.  
 — normal, albumin in, 390.  
 — of the tortoise, 170.  
 — pathological, occurrence of reduction products of hæmatin in, 1127.  
 — peptones in, 188.  
 — quantitative estimation of oxalic acid in, 401.  
 — reactions for distinguishing between chrysophanic acid and santonin colouring matters in, 406.  
 — separation of globulin from albumin in, 406.  
 — sugar in, 1060.  
 — trypsin in, 69.  
 — xanthine-derivatives in, 739.  
 Urns, ancient, analyses of, 218.  
 Urobilinoïdin, 1127.  
 Utah, rare copper minerals from, 19.  
 Uvinone, 658.

## V.

Valeric acid,  $\gamma$ -amido-, 463.  
 — preparation of, 1028.  
 Valerolactone, action of phenylhydrazine on, 490.  
 Vanadates, 1018.  
 — alkaline, 639, 705.  
 — ammoniacal, 899.  
 — arsenates and phosphates, analogous, TRANS., 94.  
 — metallic, 898.  
 — of the alkaline earths, 339.  
 — organic, TRANS., 751.  
 Vanadic acid, estimation of, 691.  
 — reactions of, 896.  
 — anhydride, colour reactions of, 305.  
 Vanadinite, crystallised, from Arizona and New Mexico, 347.  
 Vanadium, detection and estimation of, in minerals, 690.

Vanadium, extraction of, from iron ores, 449.  
 Vanillin, preparation of, from *m*-chloro-*p*-nitrobenzaldehyde, 483.  
 Vanillinoxycetic acids, 259.  
 Vapour-densities, apparatus for determining, 431, 632, 882.  
 — determination of, 695.  
 — of phosphorus, arsenic, and antimony at a white heat, 888.  
 — density, determination of the, of high boiling substances under reduced pressure, 882.  
 — determinations, apparatus for, 695, 765.  
 — of zinc, 218.  
 Vapour-pressure, influence of change of condition from the liquid to the solid state on, 430.  
 Vapour-tension, measure of the chemical attraction of water of crystallisation derived from, 436.  
 — of ethereal solutions, influence of concentration on, 631.  
 — of sodium acetate solutions, 322.  
 — of water from salt solutions, 321.  
 Vapour-tensions, apparatus for measuring, 207.  
 — of ethereal solutions, 207.  
 — of saturated solutions of salts; relations to efflorescence and deliquescence, 208.  
 Vapours, electrical conductivity of, 4.  
 Vaselin, 456.  
 Vegetable tissue, presence of albumin in, 407.  
 Vegetation, effects of thiocyanates on, 519.  
 Velocity of chemical reactions, 697.  
 Vesuvius, minerals from, 17.  
 Victoria yellow, colour reactions of, 624.  
 Villarsite from Traverselle, 351.  
*Vincetoxicum officinale*, active principles of, 377.  
 Vine leaves, physiological rôle of, 685.  
 Vinyl chloride, action of ammonia on, 793.  
 — oxide, 1089.  
 — sulphide, 1089.  
 Vinylbenzoic acids, *o*-trichloro- and *o*-dichloro-, 955.  
 Vinylphenol dibromide, bromo-*p*-, 1110.  
 $\alpha$ -Vinylpyridine, 737.  
 Violan from Piemont, 784.  
 Virus, zymotic, and fermentation, 292.  
 Vitellin, products of digestion of, 286.  
 Vitelloses, 286.  
 Volatilisation of dissolved substances during the evaporation of the solvent, 211.

- Volcanic ash from Cotopaxi, occurrence of silver in, 454.  
 — fragments from the Lake of Bracciano, 21.  
 Volcanoes, origin of hydrogen chloride, sulphurous anhydride, and iodine in the gases of, 643.  
 Voltaic action, theory of, 417.  
 — combinations, new class of, in which oxidisable metals are replaced by alterable solutions, TRANS., 672.  
 Volume, change in, during the formation of metallic oxides, 1073.  
 — changes in, accompanying solution, 436.  
 Volumes, law of, in chemistry, 99.  
 — molecular, influence of double and ring linking on, 545.

## W.

- Water analysis, 1141.  
 — bacteriological examination of, 619.  
 — changes induced in, by the development of bacteria, 615.  
 — colorimetric determination of nitrites in, 533.  
 — determination of sulphuric acid in, 862.  
 — estimation of carbon in the organic constituents of, 184.  
 — estimation of formic acid and organic matter in, 1000.  
 — estimation of nitrates in, by means of aluminium, 184.  
 — expansion and compressibility of, 695.  
 — from an artesian well in the Tunisian Chotts, 455.  
 — from Flitwick, 1087.  
 — from the hot springs of Wiesbaden, 352.  
 — from the spring at Oued Ref, 455.  
 — from the wells of Zemzem, 455.  
 — liquid, influence of, in promoting the interaction of hydrogen chloride and iodide on exposure to light, TRANS., 806.  
 — mineral, from Woodhall Spa, occurrence of free iodine in, 221.  
 — — of Schützenhof-Quelle, Wiesbaden, 647.  
 — natural, determination of organic matter in, 533.  
 — of a saline lake near the Stolüpin mineral springs, 648.  
 — of crystallisation, amount of, in certain salts, 766.  
 — — measure of the chemical at-

- traction of, derived from the vapour-tension, 436.  
 Water, rain-, at Cirencester, amount of chlorine in, TRANS., 92.  
 — — at Rothamsted, chlorine, sulphuric anhydride and ammonia in, TRANS., 501.  
 Water-gas, composition of, 1078.  
 Waters, drainage-, composition of, TRANS., 506.  
 — estimation of organic carbon and nitrogen in, 619.  
 — mineral, from Java, 224.  
 — — from Servia, 648.  
 — river-, of La Plata, 786.  
 — sulphuretted, of Olette (Pyrénées Orientales), 710.  
 — well-, determination of nitrates in, 691.  
 — — of Harpenden, study of, TRANS., 500.  
 Waxes, sp. gr. and other characters of, 186.  
 Weight of drops and their relation to the constants of capillarity and the capillary meniscus angle, 210.  
 Well-waters. See Waters.  
 Wheat, loss occasioned by improper methods of pickling, 293.  
 Willemite, artificial production of, 345.  
 Wine, detection of aniline colours in, 1147.  
 — detection of cane-sugar, glucose, and dextrin in, 692.  
 — estimation and detection of aluminium in, 690.  
 — estimation of glycerol in, 86, 184, 306.  
 — from raspberries and strawberries, 292.  
 — red, detection of artificially coloured, 91, 187.  
 Wines, estimation of glycerol in, 184.  
 — estimation of solid matter in, 87.  
 Wollastonite from Sardinia, 709.  
 Wood in paper, estimation of, 620.

## X.

- Xanthine-derivatives in urine, 739.  
 Xanthocreatinine, formation of, in the organism, 613.  
 Xantho-rhodium bromide, 115.  
 — chloride, 115.  
 — dithionate, 115.  
 — hydroxide, 115.  
 — nitrate, 114.  
 — oxalate, 115.  
 — platinochloride, 115.  
 — silicofluoride, 115.  
 — sulphates, 115.

Xenotime from North Carolina, 118.  
 Xenylenedihydropyrazine, 493.  
 Xeronic acid, synthesis of, from  $\alpha$ -di-bromo-normalbutyric acid, 917.  
 Xylene, diamido-, 668.  
 — meta-, action of methylene chloride on, in presence of aluminium chloride, 1102.  
 — ortho-, oxidation of, 240.  
 Xyleneazoresorcinol, 820.  
 Xylenol, *p*-amido-, 668.  
 — ethers, heat equivalent of, 428.  
 Xylidinesulphonic acid (meta-), constitution of, 382.  
 Xylorcinol (meta-), 39.  
 Xylorcinolcarboxylic acid (meta-), 39.  
 Xyloquinol (para-), oxidation of, 1035.  
 Xyloquinonedioxime (para-), 668.  
 Xyloquinoneoxime (para-), 667.  
 Xyloildiphenylamide, 935, 936.  
 Xylol ethyl ketone, para-, 253.  
 — phenyl carbinol, *o*-, *m*-, and *p*-, 941.  
 — phenyl ketone, *o*-, *m*-, and *p*-, 941.  
 — phosphorous compounds, 824.  
 Xylalamines from xylenols, primary and secondary, 664.  
 Xylol-*p*-cymylphenylmethane (para-), 942.  
 Xylylene oxide, tetrachloro-, 832.  
 Xylglyoxylic acid (ortho-), 826.  
 Xylol- $\beta$ -ketonic acid (para-), 253.  
 Xylol- $\gamma$ -ketonic acid (para-), 827.  
 Xylolphosphinic acids,  $\alpha$ -*m*- and  $\beta$ -*m*-, 825.  
 Xylolphosphochloride [1.3.4], 824.

## Y.

Yeast, elliptical, products of fermentation of sugar by, 714, 746.  
 Ytterbium, phosphorescence of, 1068.  
 Yttria, phosphorescent, sharp line spectrum of, 1070.  
 — — spectra of, 1066.  
 — purification of, 13.

## Z.

Zinc-blende, black, of Freiberg, 451.  
 — bloom, and fibrous, from Carinthia, 1021.  
 — chlorides, ammonio-, 551.  
 — containing lead, action of acids on, 1074.  
 — corrosion of, by ammonium chloride and potassium nitrate, 889.  
 — determination of, 689.  
 — dust, valuation of, 301.  
 — effect of, redistillation on, 446.  
 — eisen, 550.  
 — electrolytic estimation of, 1000.  
 — equivalent of, comparison of, with that of hydrogen, TRANS., 854.  
 — estimation of, as pyrophosphate, 398.  
 — ferrite, 557.  
 — manganese ammonium sulphate, PROC., 53.  
 — microchemical test for, 300.  
 — nitrate, basic, 1080.  
 — powder, titration of, 865, 1000.  
 — — valuation of, 80.  
 — residues obtained from, by the action of acids, 894.  
 — separation of, from iron, cobalt, and nickel, 182.  
 — sulphate, TRANS., 681.  
 — sulphide, phosphorescence of, 1068.  
 — — titration of, with iodine, 301.  
 — vapour, density of, 218.  
 Zincite, artificial production of, 345.  
 — crystallised, from Stirling Hill, New Jersey, 343.  
 Zinkenite from Arkansas, 782.  
 Zirconium, 896.  
 — crystallised compounds of, 778.  
 — sodium phosphates, 1017.  
 Zirconyl compounds, 778.  
 Zymogluconic acid, 468.

# ERRATA.

VOL. LII.

| Page | Line     |           |  |
|------|----------|-----------|--|
| 30   | 18       | from top, | for " $\alpha$ - $\beta$ -dimethylglycidic acid" read " $\alpha$ - $\beta$ -dimethylglyceric acid."  |
